[a] Including mining, industrial, and chemical engineers. [b] Percentage of the total number reported for the one year 1939 whose income from wages and salaries was within the salaries ranges indicated. This does not include income from professional fees and partnerships, or from other kinds of work or sources of income.

Engineers," and to certain other occupational classifications. Technical engineers are somewhat better educated than the average of the professional and semiprofessional group, but they fall behind the members of the medical and legal professions. Three out of four technical engineers have completed three

years of college, and three out of five have completed four years or more. As a member of the California State Board of Registration for Civil Engineers, the writer reviewed the professional biographies on about 6,000 applications for registration. Many of these applicants had received degrees from colleges everywhere in the United States and many of them were engaged in branches of engineering other than civil. From this experience, the writer is inclined to believe that the ratios in Table 3(*a*) would be somewhat reduced if applied to the entire number of engineers in the United States.

Age.—Table 3(*b*) indicates that technical engineers are somewhat older than the average of the professional and semiprofessional group, but slightly younger than the members of the medical and legal professions. A significant fact revealed in this table is that one third of the total number of technical engineers were within the range of from thirty-five to forty-five years old, whereas only one quarter of the members of the medical and legal professions were within this age bracket. Furthermore, although 86.9% of the technical engineers were younger than fifty-five years, only 77.2% of the lawyers and judges, and 71.3% of the physicians and surgeons were less than this age. This would indicate that a substantial number of technical engineers leave the strict practice of engineering during their forties, either to assume more or less nontechnical administrative duties in engineering or industrial organizations, or to leave the field of engineering completely. A much higher proportion of the members of the medical and legal professions remain in their respective professions throughout their active life.

Income.—Table 3(*c*) gives the relative proportion of those employed as technical engineers and in certain other occupational classifications in various income brackets, such income being derived solely from wages and salaries. The census report states that very few of those listed as receiving incomes of less than $100 per year from these sources reported any income whatsoever from wages and salaries, indicating that they undoubtedly were engaged in private practice and received their income almost entirely from professional fees. This would indicate that about one out of fifteen technical engineers was engaged in private practice as against six out of sixteen architects, five out of eleven lawyers, and two out of three physicians and surgeons. It might reasonably be assumed that a substantial number of those listed as receiving an annual income of less than $1,600 from wages and salaries were engaged primarily in private practice.

Effect of Professional Registration.—According to the latest reports, there are about 70,000 registered professional engineers in the United States, registration statutes being effective in all but three states. This number is only one quarter of the total number of technical engineers listed in the 1940 Census, and probably less than from 10% to 15% of the actual total number of engineers in the United States. Professional registration has been effective and accepted by other professions such as law, medicine, and dentistry for many years, and has served to identify in the mind of the public at large what constitutes the practice of these professions. For this reason basic data pertaining to them are far more comprehensive, conclusive, and definite than are data pertaining to engineers and engineering. The attitude of the profession toward engineering

registration (or at least that of its leaders) was one of antagonism at first, but later developed into one of more or less indifference (or at least of only mild interest). This is more or less typical of professional attitudes toward other social and economic problems confronting the engineering profession.

The necessity of admitting to practice (when registration becomes effective) many persons of "borderline" qualifications, the wide variation in the standards maintained, and the wide variation in the diligence of enforcement of registration by the boards of the various states, combined with this professional indifference, has caused the results of registration to fall far short of those anticipated by its early proponents. It is a long-range program, however, and its full effectiveness will not be felt for several decades. In general, engineering educators have supported the movement, but not so actively that one of the strongest ambitions of every engineering graduate (recent or otherwise) is to receive, through it, official public certification of his technical qualifications as a member of his profession.

Organization and Structure of the Engineering Profession.—Definitions of engineering are legion, from the short ones found in dictionaries to the more complicated one encountered in engineering registration statutes. In essence,

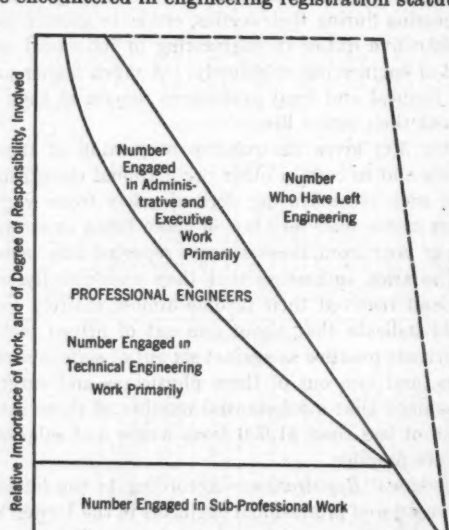

FIG. 1.—CROSS SECTION OF THE ENGINEERING PROFESSION (NOT TO SCALE)

however, engineering is applied science—the application of scientific knowledge, pertaining to the properties of matter and the sources of power, to the creation of structures, machines, and manufactured products. Half a century ago, these products could be created by a small organization, few members of which were

considered specialists. Today the field of engineering knowledge and likewise the products created have increased to such an extent in size, complexity, and cost that a large group or organization (including subprofessionals, professionals, specialists, and administrators) is required to perform such a function. The current practice of engineering, except by those who serve in advisory or consulting capacities, is a mass-production activity, in which each individual serves as a cog in a machine and performs his specific duties as a unit of a much larger group. It is far more similar to the practice of banking or insurance than it is to that of medicine or law.

A cross section of the engineering profession, as shown in Fig. 1, is typical of those of other organization activities, being triangular in shape. At the bottom are large numbers of persons in positions that involve limited technical responsibility or knowledge, with few in the top brackets, most of the latter being engaged primarily in executive or administrative duties. It is more or less peculiar to the engineering profession that, as the importance and responsibility of the duties of the positions held by its members increase, the proportion of time spent in strictly technical activities decreases. This is not true of such professions as law, medicine, or dentistry.

TABLE 4.—SPECIALIZATION OF CORPORATE MEMBERS, AMERICAN SOCIETY OF CIVIL ENGINEERS (ASCE) AND AMERICAN INSTITUTE OF MINING AND METALLURGICAL ENGINEERS (AIME), EXPRESSED AS PERCENTAGES

Society	Engaged in Engineering			Not engaged in engineering
	Their own specialty	Another specialty	Total	
	(1)	(2)	(3)	(4)
ASCE...	52	5	57	43
AIME...	36	6	42	58

Furthermore, an increasing number of engineers leave the profession as they advance in it. Table 4, based upon a 5% sample of the corporate membership of the American Society of Civil Engineers and the American Institute of Mining and Metallurgical Engineers, uniformly distributed throughout the 1937 membership roster of these societies, indicates this. When it is realized that all members listed as not following engineering had followed it for from at least six to eight years prior to their admission to the corporate grade in their society and had had at least one year in responsible charge of engineering work (which fact indicates that at the time they entered such grade they must have intended to follow engineering as a career), the results shown in Table 4 are rather significant.

THE PRACTICE OF ENGINEERING

Subject Matter.—Whereas a person engaged in the professions of law, medicine, banking, teaching, art, or drama deals primarily with the subject matter of his profession throughout his practice, a person engaged in the practice of engineering usually finds himself involved more and more with subjects in other fields as he advances in his profession. These subjects may be grouped under three headings, matter, men, and money—the three M's. Under the heading of "matter" are included technical subjects—problems of an engineering character. The heading, "men," would include subjects pertaining to human beings—activities, traits, habits, characteristics, and institutions. The

heading of "money" would embrace subjects in the fields of economics, finance, and business.

A young engineer, just graduated, finds himself dealing with more or less routine, or mechanical, matters; but, as he acquires knowledge, experience, and maturity, he is assigned problems involving professional knowledge and judgment. Working as he usually does, as a member of an organization, he continues to advance professionally; but he also begins to assume administrative duties, at the same time depending on his subordinates more and more for technical results and opinions. He is then dealing with both "matter" and "men." Unless he develops into a specialist, he also begins to encounter problems in the field of money if and as he continues to advance. He becomes responsible not only for the technical correctness of his work and that of his subordinates and for the efficiency of their output, but he becomes responsible for the cost and economy of the thing or things produced. If he still continues to advance, he enters the field of "management," the fourth M, which embraces the other three—matter, men, and money. In this field whether he operates in a large or in a small organization, he becomes involved in such problems as the relation between volume of production and absorptive capacity of markets, and as the cost of production in relation to profits, working capital, financing, taxes, interest, and dividends. He must retain his broad knowledge and judgment in technical matters, even though he forgets technical details; but he must also exercise knowledge and judgment in other fields.

Not all engineers progress through these three fields to the fourth one, many remain strictly in fields concerned with the first M—matter; but the highest rewards, except in the case of outstanding specialists, come to those who attain positions in the field of management. In addition to those who follow the foregoing course, and retain their connection and contact with technical activities, many leave the field of engineering entirely, and become engaged in nontechnical activities in which their engineering education and training in the approach to and the solution of problems, the orderly collection and assembly of factual data, its analysis, interpretation, presentation, and use prove to be of extreme value. Engineering educational institutions should recognize the foregoing condition in the subject matter included in their curricula.

Employment Conditions in the Practice of Engineering.—The engineering graduate, on entering his profession, is faced with the strong probability that his specialty, his employer, and his place of employment will undergo a considerable number of changes during his career, if he continues to follow his profession. Table 5, although based on data concerning members of the American Society of Civil Engineers, is probably representative of the situation in other branches of engineering. This table represents changes in employment in the case of one hundred Juniors and one hundred Associate Members of the Society between 1930 and 1940. Intermediate changes during this ten-year period were not noted. The names selected were of members who had entered their respective grade during the five-year period, from 1926 to 1930, inclusive, who were picked at random, but who were uniformly distributed through the membership rosters for the selected decade. Specialities and employers were based upon titles given in the roster.

It is significant that nearly one half of the Juniors and one third of the Associate Members either had left engineering during this period or had changed the specialities they followed in 1930; that three out of five Juniors and one half of the Associate Members had changed employers; and that nearly three out

TABLE 5.—CHANGE OF STATUS, AS ANALYZED BY THE RECORDS OF 100 JUNIORS (JUN.) AND 100 ASSOCIATE MEMBERS (ASSOC. M.), ASCE, BETWEEN 1930 AND 1940

Item	Description	Jun.	Assoc. M.
	(a) CHANGE IN SPECIALTY		
1	Abandoned engineering	11	5
	Remained in Engineering:		
2	Changed to another kind of engineering	36	29
3	Stayed in their original specialty	53	66
4	Total	100	100
	(b) CHANGE IN EMPLOYER		
5	No change in employer	40	49
6	Changed employer	60	51
	(c) CHANGE IN LOCATION OF EMPLOYMENT		
7	No change in location	43	58
8	Changed location	57	42
	(d) CHANGE IN SOCIETY STATUS		
	Advanced One Grade:		
9	Number advanced	100	36
10	Years required for advancement	7.0	6.8
	Advanced Two Grades:		
11	Number advanced	9	....
12	Years required for advancement	12.0	....

of five Juniors and two out of five Associate Members had likewise changed the location of their employment. Undoubtedly a higher proportion of members than that shown in Table 5 had left the practice of engineering during the decade, as those enumerated were those who retained their membership for the period, and members who had left the Society during the period because they had left the practice of engineering were not included. There appeared to be somewhat greater stability in employment conditions among Associate Members than among Juniors. Whether this lack of stability among Juniors was accelerated because of conditions created by the economic depression during the period cannot be determined; but, from personal observation, the writer is not inclined to believe that this was so to any great degree.

Rate of Advancement.—Another feature of interest revealed by Table 5 is the apparently slow rate of advancement by these members to more important positions. Slightly more than one third of those who were in the grade of Associate Member in 1930 had advanced to that of Member ten years later. The Member grade in the Society requires that an engineer shall have had five years of experience in responsible charge of important work—four years

more than that required for the Associate Member grade—and shall be qualified to conceive and design engineering work. It likewise requires at least twelve years in the practice of engineering. It does not involve any financial outlay for transfer in grade, nor any increase in annual dues. It has been the writer's observation that a high proportion of Associate Members of the Society are extremely ambitious to advance to the Member grade, and the small proportion of those who had made such advance would seem to indicate a lack of opportunity for achieving the qualifications necessary for such advancement. Of greatest interest, however, is the relatively slow rate of advancement of Juniors. Of the one hundred Juniors considered—

> Forty one required less than seven years,
> Twenty nine required between seven and ten years, and
> Thirty required more than ten years

—in which to advance to the grade of Associate Member. Theoretically, except for the age limit, a Junior of the Society, if he be a graduate of a recognized school, could attain the grade of Associate Member within a little more than two years after he is graduated. Few Juniors, if any, do so even upon reaching the minimum age (which is attained in from five to seven years after graduation). In the decade studied, advancement to the grade of Associate Member was optional until the Junior reached his thirty-third birthday, at which time he was dropped from membership if he had not advanced in grade.

During the three years from 1939 to 1941, inclusive, for every one hundred Juniors who did advance to the grade of Associate Member, there were forty three dropped for failing to advance on reaching the limiting age; seventy three were dropped for other reasons, and twenty one resigned—a total loss of one hundred and thirty seven. These figures indicate that the younger engineers, at least those who follow civil engineering and who have joined their own professional society, during this period at least, were making rather slow progress in their professions. This condition was recognized by the Society in 1942 when the limiting age for transfer from Junior to Associate Member was increased from thirty-three to thirty-five years.

In general, it is the writer's observation (based on a review of the professional biographies of from 6,000 to 7,000 engineers of all ages and lengths of experience who sought registration as civil engineers in California, or who sought admission to, or transfer in, membership grade in the Society) that the average engineer—at least if he follows civil engineering—does not attain a position in which he is called on to exercise independent engineering judgment or to assume engineering responsibility for anything except work of the simplest character, until at least from eight to ten years after he has graduated; and many do not attain such a position within that time. There are many exceptions to this statement, of course; but for all those who do make better progress there are a comparable number who require a longer period. During this period (which is at least from two to two and one-half times the period spent on the normal engineering course in college), a very substantial number of graduates will have changed specialties, employers, and location of employment, and a considerable number also will have left the practice of engineering to enter other fields. This period, during which the graduate has the oppor-

tunity to specialize in engineering, and likewise to acquire knowledge in other fields, should be recognized by engineering educators in designing their courses and curricula; and they should provide opportunity during this period for the guidance and assistance which graduates both desire and need.

Change in Character of Employment.—Another trend that became very significant during the decade from 1930 to 1940, at least in civil engineering, was the substantial increase in employment of civil engineers by public agencies. Table 6, based on a 5% sample uniformly distributed through the membership

TABLE 6.—TREND IN THE EMPLOYMENT OF ASCE MEMBERS

Item	Number, per 1,000 members, employed by:	1920[a]		1930[a]		1940[a]	
		No.	%	No.	%	No.	%
1	Private concerns	53.9	100.0	54.6	101.4	38.0	70.5
2	Public agencies[b]	23.9	100.0	22.6	94.5	45.8	191.8
3	Private practitioners[c]	22.2	100.0	22.8	100.7	16.2	72.9

[a] Under each year are listed the number (No.) in each 1,000 members who are employed as shown, and the percentage (%) of the 1920 value. [b] Excluding members in the armed forces. [c] Including employees of practitioners.

rosters of the Society for 1920, 1930, and 1940 indicates that, although there was little change in the relative proportion of Society membership employed either by private business or by public agencies, or engaged in private practice (or employed by engineers in private practice) between 1920 and 1930, in the following decade between 1930 and 1940 the number per 1,000 members employed by private concerns and engaged in private practice or employed by private practitioners, dropped almost one third. The number per 1,000 members employed by public agencies almost doubled. No doubt, some of this shift to employment by public agencies resulted from the economic depression of the 1930's but the outlook is for it to increase rather than to decline. The subject is worth further investigation.

The relatively slow advancement of Juniors may be due to the relatively large numbers employed by public agencies, mostly under civil service, where advancement is more dependent on seniority and increase in size of organization than it is in private employment.

THE MARKET FOR ENGINEERING SERVICES

The foregoing discussion and statistics have been presented to furnish a concise picture of the engineering profession and of the practice of engineering, for which engineering education is presumed to furnish the preliminary preparation. The statistical data are not complete; nor are they conclusive; but the size of samples is sufficient to make the results at least indicative of conditions and trends. The data also indicate the further research which might be made from existing information. If engineering education is considered as only the initial processing of a raw material to meet the subsequent needs of a potential market (and it is assumed that such initial processing must be followed by much further processing), two alternatives exist in the planning and design of engineering courses:

1. A rather complete knowledge of the character and volume of the present and the future market should exist, if the initial processing is to be refined in character, or

2. The processing should be of a character that will allow the product to adapt itself to the existing and future market, if information as to the character and volume of the latter is lacking or deficient.

If data were available as to the number of persons who had been employed in occupations involving a greater or lesser degree of engineering knowledge and experience over the past few decades, it might be possible to forecast, with reasonable accuracy, the character and type of existing and future markets for engineering services. Few data of this type are available, however, and little has been done with those that do exist. The result has been that large numbers of engineering graduates have been produced in the United States, each year for many years, by plants representing substantial investments and operating costs; and these plants have had little or no information as to the capacity of the market to absorb or to utilize their product in its latter stages of processing. They knew that their product was absorbed after initial processing, but had little knowledge of its fate, or of the requirements of the market for its services, subsequent to a period of from three to five years following such initial processing. Although quantitative data pertaining to the general volume, type, and character of market for engineering services are almost completely lacking, some information is available as to the character and type of product sought by the consumers who constitute this market—the employers of engineers.

The American Association of Engineers in 1940[2] published an analysis of "job orders" or descriptions and specifications given by prospective employers seeking men through the association's employment department in Chicago, Ill., during the previous ten-year period. Positions to be filled from these orders numbered into the thousands; and annual compensation ranged from a few thousand dollars upward to five figures. Most requests were from employers in the Great Lakes area, but a considerable number were from various parts of the United States, and the basic data available were of sufficient magnitude and distribution to warrant the conclusion that they represented a good cross section of employer requirements throughout the nation. In addition to requiring that the employer specify the technical training and experience, salary offered, and duties involved in the position to be filled, he was requested to specify other characteristics and traits desired in the prospective employee. In most instances employers gave as much weight to nontechnical as to technical qualifications.

A summary of the required qualifications showed the following to be prominently stressed:

Item	Qualification
a	A soundness in engineering fundamentals that would enable the employee to translate experience gained in one enterprise to a different type of industry, but in the same general branch of engineering;

[2] *Professional Engineer*, November, 1940.

b A habit of continuing study, not only of technical theory, discoveries, products, and processes as they are developed, but also of commercial developments;

c A cost consciousness that would allow the engineer to appreciate the cost of engineering and its results, in relation to the profit possibilities of the entire enterprise, and to understand the problems of the accounting department;

d An ability to handle men, which involves the abilities to secure the co-operation, confidence, and respect of subordinates, associates, and superiors; to inculcate in others the desire to do things for one and to follow one's leadership; and to lay out and plan future operations in such a manner that these operations, when undertaken, would achieve a desired result;

e An initiative and resourcefulness indicated by a desire to step out and solve problems without having to be urged by others to do so; and

f An ability to express ideas in written and spoken form, in a manner that would convey them not alone to other engineers but also to laymen.

The demand for technical graduates was not insistent, although there was an increasing desire throughout the period for some technical education. Where graduates were specified, stress was laid on good, rather than on high, scholastic records; and equal or greater emphasis was placed upon participation in extra-curricular activities while in school—the latter being considered as sound training for leadership.

Although specialization in college courses was requested by some employers—where recent graduates were sought—most prospective employers stressed training in fundamentals, and broad application in the various fields of engineering, preferring to train their own employees in their respective specialities. Considerable opposition was voiced to scholastic specialization, on the basis that it tended to develop an inflexibility in the employee which did not readily allow his being transferred from one department to another in the course of his advancement. Some of the foregoing qualities sought by employers may be considered as being more or less a matter of inherent native traits or qualities; but all of them can be improved, and many of them developed by proper educational processes and instruction, which frequently will bring out potential qualities that otherwise would remain dormant.

Postwar Engineering Education

Advances in science and technology as a result of the war effort indicate a postwar market for engineering services greater in volume than that existing before World War II, with a demand for services of a more diversified, and in many instances of a more specialized, character. Other things can likewise be expected of this market—among them: (1) A longer period of study and training for engineers (because of the more complicated subjects involved in engineering practice); (2) the broader knowledge of a wide range of both technical and nontechnical subjects necessary to provide maturity of judgment; and (3) the greater demand in the increasingly industrialized postwar economy for executives and administrators who have had background and experience in engineering.

To meet the requirements of such postwar market, and to equip engineering graduates properly to cope with the situation adequately and to make the most effective contribution to the postwar economy, it would appear that the following changes in engineering education, as compared with those generally offered during the fifteen to twenty years prior to World War II, are indicated:

(*a*) Engineering courses should provide a broader scope of basic instruction in subjects that cover the entire field of engineering, should include in the curricula a greater proportion of nontechnical subjects of a character that will be of value to the engineer who may engage in executive or administrative activities, and should leave specialization primarily to the period following graduation.

(*b*) Provision should be made for the instruction—through night classes or correspondence courses, or in some other manner—of those students who desire to continue their studies in specialties or nontechnical subjects following graduation and who do not, or cannot, return for resident postgraduate study.

(*c*) Extensive research concerning the engineering profession, the practice of engineering, and the market for engineering services should be sponsored not only by engineering schools but also by engineering societies.

The first change suggested will unquestionably entail a drastic revision of curricula. Many courses in specialized subjects, given in the last two academic years, will have to be resident graduate courses, night courses, or correspondence courses. Many courses which are essentially training in skills will have to be discontinued, and likewise many nontechnical courses will have to be added. To the writer, it has always seemed rather fruitless for a student to take a highly specialized course in theory and practice in his senior year, and then wait for six, eight, or ten years following graduation before he has an opportunity to apply the theory or practice learned in such course in any capacity except that of a subordinate under immediate supervision. The excuse usually given for such courses is that, even if they are never utilized in later practice, they were good mind training. Granting that this be true, comparable training could be achieved through more courses in mathematics or science, the tools that the student will use in later life to aid him in increasing his technical knowledge. The specialized knowledge acquired in such courses, if needed, could be acquired during the six, eight, or ten years following graduation.

With the considerable changing from specialty to specialty that exists in engineering practice, it would seem that the student would be better equipped to make such changes if he had a broader knowledge of general engineering. He would not then have to go back so far to start acquiring basic knowledge of a new specialty when such a change was made.

Particularly in the first two years, many of the courses that seek primarily to impart certain skills, could well be eliminated; or the time spent upon them could be reduced, although the purpose for which they are offered could still be achieved. Such courses include surveying (essentially applied trigonometry and use of precise instruments), drafting, and certain shop courses. Ordinarily these are not of sufficient length to produce skilled craftsmen. They

could well be supplanted at least in part by courses which would help to prepare the student to express himself clearly and well, which would teach him something of human nature, of institutions, of the laws of economics, of money, and of business practice; and how to figure costs and to determine values. If the student is to follow a career that will cause him to deal with "men" and "money," as well as with "matter" (and most engineers do follow such a career at least part way) he should be given some basic instruction in these subjects while in school and should not have to acquire a knowledge of their first principles following graduation.

The student should also receive a realistic picture of the profession which he has chosen for a life career—not the glorified aspect usually presented by older alumni or distinguished engineers who address upper classmen at meetings. He is entitled to know what he is "getting into"—something of the organization of his profession, of its ethics, and of its code of practice; of the kind of life he might expect to lead five, ten, twenty, or more years after graduation if he follows this or that branch, specialty, or type of employment; of the probable rate of increase in compensation to which he may look forward in later years; and of the probable opportunities in various fields of activity.

He should be furnished information as to opportunities in business and industry for a person with a technical education and some engineering experience. Too many graduates, after a few years of experience in engineering, find that they do not like it, but feel that, since their training and education have been along technical lines, there is no opportunity for them in other fields. They then remain as misfits in this profession when they might have made a success in some other line.

An engineering course that would prepare its graduates to enter the bottom strata in any branch of engineering, that would give them a foundation in those subjects which are fundamental to business and industry, and that would emphasize training in the engineering or scientific approach to the solution of problems will produce graduates who meet the requirements of the postwar market for engineering services far more adequately than a course which attempts to produce a graduate who has been prepared to enter one branch or specialty in engineering.

Every engineering graduate realizes—either on graduation or very soon thereafter—that he has just begun to accumulate the knowledge which he will need before he attains a position of responsibility in his profession. When he was graduated, he had the habit of study and a keen desire to continue to increase his knowledge. Too often this was soon lost for the lack of a properly supervised and directed course of study or reading that he could, and would, follow if he had proper guidance plus a goal toward which he could strive. Even if he desired to increase his knowledge of the work in which he became engaged on graduation, he was met with such extensive literature that he became confused, did not know where to start his further study, and too often contented himself with merely reading current articles in such technical journals as came to his attention.

Many engineering schools offer extension courses; but either these seldom lead to a specific objective or they are designed to provide complete instruction over a period of years in a given specialty. In addition, these courses do not

set up any goal of accomplishment toward which the student can strive as he could for his engineering degree. The habit of study and the desire to increase knowledge is a very real asset in a graduate; it should be conserved and not allowed to dissipate, as too often happens. Only a small proportion of graduates can, or will, return for resident postgraduate study. Many of them are not able to attend night courses. They can enrol in correspondence courses, however, or pursue systematic reading courses which have been outlined under proper guidance.

If graduate instruction were planned and arranged so that the student, after completing a given course of study, taking an examination similar to those given by the better engineering registration boards, and submitting a thesis indicating his ability to perform original and responsible engineering work, was awarded a professional degree, many graduates of four-year courses would avail themselves of such opportunity, and the profession would benefit. Such courses would furnish preparation in specialized subjects offered in many undergraduate courses.

The foregoing suggestions would cause some changes in existing practices and habits of engineering faculty members; but they would probably result in an increase, rather than in a decrease, in the size of engineering faculties. Broad general courses covering the entire field of engineering would tend to increase the number of students returning for graduate work. Specialists who formerly gave instruction orally in their specialities would give more of it by correspondence and might have more time for research or possibly for outside practice. Because of the longer time over which they had contact with their students, the faculty would secure a better knowledge of the market for engineering services; and they would be able to exercise better control over courses and be better equipped to modify instruction to keep abreast of current needs.

Research concerning the engineering profession, the practice of engineering, and the market for engineering services—in brief, along the economic and sociological aspects of engineering—is sorely needed. As stated heretofore, this research is a responsibility not only of engineering educational institutions but likewise of engineering societies. Tools for this research have been developed during the past decade or two which allow a great amount of research to be done economically. The technique of scientific sampling has made great advances since 1935 enabling many basic data of a fully adequate quality for the purposes needed to be secured. Use of punch cards and tabulating machines has greatly reduced the cost of analyzing data.

Professional biographies of registered engineers and members of engineering societies, and records filed with civil service boards and commissions and with concerns employing large engineering staffs provide an untouched mine of information concerning the profession. New data are included in the 1940 Federal Census. The lack of such data in the past was probably due to the fact that engineers, engineering societies, and engineering instructors were far more interested in the technical aspects of engineering than in the economic or sociological aspects. Developments during the past few years indicate that engineering societies and schools must give thought and study to engineers as well as to engineering. Not only should the profession know something about itself and its members; but those who are preparing to enter it are entitled to this knowledge, and an obligation rests upon engineering schools and engineering societies to furnish them with it.

DISCUSSION

E. S. BOALICH,[3] ESQ.—Something has been radically wrong with engineering education as two groups of engineers will testify. In the language of the paper (see heading, "The Practice of Engineering") these groups are:

Group I—The wizards in matter, who "fell down" when they came to men, money, or management. Mr. Baker's recommendations should take care of most members of this group perfectly.

Group II—Those who were never too proficient in M-1, including some who might have been wizards in M-2, M-3, or M-4 (or in art or literature!).

An added suggestion is to go back just one step behind Mr. Baker's starting point and to do as the steel plant does when it analyzes carefully each batch of iron ore before processing it.

By intelligent screening in the first college year, of a five-year course, "ore" which would never produce "good steel," but which might be in demand for "ballast," could be properly diverted; and as a dividend an occasional "gold nugget" would turn up which might otherwise have been forever lost in "the fiery furnace."

RUSSELL C. BRINKER,[4] ASSOC. M. ASCE.—To one who has returned to the teaching profession after some years in the armed forces where the results of different types of training could be observed, this paper presents many points of interest. Consideration of the most desirable content of engineering curricula is occupying the time of many deans and heads of engineering departments. Various engineering and educational societies have gone on record as favoring an increase in the time spent on humanities courses. This increase means either elimination of some technical courses, or expansion to a five-year program. The University of Minnesota at Minneapolis and Ohio State University at Columbus are representative of schools adopting the latter plan. Doubtless many others will follow, although a desire to permit returned veterans to graduate in as short a time as possible will retard this trend temporarily. In past years, fear of loss of students who could not afford the additional year delayed the change-over. Problems arising in connection with a change to the five-year program illustrate some of the difficulties to be overcome if Mr. Baker's recommendations are to be accepted.

Reduction in time, or elimination of some courses seeking primarily to impart skills, is suggested. Many graduates use these "skills" to begin or to continue their work. In normal times an estimated 60% of the civil engineering graduates of the University of Minnesota start their engineering careers in surveying or drafting. Without such skills, these men would be rodmen instead of instrumentmen; tracers instead of draftsmen. The self-confidence and additional compensation resulting from extended work in surveying and drafting might well keep the young graduate in his profession. It is not proposed

[3] Valuation Engr., Bureau of Internal Revenue, Washington, D. C.

[4] Associate Prof., Civ. Eng. Dept., Inst. of Technology, Univ. of Minnesota, Minneapolis, Minn.

that all these men remain in "skilled" jobs. Nevertheless, if advanced theory and specialty courses are to be deferred until some time after graduation then the engineering graduate should be well trained—if that properly describes his status—for the job that he will have a 60% chance of taking immediately after graduation.

Drawing and surveying courses fill a definite need for some work in engineering during the first two years of college if student interest is to be maintained. This point becomes increasingly important if curricula are extended over five years and the professional courses held back a year. Pre-engineering requirements, like prelaw or premedical standards, might be desirable. It is undoubtedly true, though, that many men who apply themselves well in the later professional courses are concerned only with obtaining marks high enough in the preliminary work to insure entry to the professional schools.

Substitution of two-year programs of the trade school variety is not generally favored by the faculty or acceptable to a large percentage of students. The unlimited educational opportunities so characteristic of the United States inspire engineering students to try for the status of a four-year graduate or nothing.

It has been stated frequently that many engineers are unable to express themselves well, or to write good reports. One reason for these handicaps is probably the failure of most engineering faculty members to insist upon the continuation in all later subjects, of the standards set up in freshmen English courses. Professors and instructors are apparently not willing to take time to correct spelling and sentence construction and stress the need for improvement. Students, of course, feel that freshmen English courses are hurdles to get over or around, and that they are of no practical use in succeeding work, where "anything goes." Too often anything does go!

There is a tendency for faculty members to be specialists, perhaps engrossed in some isolated research problem that has little or no connection with class work. Teaching therefore becomes boring, and all interest is lost in the meticulous checking of problems and reports by students. National reputations for research or publications are not maintained by long hours of student consultations or paper grading. On the other hand, few professors in mechanical drawing, surveying, mathematics, and freshmen English courses (which require "plugging" at details) attain any great prominence; yet to be an inspiring teacher in these subjects—as compared with structural design courses, for example—really "takes something"!

Lack of the "dollar sense" is a highly valid criticism of new graduates in engineering—and of many experienced ones too. How many instructors or full professors touch even lightly on the mill price per pound of a steel beam or column that has been designed in class, and follow with statements on fabrication and erection costs? How many mention the cost of formwork and discuss its influence in selecting an economical design? Less than one hour's time spread over a semester would develop the ever-present student interest in "How much does it cost?" Probably not one surveying instructor in ten has discussed the cost of operating a survey party, including interest and depreciation on equipment, etc. Lowered professional standards are certain to result as shown by a recent case when a well-qualified senior student made a detailed

land survey for $5—his hourly wage probably being less than 25¢ per hr. Such practices may well be extended into succeeding work unless checked early by proper instruction.

Too few students know about the advantages and requirements for registration as a professional engineer. Medical students are indoctrinated early in the responsibilities imposed by the degree of Doctor of Medicine. Engineering students should begin hearing in the freshman year, and frequently thereafter, about professional registration so that it will become a goal secondary only to graduation. Unfortunately some faculty members are not registered and may hesitate to assume a "Do as I say, not as I do" attitude.

Engineering faculties should emphasize in junior and senior classes the need for continuing study after graduation. This may be done by mentioning in each course some of the important theories and problems omitted because of lack of time.

Except in large cities or college towns, postgraduate work must be conducted by correspondence courses since the absence of faculty and sufficiently large groups interested in a particular subject make the cost prohibitive. A "Center for Continuation Study" established at the University of Minnesota typifies the facilities needed in many cities to provide wide coverage. Correspondence study is commendable and the material covered "sticks" with the individual; but it does not have the advantage of personal contact with a teacher, and it is likely to be long drawn out and time consuming. Human nature being what it is, relatively few men will progress steadily unless a rigid schedule is set up. Class hours provide this schedule. Personal observation of the attitude of many men in the armed forces indicated a desire to take correspondence and classroom work but also a frequent lack of "push" to complete it.

Most important, a tangible goal must be extablished that a graduate can hope to reach within a reasonable and specific time. Several three-year or four-year "plans" could be set up. At the end of the first, a degree of Master of Civil Engineering might be the goal. Following a second plan the professional degree of "Civil Engineer" might be awarded. At the present time only two schools in the United States confer the "professional" degree (not in civil engineering) on a graduate at the end of four years. In other institutions, however, the requirements form a confused picture.[5] Some schools give it as an honorary degree, some for graduate work and a thesis, and some for a thesis only. Usually a minimum period of from four or five years after graduation is specified. On the basis of a broad outline to permit numerous options and substitutions, a definite program could be planned which would permit a graduate to study by correspondence and in the classroom, so that he would know how and when he might obtain a degree. Isolated courses are helpful and desirable but they are far from being a solution to the problem of continuation of study.

This program might be extended still further. The author mentions the progression through the three M's—matter, men, and money. At about the time that a man has finished work for the professional degree he should be interested in the second and third "M's." A third four-year plan could be laid out leading to a degree in business or administration. Education is not a

[5] "Status of Engineering Degrees," by O. M. Leland, *Proceedings*, S.P.E.E., Vol. XLVI, 1938, p. 322.

matter of regimentation in thought. It is, however, a problem in regimentation of scholastic resources and an individual's time which planned programs will help to solve.

Personal experience with men taking isolated evening courses indicates that a troubled conscience rather than a desire for knowledge impels some of them to register. A man feels he is not advancing, so he registers for a course, pays his fees, and sits back with the inner voice silenced. He may come to class to be amused or to acquire bits of information the easy way without studying. Little or no work is done outside class and absences are frequent. This type of individual will always increase evening enrolment in no-credit "occasional" courses, and perhaps he benefits enough to justify the tuition fee. A definite planned program, however, as opposed to isolated courses or lectures based on sales appeal, should reduce or eliminate the number of such men.

Engineering theory and computations are a difficult "grind" after a day spent on similar problems in field or office. It is a personal belief that, once past the fundamental humanities courses, a graduate would find it easier to begin and continue a program of study, either by night classes or by correspondence, in that field rather than in engineering. Schools contemplating preparation of long-range programs for graduates might consider this point when "pruning" engineering courses and "grafting" humanities subjects. Physicists have moved into many fields formerly claimed by engineers. This trend will continue if basic sciences and technical work are sacrificed to the humanities.

Many developments of the extensive service training programs should be introduced in high school and college teaching. The "Instructors Guide"[6] gives some hints that professors may long since have forgotten. A theory of service teaching is that students remember only 10% of what is heard in lectures. This is a point that "long-winded" faculty members might well take to heart. Emphasis on slides to reduce time and improve instruction is needed. Exposure to Japanese language instruction by the newer method of conversation first and grammar later was convincing proof of its advantages.

Faculty members probably know the needs of industry for new graduates but they do not know much about the market for older engineers. Graduating students are likely to consult with professors about that all-important first job but seldom request advice later when a change of position is contemplated. This may result from being too far from the campus, or from a desire to make one's own decisions. Possibly more recent contacts in the particular field are considered to carry greater weight. Also, a representative cross section of graduates does not return for consultations with the faculty. One of the compensations of teaching is having former students drop in for social calls or advice. Unfortunately, except for a few job hunters, only those in the higher scholastic brackets do so, and the problems of men who just "squeaked" through are not brought to light. During depression years, the school employment offices, run at least informally by most engineering schools, have many calls. Mainly, however, service to the new graduate is their primary function.

[6] "Instructors Guide," Marine Corps Schools, Marine Barracks, Quantico, Va.

Mr. Baker's data show that many engineers leave their profession—more so than in the case of doctors, dentists, and lawyers. This is natural since an engineer is not handicapped by such a change. The training he has received fits him for many types of work. Doctors, dentists, and lawyers have a heavier investment in time and money for their highly specialized training, hence, there is a greater incentive to remain in their profession. Many college graduates in education, business, etc., also desert their spheres of specialized training for the "greener grass" of other fields. Men trained in engineering find it desirable to seek other employment because of the low salaries paid to engineers. This is a serious condition facing the profession. Fortunately, graduates of engineering schools prove capable of competing out of their own fields with personnel from business and arts colleges. This seems to indicate the type of training given in engineering schools, even if it develops only the habit of hard work and long hours, is reasonably satisfactory.

Mr. Baker's paper has undoubtedly crystallized the thoughts of many engineers and educators. The collection of supporting data is a worthy contribution.

I. Oesterblom,[7] M. ASCE.—"Thoughts on Education" is a very wide field, and it is pleasant that the author has strolled deliberately beyond its normal limits. Since the engineer has just proved to the world by his extraordinary performance in war that he is a giant in both mind and body, the education that lies beneath all his achievement is interesting. It must be good, and yet it might be better.

It must be good—for otherwise the performance would not have been so stupendous—and it might be better—for that is the spirit of the engineer. There is always a better way to do things. Were this not so there would be an end to progress.

A review by anybody with a keen and open mind must therefore be instructive, constructive, and of good purpose, and this review by Mr. Baker is especially so. The paper meets all these specifications and it also looks well into the future. However, something seems to be missing. There is a forgotten field which needs to be explored.

When the Hoogley River Bridge was built a few years ago from Calcutta to Howrah in India, it came into being through intense economic pressure which had accumulated over a number of years. As far as the bridge was concerned those years had not been idle ones. There was a temporary pontoon construction across the river which had been forced to serve for a very long time. Over the bridge had gone for years very heavy traffic between two large cities; and through the bridge there was also heavy river traffic. Each was increasing every year—dangerously so. Thus, the social and economic statesmen—and the engineers—had been set to work to plan a new bridge. These groups worked hard for many years because the problem was a difficult one. A huge structure was required, and a flexible one which would take care of the two antagonistic streams of traffic. Much space on land was needed, and all the land was occupied. The river was treacherous and "emotional," and it ran over a soil that was soft and shifting.

[7] Engr., Carbide & Carbon Chemicals Corp., South Charleston, W. Va.

Thus, some official authorities and many consultants produced a number of bridge plans, all of which were excellent and beautiful and one of which was finally selected under the economic pressure of the conditions.

This case is selected as an illustration because it is so broadly typical and because substantially the same conditions exist for all the large engineering projects as they also do in a small way for the minor tasks. The economist—especially the contentedly Marxian—has a fine example of the economic pressure that governs the destinies of man—and he can see that only. However, there is something even more fundamental at work.

Thus one arrives at the forgotten field—to the creative urge in man; to the dreams of constructive work to be done; to the dreams of the engineer, which are born in his mind and which he sets down on paper in his waking hours. They are brilliant flashes, sometimes, but more often they came into being slowly and painfully, borne from experience and knowledge and from that curious urge in all men to create new things out of scattered stones.

The point that this commentator wishes to stress is that these dreams are the most important fact in engineering. Also that in both education and discussion this is officially a forgotten field. In fact, it is even worse than forgotten.

In any school or in any office "thou shalt" or "thou shalt not" predominates. The professor does his utmost to train a flexible mind into a rigid form; and, after school is finished, whatever is left of flexibility is hardened by office standards and specifications. It is not to be inferred that all these tokens of rigidity should not be and that they are not useful, but they should be accepted as servants of the mind and not as prisons to hold the mind captive or as urns in which the mind may be slowly petrified.

How is it then that, even under these conditions, so much is being created and that the performance in the war was so unusually and successfully creative?

This is a most interesting question. For in the welter of minds there are always a few that refuse to be held captive; or, if so held, that are ready to explode into action the moment they sense a call of urgency. They are just like the "Prodigal Judge" of Old Tennessee—besotted and contemptible as long as the soil seemed like a prison but magnificent and a supreme leader when there was work to do.

There is tragedy in the other side of the picture—and that is the prime justification for these comments. Fine minds with a fine education and high diplomas, frozen forever to the drafting boards—once minds ready for constructive dreams but condemned to the drudgery of "routineering." They are now mere slaves of formulas which the mind of a clerk would be happy to use and set down on paper and which he could do even better.

The world therefore is so much the poorer.

These minds have been destroyed by the authoritative attitudes of professors and chiefs, because so many of these have been fascinated by the exterior forms and have not yet seen the rich field of thoughts and dreams beyond. This, therefore, is an invitation to reorganize both material and methods accordingly. More imagination is needed in both school and office as is a better understanding that convention and rigid form should be aids and not masters and that each should be destroyed when it can no longer serve as an element of efficiency and progress.

Should there be special courses in creative imagination in the universities? Perhaps there should be in the future but not now—the time is not ripe. If such courses were started now, some professors would drop dead from fright at such sacrilegious interference with the worshipped forms and formulas. That result would be even more disastrous, for good conventions set the limits to the dreams and without them there would be, at best, beautiful chaos. By preference the thought of the constructive dream should always be present in everything, including seemingly dry calculus, that the teacher tries to convey to the student's mind and in all things the chief of an office attempts to create.

How much more attractive would be the work of each man if such inspiration were always present to pull the potential leader out of his weary armchair of humdrum formalism.

Samuel T. Carpenter,[8] Assoc. M. ASCE.—The clear thinking evidenced in this paper relative to the important problems faced by the engineering schools and engineering societies should be commended. It is to be hoped that in the future there will be more articles by men active within the profession, as their ideas are valuable in formulating the objectives of engineering curricula and standards for professional training.

The factual information in the paper represents important data and furthermore shows that a fundamental, rather than a highly specialized, training in engineering is desirable. It is interesting to note that the questionnaire study performed jointly by the Society's Committee on Engineering Education and the Cooperative Committee on Civil Engineering Education of the Society for the Promotion of Engineering Education verifies Mr. Baker's contentions. The survey indicates that, in general, engineering graduates are very weak in their ability to address a private group or public gathering, and very poor in writing a letter or report. They were also found to be practically deficient in their interest in public affairs. These deficiencies and other deficiencies noted by this survey can be largely corrected by a general improvement in engineering teaching staffs.

Mr. Baker appears to emphasize the part that engineering schools should take in the development of men after graduation. The writer heartily agrees with this, and believes that most engineering schools do attempt to do all they can for their graduates. However, the writer believes that the Society, as well as all other engineering societies, must take an increased interest and be a key factor in the professional development and postgraduate education of the young graduate. There are so many ways in which the engineering societies can and should assist in the professional development of the graduate that each and every one should have a full-time staff man to direct all its relations with engineering education and professional training. The Society should make a continuous survey of the needs of industry for graduates with a civil engineering education.

The Society should also sponsor a campaign directed toward employers of civil engineering graduates to encourage the treatment of the graduate as a prospective professional engineer. The Society should not approach engineering employers and ask them to be altruistic, but instead should sell them on the merits of the professionally trained man in such a way that employers will give

[8] Chairman, Civ. Eng. Dept., Swarthmore College, Swarthmore, Pa.

the graduates an opportunity to rise from the subprofessional status in which many find themselves. Employers could be urged to adopt a training program which would indoctrinate the young man in all phases of work encountered in the engineering office. This is essential since, with the advent of the "Engineer-in-Training" status, the young man must be prepared to take his professional examination within a period of from five to ten years.

The Society has recommended that a more fundamental education be given by civil engineering schools. It is believed that this places a responsibility upon the Society to use the Society organization more effectively as an instrument for professional development. Such a result could be brought about by a coordinated and unified effort on the part of the Society's Committees on Engineering Education, Juniors, and on Student Chapters; the civil engineering members of the Committee on Professional Training of the Engineers' Council for Professional Development; and other agencies of the Society. The over-all problem is so immense that space does not suffice to discuss it here. Accelerated trends in science and society call for education throughout a man's career. It is hoped that Mr. Baker's excellent article will stimulate the engineering societies, as well as the engineering schools, to action.

LYNN PERRY,[9] M. ASCE.—By the publication of this paper, the author has done much to help engineers see themselves as others see them. He has pointed out the usual personal shortcomings of many of the members of the profession. Then with grace and tact he has placed the blame squarely on the shoulders of the professors of engineering who are responsible for the curricula. Curricula considerations are very much more involved and far reaching than the engineer practicing his profession realizes. Perhaps some professors of engineering will follow the suggestion of T. R. Agg,[10] M. ASCE, and "talk back." Probably no more appropriate time could have been chosen to reopen this subject.

In the opening paragraphs, the author, after admitting technical competence and skills, frankly states that the colleges have been training rather than educating the student body. He is concerned about the pattern and structure of the engineering profession, the practice of engineering, and the marketing of engineering services. Without plunging into a deeper discussion by defining education, few professors will award any considerable educational value to such subject matter, by itself. The engineering societies have authorized student chapters for the very purposes indicated—that is, to hasten the student's conception of the breadth of his profession, to bring the activities of the profession and its members to his doorstep, and to place in his very hands the professional literature available. However, some students never attend a meeting of their student group just as some engineers never attend a meeting of their local section, some physicians never attend a meeting of the medical society, and some attorneys never attend a meeting of the bar association. Incidentally, such men are not likely to attend class reunions in great numbers. That is personality. Its roots are congenital, hereditary, or fed by earlier environment. The way to improve the professional personality is to nurture

[9] Designing Engr., Dept. of Water and Sewers, Miami, Fla.

[10] "Freedom to 'Talk Back,'" by T. R. Agg, *Civil Engineering*, September, 1940, p. 549.

the promising and eliminate the hopeless. Do not imagine that a college professor can be influenced to change an engineering curriculum for the purpose of raising the personality standard of his student body.

It has been stated that every man should be a salesman—that, if he has nothing else to sell, he has to sell himself. This is only partly true. Many of the most successful engineers never seek an engagement; engagements come to them. The same is true of the other professions. Being a broad and progressive profession, engineering has opened a field of technical salesmanship to introduce new techniques and new equipment in a conservative and stable society. Engineering salesmanship has been and will continue to be apparently more remunerative in the earlier years than design, construction, research, or production. Large firms have sales or contracting organizations, and technically trained young men who have a flare for that type of work seem to be in demand. Salesmanship, however, is almost as technical as surveying or thermodynamics and, instead of being founded on the immutable principles of mathematics, is based on human nature with all its vanity, superstition, and dogma. This field involves "how to make friends and influence people" and successful salesmanship requires much more study of human nature and self-discipline than most people realize. In the past, professional engagement has been based largely on record and recommendation, and has been continued because of performance. Agreeing that Alexander Pope was correct when he wrote "the proper study of mankind is man" and that popularity among one's acquaintances and geniality among strangers are desirable personal assets worthy of development, then, is or is not the engineering curriculum the proper place for this training (not education)? If "yes" is the answer to the question, it should be decided what subjects are to be removed from curricula to provide the necessary time and someone must accept the responsibility for the decision.

Mr. Baker states (under the heading, "Introduction") "Four years is too short a time," a fact not new to educators or engineers. From the purely professional standpoint, a longer course offers the solution to most of the problems. At the beginning of the century a number of universities offered longer courses; some still do, with a very small registration. Such courses are available, now, for the student who chooses them and, as they become more popular, the supply will probably meet the demand. The New York Section of the National Society of Professional Engineers has taken action on this subject and such action on the part of a few more such societies might force a five-year or six-year course. This trend may develop much faster than is realized. Thus, the effect on the student, the profession, and the university, somewhat interlaced, may be considered briefly.

The time and cost will increase and, presumably, result in fewer alumni. That is what happened in the medical profession. The next generation will have fewer engineers, but better trained ones. The demand for services will net the profession a larger slice of the fruits of the individual engineer's effort—an attractive prospect to the student who has the funds and is willing to devote the time required. It appears somewhat as though it would be a cog in a program to "make the rich richer and the poor poorer."

From the professional standpoint, most engineers are ready to endorse a program that promises to raise the standing of the profession. Those who

have given time and thought to the subject feel that more time is the only solution and that the social problem can be met. Published data indicate that engineering is already a tolerably well-paid profession. It may be that engineers are already taking from society in a closer proportion to what they put in than is realized. Any movement that will result in the ability of the profession to contribute more to society will entitle the profession to a proportionally greater reward.

Engineering educators are likely to point to the first half of the twentieth century, with justifiable pride, as the era of most elaborate technical development in the history of human culture. This development has demanded and used both quality and quantity of effort. It has been predicted that, to maintain the present acceleration in development, society will require engineering talent of an increasingly higher quality in successive generations. On the other hand, it has not been predicted that it will require less; the reverse is more likely. The truly professional man would suffer from insomnia after participating in a plan to increase his emoluments by decreasing service. So it may be unwise to enter on a program likely to decrease the number of professional engineers without plans to supply the demand for a subprofessional group.

Many of the largest universities, supported by public funds, are enjoying mass educational programs developed on the basis of giving the greatest value to the greatest number. Hoards of students have crowded the classrooms and laboratories of these institutions for technical educations in four years although registration remains pitifully low at institutions offering longer courses. The general result has been that men with vision, foresight, energy, and determination have forged ahead into places of responsibility whereas those less abundantly endowed with personal qualities have remained in the subprofessional group longer. This program has placed engineering in its current position.

Now suppose the profession should force a six-year course. The student would probably register in the arts course, elect the first two years of an engineering curriculum during his last two years, stay two years longer, and be graduated. Such a procedure presents no unsurmountable curricular problem. There will be fewer alumni but the university budget could probably be balanced by an increase in tuition. The supply of talent will be better qualified but smaller. The quantity will have to come from elsewhere. The most likely sources are the technical high schools or a forced development of technical junior colleges. A number of these are functioning in the larger cities of the United States. The popular four-year course will be unjustified in its present form. Concurrent operation of both the longer course and the shorter course on the same campus has not proved satisfactory. Universities with adequate equipment and staff will likely follow the signpost to the longer course and adapt themselves. Industry, already short of technical talent, will have to endure through the transmission years. Will it? Can it? That is a personnel problem.

The 1945 report of the Society's Professional Committee on Engineering Education [11] indicates that the Society is likely to adhere to the four-year course in substantially its existing form for the present and suggests that at least 20% of the students' time be devoted to humanistic-cultural subjects. What can or should be placed in this 20%?

[11] *Proceedings*, ASCE, March, 1946, p. 386.

The standard unit of credit, or "credit hour," is one hour of class per week per semester, requiring preparation—an average of two hours of preparation. Arts courses usually require 120 credit hours for graduation, 15 per semester or five courses meeting three times per week. Three hours of laboratory work per week is usually awarded one credit hour. Engineering courses are proverbially longer, requiring from 132 to 144 credit hours for graduation—an average of 16 to 18 per semester and five or sometimes six subjects. After World War I, most of the short courses in such subjects as masonry, tunneling, descriptive geometry, stereotomy, railroad location, railway track and trackwork, and modern languages were eliminated, grouped, or taught with some other subject. In this way room was made for electives in the humanistic-cultural field. At present, the required courses comprise about 80% of the time and electives about 20%; 20% of 132 hours is 26.4 credit hours, or just about one standard three-hour elective throughout the entire four years. Assume that a student has a patriotic urge and wants to elect a course in the Reserve Officers' Training Corps so that he can become a reserve officer in the army or navy upon graduation. That activity absorbs all his electives. The variety of subjects that a class of students desires to elect embraces almost all that can be offered. A fairly large number have visions of travel and elect a modern language, the subject which requires more of the student's time and from which he drives less benefit than any subject which is likely to be available. Nevertheless, if electives are offered, they should be free electives. Much can be stated in favor of a rigid curriculum; it is good training to form the habit of doing what has to be done.

A "letter to the editor" by Don Johnstone,[12] Assoc. M. ASCE, includes some diagrams that show very well how a curriculum is arranged with the fundamental subjects first, then the techniques based on those fundamentals, and finally a smattering of design. The present work requiring 80% of the four-year course will comprise 64% of a five-year course or 53% of a six-year course. The five-year course would permit time to cover some of the most glaring deficiencies that Mr. Baker has indicated but the six-year course would give much more latitude.

Many institutions have courses required for every student. Such courses are usually broadening and have the virtue of being taught by inspiring professors. Every course or subject should have two elements—education and training. Even purely engineering subjects are presented in such a manner that the student must derive some education from the course as a whole, even if it is primarily intended as a vocational subject. If the professor fails in this objective, he is a failure and his students are merely trained in a prospective vocation. Much pressure has been brought on the colleges to insert almost entirely informational courses. Most technical courses are sufficiently informational to keep the memory pliable. Faculties have resisted suggestions for subjects that can be learned by postgraduate reading and have insisted on subject matter that requires teaching rather than merely reading—factual and descriptive teaching. The former practice of making an assignment in a textbook and hearing the lesson is not nearly so prevalent as it was a generation ago.

[12] *Civil Engineering*, June, 1946, p. 267.

For present purposes, subject matter may be considered as (1) distinctly intended for use in earning money (vocational); and (2) for the student to live with during his entire life (cultural). The educator has felt that it is fully as important to show the student the importance of living a full and fruitful life as it is to teach him how to earn some money. There is little time for such work in a standard four-year engineering course. At the same time, the professors who recommend their progeny to prospective employers, and the universities they represent, would feel it very keenly if one of their former students failed to meet the requirement on the first task to which he should be assigned by his employer. It is much more likely that the young engineer's first assignment will be routine in type rather than a monumental design or even an economic investigation. Therefore, professors take much care to assure themselves that, with little or no assistance, the student can make a presentable drawing, run a line of levels, make readable field notes, and follow specifications and directions. They will probably continue this practice even in the face of criticism.

Criticism has been directed at surveying and drawing. Most universities devote about 6% of the students' time to the former and 4% to the latter. Surveying is the first course to which the student is subjected in which he is shown how to apply mathematics. Prior to this, mathematics has been something that his elders have forced upon him and which had to be mastered, perfunctorily in too many cases. If he cannot develop a flare for applied mathematics, he learns it quickly and changes his course. No attempt is made to create a supply of expert witnesses in court cases but the adept student will form some conception of the relativity of measurements, the limitations of accurate physical measurements, the inaccuracy of the arithmetical mean, the value of neat and accurate records (dated and witnessed), and the shape and movement of the earth and some of the heavenly bodies, as well as the construction, use, and adjustment of some measuring equipment. Such subjects are by no means purely vocational for it is a known fact that few engineers practice surveying or geodesy as a vocation. Much the same may be true of drawing. Few students know how to ink a right-line pen when they report in their first class. Some lettering and draftsmanship must be taught. If a little freehand sketching is included, it may supply the basis for a refreshing avocation—Leonardo da Vinci did very well. The time allotted to these subjects has been cut to the very bone already.

English has been and is the most usual subject of criticism; it has been a problem for years. Engineering is taught by engineers, medicine by physicians, law, even business law, by attorneys; but English—well—few instructors have succeeded in creating any considerable enthusiam in the student body. It certainly is as important a tool as some technical subjects, and has educational and cultural value. The scholarly instructor who is a leader and who fires the imagination with the beauty of metaphor, harmony, and clear concise exposition, is only too rare—so the boys use a formula to secure a grade. Consequently, the diction, choice of words, and clarity of expression of a senior show little improvement over those of a freshman. He knows more to say; he has a broader interest but his language discloses his early environment. This condition is not a matter of curricula; few engineering faculties can secure the solution; it is an institutional shortcoming that can be corrected only by the institution.

Graduate "refresher" courses have not been supported with enthusiasm. The formal part of a person's education usually ends with the valedictory. It is doubtful if this will change considerably; certainly it will not change quickly.

A rather important aspect of education has not been mentioned by Mr. Baker—graduates who do not follow engineering. The writer entered college with sixty freshmen, twenty six of whom were graduated (in civil engineering). Five years after graduation, only five were practicing their profession. A contribution of five per year to the profession by a large university is not great. Some sixteen hundred were graduated at another institution with the writer's approval. Of these, probably not more than four hundred practiced engineering more than a few years. The others are in every walk of life from politics to the ministry; they are even newspaper reporters and authors. Their careers justify their training and the existence of their alma mater.

To assist the student in the solution of his financial problem, colleges have appropriated funds for scholarships up to one third or more of the student body. A point that has not been solved satisfactorily is the creation of a motive, on the part of the student—a motive sufficiently strong to drive him over the goal. The postwar student body will consist largely of former service men. The expenses of the men have been provided for and few of them will require artificial motivation. They will have a standard four-year course with its virtues and its shortcomings. Industry and the coming generation will extend to them a hearty welcome, subject them to the usual hardship, and life will be the better as the result of their training.

L. E. Grinter,[13] M. ASCE.—The sincere appreciation of the colleges of engineering should be extended to Mr. Baker for his thoughts on engineering education. He is more complimentary than the men who are responsible for the present form of the engineering curriculum would be. The singular "curriculum" is used with justification because the variations between schools and departments has never been great and the band of variations has been narrowed by accrediting procedures. One question to be considered is whether the author's concept that specialization is bad and that a broad general curriculum is to be preferred might not lead to further standardization without adequate justification.

It is fairly clear from published reports that during the past two years nearly all colleges and universities have been reconsidering their objectives, their methods, and the results obtained. In another year, most engineering curricula will have been rewritten. Educators have been taking very seriously the common criticisms that their graduates are poorly qualified to communicate their thoughts to persons in other groups and that engineers are almost antisocial in their public lives. Certainly it is clear that engineering does not attract young orators and perhaps infrequently enlists anyone who could earn his living through writing. Furthermore, the study of facts, theories, and more facts does not stimulate the development of either the communicative arts or the ability to make friends or influence the actions of others.

Engineering educators want to broaden their students, but few are convinced that a course in public speaking and another course in English literature,

[13] Vice-Pres. and Dean, Graduate School, Illinois Inst. of Technology, Chicago, Ill.

technical writing, history, or public affairs will accomplish the desired result, They believe that a good long list of such courses under cultured stimulating teachers might produce results, but they fail to see how one can study such subjects in sufficient quantity and still end up as a trained engineer. The writer adds that the result would be a total lack of education unless the engineering student could be made to want to study these nontechnical subjects.

Whether educators like to believe it or not, it is true that the student himself has a considerable influence upon the engineering curriculum. By simply doing poorly in courses that do not attract his interest, the student can eventually change their content or even eliminate them from the curriculum. Educational administrators would prefer to maintain common studies for all engineers through the first two years of the curriculum. The student, by continually expressing his desire to start the study of some special branch of engineering immediately, has kept most institutions from adopting this eminently commonsense procedure. A uniform freshman course is as far as administrators have progressed against the desires of the student and of teacher specialists. Could it be that students and teachers are closer to the real purpose of education than the administrator plagued by schedules and budgets?

The question often arises as to whether the study of advanced technical problems in college has merit. In the words of the author (see heading "Prewar Engineering Education"), the student

> "* * * grappled with problems of a character that he would never meet, or at least would not have to solve, on his own responsibility for from at least twenty to twenty-five years after graduation."

Times are changing, or have already changed, to such extent that many laboratories are directed by engineers thirty years old or less. During World War II, young structural engineers carried grave responsibilities for airplane design work, and they will soon hold equivalent responsibilities in bridge and building design. There is no technical responsibility that a first-class engineer of thirty may not have an opportunity to assume. To this extent, the most advanced scientific training can be justified fully if it is not at the expense of a reasonably rounded education. The other objective of advanced scientific study is mental training in how to attack the analysis of such problems. It is not the particular problems that are important, but the experience of having solved difficult problems that develops self-confidence.

On the credit side of the engineer, the author rightly lists resourcefulness, persistence, and a willingness to accept hard work. Engineering education, as it has existed, must be credited with some of the development of these traits which are not common in liberal arts graduates. On the debit side are carelessness in the use of spoken and written English, lack of salesmanship, and an unawareness of the responsibility of the professional person for political and social relationships. The author wrongly criticizes the engineer for lack of a "dollar sense" which has long since become an inherent part of engineering education. In fact, no other group except business men shows so much interest in the practicality of its work.

The experience of counseling with young engineering students makes one skeptical of the practical results of attempting to force such individuals into the

single pattern of broad general education of an engineering nature. The major institution that is famed for giving a single degree to all its engineering students still has been forced to provide considerable optional study despite tradition and the natural preselection of its students. It may be questioned, however, whether the number of vertical or professional subdivisions of the field that now exist are necessary or desirable. It is evident that the choice between mechanical and civil engineering, for example, should be made on the basis of interest rather than aptitude, and the same may be true for the various subdivisions of civil engineering. There are job classifications within the engineering field, however, which do require different kinds of aptitudes.

As an example, one may compare research and design on the one hand with operation and maintenance on the other. Another job classification clearly demanding a special group of aptitudes is management. As a contribution to the author's desire to educate some engineers broadly without missing the need that the writer sees for training others as specialists, the proposal of broad horizontal options through the entire group of engineering curricula deserves careful study.

One such option designed for the training of specialists might properly be in research, development, and design. Such an option would stress mathematics and its application to the solution of engineering problems. It would emphasize analysis and would also provide students with an opportunity for an internship of a few credit hours either in theoretical or laboratory research. At the opposite end of the educational spectrum would be the broad option in management which would provide for all the studies so aptly described by the author. In between would be professional engineering options, not essentially different from those in the present curricula, for students desiring to construct, operate, and maintain engineering works. These horizontal options are equally needed in all engineering fields.

It will become clear that the system of horizontal options provides an opportunity for the full use of the student's aptitudes within the field of engineering to which his interests lead him. He can still be a civil engineer while developing his talents for research, management, or practical engineering service. This is merely the theory of specialization applied in a new direction in engineering education. The result, if this concept is carried out at other institutions as it is planned at Illinois Institute in Chicago, will be to produce one limited group of highly trained specialists in research and the more scientific phases of design. Another limited group will be broadly educated with emphasis upon ultimate work in management within the field of civil engineering. No doubt this group will be more vocal—more interested in economics, politics, and social problems than have engineers of the past, but a larger group than either of these will still be trained for practical engineering work with considerable emphasis upon early competency for earning a living as civil engineers. If this is shortsighted, it is because practical young Americans will it so.

Robert O. Thomas,[14] Assoc. M. ASCE.—The parts of this paper that deal with the practice of engineering and the future market for engineering services are of especial interest. The subject should be given the widest possible consideration among all members of the profession. It should be kept

[14] Engr., Edward R. Bowen, Cons. Engr., Los Angeles, Calif.

continually alive by extended studies and reports in the technical press so that the profession as a whole may be made aware of the dangers confronting it and so that they may be informed of the measures which must be formulated and practiced in order to arrest the present apparent trend toward artisan rank.

For a number of years, the writer has been aware of trends in the practice of engineering which have been so well illustrated by Mr. Baker, and to which attention was called by the writer[15] in 1940.

A study of past annual reports of the Society has developed information of considerable interest relating to the growth, both of the Society itself and of the engineering profession in general. The disparity between the number of new members admitted each year since 1929 and the total gain in Society membership is very striking.

Table 7 illustrates vividly the fact that it is necessary for the Society to admit three new members to secure a permanent gain of only one member. Such a condition in a profession is one which invites extensive research into the causes underlying the movement of men into and out of the profession. Engineering is not a trade, nor is it a type of clerical work that can be taught quickly to an untrained candidate for a job. The 11,126 lost members represent at least four years of study per member—a huge investment in education (individual) and educational facilities (institutional). They represent a group which certainly, at one time, expected to follow the profession of engineering as a life career and prepared accordingly.

Over the sixteen-year period, the actual loss, not counting deaths, amounted to a total of 8,485 members. Each member should be regarded as an avoidable loss—either avoidable through the retention of the men in the profession of engineering and in the Society, or avoidable through more enlightened guidance in the precollege period to those seeking to follow the profession. It must also be remembered that this group of lost engineers represents only those who are able to number themselves among the group of former members of the Society; and it does not include the loss of the considerable number of engineers with which the Society has never come in contact. In considering the loss to the Society, several questions present themselves for discussion. What has turned these 8,485 members away from the Society? Have they left the practice of engineering or have they merely left the Society? If they are still following an engineering career, why did they leave the Society? How could the profession

TABLE 7.—MEMBERSHIP STATISTICS, AMERICAN SOCIETY OF CIVIL ENGINEERS, FOR THE YEAR PRECEDING A GIVEN DATE

Date (Jan. 1)	Total members	New members	Losses	Net gain	Deaths
1929	13,315	1,066	558	508	135
1930	13,823	1,139	565	574	138

[15] "Engineering Trends in California," by R. O. Thomas, *Civil Engineering*, July, 1940, p. 466.

as a whole (or the Society as the representative of the profession) have saved these engineers, either for engineering or for the Society? Were they unsuited to practice the profession? Was some other line of endeavor more remunerative or more attractive? Were they given opportunity to advance in the profession they had chosen, or was their progress made difficult by the lack of cooperation, of fellowship, or of understanding and assistance given them by those who had already attained reputation and recognition in the profession? Whatever the causes, it is the writer's belief that they must be sought out and subjected to searching analysis, because it is only on the basis of truth that the profession can hope to progress.

To secure an admittedly approximate answer to the question of the composition in membership of those leaving the Society, the writer made a study of the membership as given in the ASCE *Yearbook* for 1945. A random 10% sampling was made which resulted in determining that 35.3% of the members listed (a total of 7,250) had been members of the Society in 1929. The 1929 membership was 13,315, from which it may be seen that 6,065 of the members of the Society in that year were no longer connected with the Society. Inasmuch as there were only 2,043 Juniors in 1929, of which a considerable number must have advanced to corporate grade; and, since there have been only 2,641 deaths to date, including both those who were members in 1929 and those joining since, it is readily apparent that a major proportion of those lost to the Society must of necessity have been corporate members. Why have these men, who had followed the profession of engineering for an appreciable period and who had advanced to responsible positions in the profession, left the Society? The answer to this question is vital. Even if these men have left the profession, both professional and sentimental instincts should have kept their membership alive and retained their interests. If they have not left the profession, why are they no longer members of the Society?

To establish some verification for the foregoing data from an independent source, the writer had recourse to the admirable chart prepared by Arthur Richards,[16] M. ASCE, from which Table 8 was prepared. The chart included the results of case studies of 5,000 civil engineers by the Society for the Promotion of Engineering Education; 9,000 mechanical engineers by the American Society of Mechanical Engineers; and 15,000 highway engineers—a total of 29,000 case histories. The writer has applied the diagram to the theoretical histories of groups of 100 engineers beginning practice in successive five-year periods. The data show that of 633 engineers of various ages, active in their profession, there will be only 272 after a lapse of

TABLE 8.—Mortality Statistics in the Engineering Profession

Age	Number in the profession	Number remaining after fifteen years	Loss
25	100	97	3
30	135	66	69
35	131	44	87
40	97	30	67
45	66	20	46
50	44	10	34
55	30	5	25
60	20	..	20
65	10	..	10
Total	633	272	361

[16] "Vocational Guidance in Engineering Lines," Am. Assn. of Engrs., 1933, p. 160.

fifteen years, the remaining 361 having either left the profession or died. This represents a loss, over a fifteen-year period, of 57% of the original total.

The number of engineers under the age of 35 is given in Table 8 as 366, or 58% of the total practicing engineers. The large percentage of younger men, contrasting with the figure of 14.9% for the Juniors in the American Society of Civil Engineers in 1929, seems to be explained by the preponderance of highway engineers in the basic data, highway engineering being particularly attractive to younger men because of the opportunities for outdoor work. Table 9 shows a comparison of data as developed for the Society for the sixteen-year period, 1929 to 1944, and as computed from the Richards curves for a fifteen-year period.

TABLE 9.—COMPARISON OF ASCE AND RICHARDS MORTALITY DATA

Item	ASCE	Richards
Number:		
Engaged in practice of engineering....	13,315	633
Remaining after fifteen years..........	7,250	272
Leaving during fifteen years..........	6,065	361
Percentage:		
Under the age of 35 (ASCE = 32 yr)..	14.9	58.0
Of the original number that has been lost..........................	45.6	57.0

Again taking into consideration the fact that a large percentage of the case histories studied by Mr. Richards applied to highway engineers (predominantly younger men), and the assumption that engineers, taken as a whole, who are the type desiring affiliation with a professional society, are somewhat more likely to remain in their profession than are those who do not so affiliate themselves—there still remains an excellent degree of correlation between the two studies. It can probably be stated as a general principle, that between 45% and 50% of the men who train for and enter the profession of engineering leave the profession for another line of endeavor prior to the termination of their working lives, and as a further corollary (assuming that practically all who leave after the age of 45 are lost by death) it can be stated that they leave the profession in the first fifteen years.

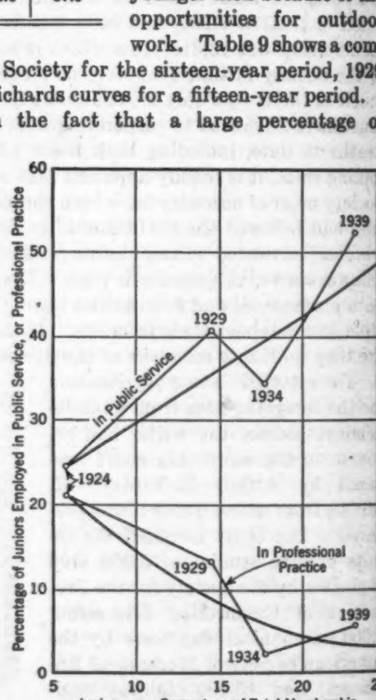

FIG. 2.—GROWTH OF PERCENTAGE OF JUNIORS, ASCE, IN CALIFORNIA, 1924–1939, AND CONCURRENT CHANGE IN EMPLOYMENT CLASSIFICATION

This brings to the fore the subject of the loss of Juniors who find themselves unable to complete the requirements for transfer to the grade of Associate Member. This question has received deep and serious study by the Society's Board of Direction, and cul-

minated in raising the age limit for Juniors to 35 in 1942. As time goes on, apparently, it is increasingly more difficult for Juniors to secure the necessary year in responsible charge of work, and this condition is reflected in the large number of Juniors dropped yearly because they have reached the age limit. This is explained by the large number of Juniors who enter the public service field, where the opportunities for promotion, and consequently for independent responsibility, are slow in coming. Fig. 2 shows graphically the trend of Juniors of the Society toward seeking employment with the large civil service engineering departments, and perhaps accounts in some measure for their failure to qualify for advancement in the Society. It may account, also, for a considerable number of the engineers lost to the profession, as the individual becomes disappointed in his chosen work when he finds the field to advancement and responsibility almost hopelessly blocked; and he turns to other and more attractive opportunities in other fields.

From the data presented herein the following questions are evident: Are young engineers being educated, or trained, properly? If so why are they (and also an appreciable portion of older engineers) leaving the profession, or the Society? If they are not being trained properly, what should be done to reorient engineering education? In the light of the demonstrated magnitude of the numbers of engineers who leave the profession, should the course be lengthened to include material from other major fields such as business administration, public administration, etc., to better prepare the candidate for an engineering degree not only to succeed in the practice of engineering but also in the pursuit of other occupations? Are opportunities in engineering, and the rewards concomitant with them, appropriate to the knowledge, ability, and responsibility involved? If not, what can be done to improve them? If they are, why is the nation losing the services of so many who were once engineers? The future of the civil engineering profession is acutely dependent on the solution to these and other interrelated questions.

Clement C. Williams,[17] M. ASCE.—Gratitude is due the author for his able analysis of the character of the profession and for his collection of pertinent information concerning its composition. The paper discusses engineering education from the viewpoint of the practicing engineer, namely, a commodity purchasable on specifications. It is a viewpoint that widely prevailed prior to World War I. Many professors of civil engineering, with experience limited to T-square operations, pointed their students to the drafting rooms of the American Bridge Company; professors of electrical and mechanical engineering aimed their instruction chiefly toward the apprenticeships of the General Electric Company or the Westinghouse Company. The standard practices of those companies dominated the instruction of the senior year. Engineering then was confined to applied science and the accumulated art. With the expansion of research and of graduate preparation of faculty, the situation has changed; engineering has germinated its own investigative science.

Few educators of today (1946) consider the training of young men for the requirements of present practice as the gage of their objectives. The future careers are too fortuitous in detail to warrant planning with specificity. En-

[17] Consultant in Eng. and Industrial Education, Madison, Wis.

gineering education is more a function of the native capacities of youth and of scientific discovery than of office requirements; instructional subject matter is derived more from researches than from practice. In this new era of education, engineering has made conspicuous advances.

Although all education has a social purpose, its social adaptation is not a primary concern of the college but is a matter for later determination. The author's analogy to steel billets and subsequent products is correct but somewhat remote. A closer, but still faulty, parallel would be that college attends to the growth of a tree so that it becomes strong and without defects, but leaves the question of what timbers may be cut from the log for later circumstances to decide. Engineering education consists in cultivating the "growth" of the faculties to observe, to think, and to express thoughts, and of the personal attributes essential to good citizenship and a full life. In mental discipline, it involves an acquaintance with the basic sciences and knowledge as thought tools and material, followed by exercises in thinking concerning supposititious engineering situations—all critically compared with the more mature and tested ideas of the teacher and the textbook. Exercises in thinking are as essential to mental development as physical exercises are to bodily improvement. The former are the crux of the learning process. The author seems to mistake these supposititious engineering exercises for an attempt to teach engineering practice. Of course, their value is enhanced by the closeness of their correspondence to actualities; and, if well chosen, they do impart a modicum of practical information. They also serve as a pedagogical device to stimulate interest, so indispensable to learning. They are of value in developing powers of ratiocination even if they relate to situations which never arise, or to situations entirely forgotten by the student, since these powers, if once ingrained, can be recalled from the subconscious mind although he may think them gone forever.

The author also seems to overestimate the maturity of student experience. What a student can absorb and assimilate depends on his previous experience. The concepts of a mature engineer cannot be grafted on to the tender experience of a youth who has had no observation of engineering work. A lecture beyond the student's clear grasp is futile, for "nothing learned, nothing taught" applies regardless of the profundity of the message.

Professions are not rigid arrangements of human services but are clusters of similar operations grouped more or less statistically according to the frequency of their occurrence. Mechanical skills fit into definite requirements, but engineering is expansible and adaptable to its social function. The sixty members of the writer's own class in civil engineering, as revealed by the annual class letter, have served society well; but relatively few of them at present are doing work closely related to the class instruction of the undergraduate years. Following the progress of hundreds of students who have passed under the writer's supervision brings the conviction that careers are affected by circumstances mainly coincidental, and that it is wholly conjectural whether any particular modification of their curricula would have improved their fortunes. Engineering education aims at a hypothetical service as a bull's-eye, but its results follow a scatter or probability pattern centered on the maximum of incidence.

It is not derogatory to engineering education, therefore, to find that those so prepared are distributed over a multitude of occupational needs in organized society. Indeed, since each particular activity cannot feasibly be accorded specialized training, this flexibility of engineering education is a social virtue. Education for the law presents a similar situation in that it prepares for a large number of ancillary vocations which contribute to successful society. In a city of 15,000, where the writer once lived, there were seventy-two lawyers—that is, persons who had been admitted to the bar—although not more than ten or a dozen practiced at court. The others were realtors, securities agents and abstracters; or were engaged in local politics, in business, or otherwise serving the community. The law touches human affairs at many points, just as applications of physical science do; hence, one may expect preparation for law, or for engineering, to be widely useful in organized society outside the strict confines of the respective professions. In medicine, by contrast, the preparation is more specific and is seldom applicable beyond health and hygiene; nevertheless, quite a few doctors become managers of business and civic leaders, as do many men who have had no higher education. From these circumstances, the inference may be drawn that specific training for unusual eventualities does not need to be included in the professional curriculum.

The author proposes that curricula provide a broader scope of basic instruction covering the entire field of engineering and leave advanced theory for graduate study. There were many protagonists of this idea a quarter of a century ago. A number of institutions, especially smaller colleges, adopted the plan of having three years for all departments in a common curriculum with departmental differentiation in the senior year. The University of Iowa, Iowa City, adopted this scheme. The writer became dean of engineering at that university in 1926 and witnessed the change back to the usual distribution of subject matter. Some of the reasons for the reversal were (1) the graduates did not make a favorable showing when they entered apprenticeship courses; (2) the classes could not use standard textbooks; and (3) most of the faculty were dissatisfied with the unstimulating elementary instruction involved. Some of the small colleges still continue the plan. Their alumni cannot enter graduate schools directly; nor are they so acceptable to industry; and their curricula are generally not accredited by the Engineers' Council for Professional Development (ECPD). Many engineering colleges have a "general engineering" curriculum which includes about equal parts of all branches, but it has not proved superior in vocational adjustment.

A longer period than four years in the engineering college may profitably be spent by many students, either (1) in pursuing the humanities or the social studies, (2) in the pure sciences and mathematics, or (3) in the technical subjects of engineering curricula other than the student's major. Many students so continued their education during the depression years when jobs were not available, and, generally, they found the additional study profitable. However, the length of an engineering education, like other engineering undertakings, has economic limitations, which, for the present scale of compensation, seems to be four years. The students of superior ability find postgraduate study,

even through the doctorate, advantageous. For students of the lower half of the class, graduate study, so far as the writer has observed, seldom advances the engineer's professional success.

As a matter of fact, the preparation of engineering students is more general than most industrial personnel directors and practicing engineers are aware. Students have some instruction in all departments, and their training in nonmajor branches is preponderantly the same as if they pursued a common curriculum. The specialization is attained by shrinking slightly the time to each nonmajor branch and devoting the total increment thus gained to the major. Personnel directors overestimate the significance of this specialization. Seeking a mechanical engineer for quite general work in a factory, for example, they will not consider a civil, mining, or electrical engineering graduate even though he be in the upper percentiles of the class. The evils of departmental specialization lie more in the departmentalized recruiting practices of industry than in the educational results.

All educational programs should aim at the development of the whole man, whether the intellectual part of the curriculum pertains to engineering, law, medicine, social studies, or the humanities. In this respect, all education should be liberal—that is, directed to the whole free man. It should not be limited to the intellectual realm, but should include the emotional, the volitional, the social, the spiritual, and the physical. The latter qualities are little affected by the particular subject matter in the courses studied and should be given separate consideration. Narrow specialization relative to today's civilization is frequently found in the humanities as well as in the sciences. Any feasible inclusion of the humanities in the engineering curriculum will fall far short of the postcollege reading and reflection requisite of the cultured man. If that small inclusion initiates a taste and an inclination, it will be justified.

Although all of these capacities are educable, most college study is directed solely to the intellectual growth, with some attention paid to the physical. Effective pedagogic processes have not been devised for the other categories of attributes of the whole man. The older British universities do a somewhat better job than do the American; and, as a member of the Board of Visitors at the U. S. Naval Academy, the writer has been impressed with the accomplishments of that institution in the development of these personal qualities. To a considerable degree, the nurture of these qualities is subconscious, the product of environmental influences and institutional traditions. The neglect of these disciplines constitutes the chief defect, not only of engineering education, but of all American higher education.

As the author so well points out, postcollege engineering education should have attention. It occurs subsequent to the impressionability of youth and when the outlines of careers are becoming more discernible. It differs fundamentally from graduate study, which is aimed primarily at research methodology and investigation. Inasmuch as it pertains to the profession, perhaps the ECPD might undertake to formulate a suitable program.

The recent reorganization and amplification of the American Society for Engineering Education (formerly "Society for the Promotion of Engineering

Education") is significant of an enlarging grasp of engineering education. The appearance of a challenging paper by a practicing engineer, in the *Proceedings* of the oldest of the Founder Societies, is a portent in the same direction. Coupled with the expanding universe of engineering as a result of recent scientific advances, fresh attention to education may be epochally significant to the profession.

N. W. Dougherty,[18] M. ASCE.—From the practicing engineer's point of view the paper is a good presentation, but it overlooks many of the changes in engineering education that have taken place during the recent past. In the "Introduction" the author suggests that:

> "It [engineering education] has not, however, made comparable progress in keeping abreast of changed conditions that have developed during that period in the pattern and structure of the engineering profession, in the practice of engineering, or in the market for engineering services."

Some of the subjects omitted probably belong to the postgraduate years rather than to college courses. Education is an experience rather than an accumulation of information; it should be inspirational and continuing rather than complete in a four-year program.

All the colleges have been guilty of neglect in their continuing activity after graduation. On the other hand, if they do their in-college instruction in an inspirational way there will be less need of continuing instruction. Why should educated men continue to be spoon-fed after they enter the world of work and application? There are many things the colleges can do to help; but all they can do cannot make educated men if the students do not want to pay the price of education.

Again, quoting the last sentences of the "Introduction": "Every engineering student must work hard to graduate. This probably was the most valuable single thing that he learned in his course." Learning to work is valuable but learning to work effectively is more valuable. If the student has not learned this lesson he probably has not learned much—learned to work with books, the printed page, and rows of books; learned to glean a magazine page and sift the wheat from the chaff; learned to trace cause to effect; learned to respect law but not worship it; and learned to continue in his search for truth.

Prewar Engineering Education.—There is so much difference in the colleges that it is practically impossible to appraise what has, and what has not, been done. When the Engineers' Council for Professional Development (E.C.P.D.) has accredited fifteen different curricula and a host of options, breaking down the fifteen into more restricted fields, one can truthfully say that there has been too much specialization. The author sums up this practice by the following statement:

> "The general objective * * * appeared too often to produce a graduate well versed in theory of, and with an academic knowledge of, practice in one particular branch, and in many instances in one specialty in the field

[18] Dean of Eng., The Univ. of Tennessee, Knoxville, Tenn.

of engineering, thus equipping the graduate to enter such field or specialty on graduation and encouraging him to do so, irrespective of what the market for services in such field might be in five or ten years."

Whenever a student enters any program of study having a definite objective in mind he will try to find employment in that field on graduation although employment is scarce in the field. It is fallacious to believe, however, that the college training in engineering in any field restricts the trainee to employment in that special field. Too many who were trained as mechanical engineers are practicing electrical engineering, or electrical engineers are practicing mechanical engineering or civil engineering, to make the statement that training in a field ties the student to that field. The author draws the conclusion from his premises that either there must be a broad general course, or there must be applications to practice in a single branch or specialty. There are equal possibilities in a broad general course in civil engineering, for example, or specialization in the various fields of civil engineering.

Educators have a notion that they should give enough technology to transmit the attitude, method, and approach to the solution of problems which depend on broad fundamental laws of physics, chemistry, mechanics, and hydraulics. The method and approach can best be acquired by solving actual problems of engineering practice. True, they must be miniature and often from assumed data to illustrate a principle, but such problems do give an introduction to the engineering approach. To many educators the field of specialization is not so important as the method and the problems.

There is educational value, of course, in sequence courses. The emphasis of engineering schools is not necessarily on specialization but rather on the application of engineering theory to some engineering problem. If the problems come in an area of later employment there will be advantages; and should this not happen no harm has been done.

Except for the idea of "the field of general engineering," the author's course, as outlined, is in general agreement with the recommendations[19,20] of the American Society for Engineering Education—formerly, Society for the Promotion of Engineering Education (S.P.E.E.). Both have the same general objectives, namely, a well-rounded engineer rather than a skilled technician.

The author points to a well-known problem in engineering education:

"He grappled with problems of a character that he would never meet, or at least would not have to solve, on his own responsibility for from at least twenty to twenty-five years after graduation."

This may be very true; but, if the teaching is to achieve method, attitude, approach, and confidence, no great harm has been done if the student never meets the problem again. For years engineering educators have recognized the problem of dissatisfaction and discouragement of students during the first five to eight years out of college. There is no question that much of the difficulty stems from the failure to use their advanced knowledge in immediate

[19] "Aims and Scope of Engineering Curricula," *Proceedings*, S.P.E.E., Vol. XLVII, 1940, p. 555.
[20] "Report of the Committee on Engineering Education After the War," *ibid.*, Vol. LII, 1945, p. 36.

practice. Judgment should come with experience but not all experiences develop judgment. A part of the remedy is to produce understanding employers along with more understanding instruction.

The writer has attended many meetings with practicing engineers where attempts were made to discover "what is wrong with the colleges" and always has heard the statement: "As a graduate he seldom had the ability to express himself adequately or a knowledge of how to acquire this ability."

This seems to be a universal trait. Engineers are about the worst on the list, but it has been discovered in preachers, lawyers, doctors, dentists, and English professors. Good expression seems so easy that all are deceived by it. The practitioner, who cannot express himself, tends to blame some professor for his lack of proficiency. Good English is "a gift of the gods" and the result of real effort to acquire ability. Much of its lack is the result of having nothing to say or of having very hazy ideas. Good expression and clear thinking "go hand-in-hand."

The analogy of the steel mill is a little overdrawn but it does emphasize a well-known educational principle: Men are not materials, and educational experience will not make them mainsprings or auto bodies, but it may make it possible for them to be either. All men act as individuals; some of them are intelligent enough and self-reliant enough to succeed, whereas others are perfectly willing to follow the leader. No educational process has been developed to make all of them become leaders.

The Engineering Profession.—The author's study of the engineering profession is thought provoking; it points a way to a better understanding of the task of the colleges. More studies of this kind will be very helpful. What changes of definition have occurred during the forty years of census reporting? From where have the additions come? The author's description of the engineer is probably more nearly true to type than Saint Luke's definition of the Athenians: "That they spend their time in nothing except to hear and tell some new thing." Quoting the paper (see heading, "The Engineering Profession: General Traits and Characteristics of Engineers"):

> "On the credit side it may be stated that engineers in general are resourceful, hardworking, ingenious, and persistent, and have a great devotion to their work. On the debit side they are extremely narrow in their interests and outlook, and highly individualistic."

When engineering is considered "as a heterogeneous rather than a homogeneous profession" engineers are likely to fall into error when they attempt too much generalization regarding the characteristics of their profession; yet the writer believes that Mr. Baker has done well in the foregoing two sentences. By training, and no doubt by birth, the engineer is individualistic. He is not the "back patter" and the "glad hander" of some other professions. Part of that is due to his training and part to his very nature; his disposition caused him to study and begin the practice of engineering. Considerable change will be required to make over the introvert who goes into engineering into the extrovert salesman who disposes of the products of the assembly line. As a

matter of fact both types are needed in industry and both types can profit by training in science and technology.

Table 3 is very interesting. A census reported in 1966 will probably raise the percentage of practitioners who enter engineering through the four-year college course. Engineering is now where law and medicine were at the beginning of the present century. Probably it should not aspire to the high percentage of college practitioners now required of law and medicine. The field is far more varied and gives much more opportunity for great variations in innate talent.

Fig. 1, giving a cross section of the engineering profession, is more than interesting. If it is at all to scale, it points to an evolution which is far more revolutionary than the preceding data suggest. The ordinate probably bears some relation to age or time spent in the profession. The author would do the profession a genuine service if he tried to make a similar diagram to scale, using professional age as the ordinate.

Postwar Engineering Education.—The changes suggested under this heading are those usually made by engineering educators as well as by those who practice engineering. Future changes will not be as drastic as those suggested because the curricula are rarely as specialized as the author assumes. More emphasis will be placed on the professional aspects of engineering—the broad bases of engineering practice—and less emphasis will be placed on specialized skills. For example, the following quotation expresses many of the ideas of the author as he describes his postwar engineering education:

> "For the scientific-technological stem, acquirement by the student of mastery of the basic principles, assumptions, empiricisms, and codes of practice which constitute the subject matter of engineering study, accompanied by acquisition of the ability to apply them to problems of practice which constitute the engineering method.
>
> "For the humanistic-social stem, development of the ability to read, write, and speak the English language effectively; to understand, analyze, and express the essentials of an economic, social, or humanistic situation or problem; and to appreciate its implications and relationship to the life and work of an engineer. There is also a goal of development of an adequate concept of the duties of citizenship in a democratic society; and acquaintanceship with the enduring ideas and aspirations which men have evolved as guides to ethical and moral values; and an appreciation of cultural interests lying outside the field of engineering."[20]

The engineering profession owes a debt of gratitude to the author for this thought-provoking paper. For their part, the colleges have already stated what they think should be done in engineering education after the war.[20]

Members of the Society should see to it that civil engineering educators do not fall into some of the snares that have obstructed their paths in the early development of education for the civil engineer.

H. A. WAGNER,[21] ESQ.—Like Mr. Baker, the writer has become convinced that the entire plan of engineering education should be revamped to meet present problems. The schools should perform three important functions:

[21] Cons. Mining and Metallurgical Engr., Chicago, Ill.

Train engineers in the scientific approach to the solution of problems; give them a foundation in subjects that are fundamental in business and industry; and provide a broader scope of instruction in subjects that cover the entire field of engineering, insuring a thorough foundation in the basic fundamentals underlying all branches of engineering.

These ends cannot be achieved by crowding additional subjects and disciplines into the present four-year course. The training recommended by Mr. Baker can be given only by eliminating from the curricula certain courses that develop elementary skills and proficiency in the use of scientific tools and instruments, and by deferring to postgraduate study those courses in advanced theory and practice, highly specialized, which now monopolize the time of students in their junior and senior years. The writer concurs in the recommendation that the schools develop strong, postgraduate extension courses that will enable engineers to specialize after they have discovered their own aptitudes and opportunities—after they have learned from experience the conditions that govern practice and the market for engineering services.

To the writer, as to Mr. Baker, this seems the auspicious time to consider drastic revision of engineering education, while curricula are still plastic due to the necessity of adapting engineering training to the exigencies of the war and its aftermath. Mr. Baker is not at all didactic in his specific recommendations for curriculum revision. He is definite and urgent in his plea that the schools and the societies conduct an extensive and thorough investigation into the composition and structure of the engineering profession, the conditions that govern and prevail in actual practice, and the market for engineering services—investigation that will provide authoritative guidance for those who may be charged with the task of revising curricula.

The very crux of the entire problem is graphically represented in Fig. 1, depicting the composition and structure of the profession. No one can appraise current curricula intelligently, much less undertake to revise them, until there is a clear understanding of these factors. A thorough investigation of the composition and structure of the engineering profession is an indispensable preliminary to curriculum revision.

After such an investigation has been made, engineering educators can properly evaluate Mr. Baker's specific recommendations for curriculum changes. It may be, however, that certain evolutionary processes, already apparent, will take the situation out of the hands of the profession and its educators. Certain developments are in evidence that already indicate a movement toward the three-pronged system of training which evolved in Germany before World War I.

This system includes three types of training. There is, first, the "Gewerbeschule," which corresponds roughly to the "technical high schools" in the United States. It equips students to use engineering tools and precision instruments, and develops rudimentary skills which are adjuncts to, rather than a part of, engineering. It is quite probable that these schools will be supplemented by union "trade schools" which, under the sponsorship of white collar unions, will serve the same purpose. They will offer only "pre-engineering" instruction.

Then there is the "Technische Mittelschule," which, in its curriculum and discipline, is equipped to prepare students to assume duties more closely related to, or actually a part of, professional engineering. This is done under the close supervision of those who are prepared to direct or perform creative work, requiring exercise of independent judgment. These intermediate schools will produce the indispensable "routineers."

A third type of school produces the fully professional engineer. This is the "Technische Hochschule," which confers state diplomas and doctors' degrees in engineering. Its graduates are masters of the fundamentals in all branches of engineering when they receive their diplomas; they are specialists, when they achieve a doctor's degree.

The present system of engineering education in America is expected to serve the needs of all these groups. Students who will spend their lives in the "subprofessional" bracket, performing only mechanical operations that are adjuncts to, rather than a part of, engineering, and those who will become indispensable routineers, pursue the same studies, submit to the same discipline that develops engineers capable of creative work, involving exercise of independent judgment. If all these groups are considered members of the engineering profession, the schools must continue to serve them all.

This is the problem posed by Fig. 1—a problem suggested, however, rather than stated. Mr. Baker has not the temerity to do what the engineering profession has neglected to do in the past fifty years—define its own scope.

There are four important segments in Fig. 1. It is fruitless to investigate the indicated composition and structure of the engineering profession, unless such an investigation leads to a clear decision, a resolution of the enigma, "What is the engineering profession?" and a question that has long been evaded: "What is its scope?" Eventually engineers must decide "Who are members of that profession?" What is learned from this investigation should enable the engineer to define and delimit the profession; to draw clear lines of demarcation between real professional engineering and the fringe of arts, crafts, and trades which now blend indistinguishably with it.

The profession must do this because it must decide how many of the segments represented in Fig. 1 require genuine engineering education. In accordance with that decision, the responsibility of the schools will be limited and curriculum revision must be controlled. Schools of engineering must know who shall be educated and for what capacities and functions students are to be "processed" before they can plan curricula intelligently.

Mr. Baker has stated plainly that the schools and the professional societies should investigate the composition and structure of the profession. He is not to be censured for withholding his own opinion as to the scope of professional engineering. He intimates that those who have "left engineering" are no longer members of the profession, by the device of a broken line, marking the outer boundary of that segment in Fig. 1. If he had felt strongly that those engaged in "subprofessional" work were not members of the profession, he might easily have suggested it by a similar device—a heavy line of separation or some other graphic representation of detachment. Mr. Baker did not allow himself to be diverted from his major thesis by a discussion of this highly con-

troversial issue. He did unreservedly recommend clarification of the point, urging educators and societies to investigate the composition and structure of the profession.

There are many conceptions of "professional status" and of the "scope of the profession" and each has a substantial number of stout adherents. First, there are those who believe that a degree in engineering is unimpeachable evidence of professional status, of membership in the profession. Second, there are those who believe that, regardless of academic qualifications, performance of engineering duties is prima facie evidence of membership in the profession. Third, there is the contention of registered engineers that the engineering profession consists exclusively of those who, by registration, have a statutory right to use the title, "professional engineer." Another faction, more realistic, discounts the statutory restriction of the title as a legal technicality; and, in support of this attitude, cites the vast numbers of eminent engineers who, although qualified, have never chosen to register because the oddly constructed license laws in the United States make it unnecessary to do so. Many argue that by membership grades the engineering societies describe the extent of real professional engineering and designate "professional status." Most prevalent of all, perhaps, is the notion that professionalism is not an absolute, sharply definable state; it is held that there are gradations, and that the measure of "professionalism" is the degree of eminence.

Not one of these notions provides guidance for educators if they attempt to put in effect the curriculum changes recommended by Mr. Baker. The schools have attempted to reconcile all these ideas, and to serve the needs of a profession that is practically undefined.

The theory is advanced that those who eventually enter the segment in Fig. 1 inscribed as "Number engaged in technical engineering work primarily," and that designated "Number engaged in administrative and executive work primarily," must earn their spurs in "subprofessional work." If the profession were to embrace this theory, the schools, regarding the subprofessional group as members of the profession, must continue to offer courses that prepare potentially professional engineers for work involving tracing, drafting, and the use of precision instruments. Graduates in the subprofessional segment will work side by side with men whose training for such duties has been entirely practical, or has been obtained in technical high schools and trade schools.

If this group is not to be regarded as a part of the profession the time now allotted to such courses can be devoted to engineering fundamentals.

Other professions, sharply differentiating professional from nonprofessional practice, train technicians apart from future professionals. Bacteriologists, nurses, laboratory technicians, and other affiliates of medicine prepare for their jobs by taking courses much less rigorous than those required for the practice of medicine. It is impossible for bacteriologists, however brilliant their contribution to medical science, to qualify as physicians without taking the courses required for a doctor's degree in medicine. The line of demarcation between "professionals" and "nonprofessionals" is sharply drawn in licensure; the training of professionals and technicians is as plainly differentiated.

If and when the engineering profession sharply defines its scope, sets up standards of membership as clear and inflexible as those statutorily established by the profession of medicine, engineering education can follow medicine's example also in eliminating courses that merely develop skills used in preprofessional capacities. When this happens, the pre-engineering group, indicated in Fig. 1 as "subprofessional," will be quite definitely excluded from the profession, and it will no longer be the responsibility of the engineering schools. Other types of schools will prepare "subprofessionals" for pre-engineering functions. Whether this group will be excluded, or will secede, is a matter about which the writer will not make any predictions.

If this change comes, it may not be on the initiative of the profession. Professional status is now being defined by governmental agencies—not one, but many agencies. The Civil Service Commission, in its classification of nonprofessional, subprofessional, preprofessional, and professional employees is assuming, but not usurping, a prerogative which engineering has never exercised, drawing distinctions as it sees fit between professional and nonprofessional engineers. The United States Employment Service is preparing a series of booklets for the guidance of its placement counselors, describing the characteristics, qualifications, and duties of engineers serving in professional capacities. The Fair Labor Standards Act (F.L.S.A.) Administrator, after futile efforts to distinguish "professional status" by academic definition, finally resorted to the rule of thumb that, for the purposes of F.L.S.A., any engineer earning less than $200 a month in base pay is nonprofessional. Case by case, the National Labor Relations Board (N.L.R.B.) distinguishes "professional" from "nonprofessional" engineers. Nothing has as yet crystallized from its many decisions definite enough to be called a line of demarcation; but a pattern is slowly emerging. The Board's line of reasoning can be traced in the following interesting decisions: Aluminum Company of America (61 N.L.R.B. 180); Bethlehem Steel Company, Shipbuilding Division (Case No. 20-R-1256); Gielow, Incorporated (Case No. 2-R-5290); LaClede Steel Company (Case No. 14-R-1148); Neches Butane Products Company (Case No. 16-R-1159); Packard Motor Car Company (Case No. 7-R-1809); Stone and Webster Engineering Corporation (Case No. 1-R-2139); and Curtiss-Wright Corporation (Case No. 9-R-1738). The Bethlehem Steel Company case is particularly interesting.

Another and even more potent force is the appeal of the labor unions who argue that "professionalism" is a fetish, and who assert that unions can do more to improve the social and economic status of subprofessional (and professional) engineers than can any professional or technical society. They scoff at the tradition that engineers are individualists and cannot advance if any restraints are imposed on professional freedom. They insist that strong, collective action insures better pay, improved working conditions, and satisfactory recognition; and point to the relatively high wages of skilled and unskilled labor, in comparison with subprofessional, or even professional, salary schedules, to support the argument. They discount the theory that engineers advance more rapidly when they are free to exercise individual initiative, capitalize on native ability and aptitudes, and bargain directly with the employer.

In any investigation of the composition and structure of the engineering profession these conflicting theories should be tested. If engineering is thought

of as a pyramidal structure (and Fig. 1 indicates that it is) there is less room at the top than there is in trades, which are more like cubes made up of a myriad of almost identical units. The engineering pyramid is irregularly stratified; and the individuals of which it is made differ greatly in ability, training, initiative, industry, and those temperamental qualities which so potently affect careers. There is also no inflexible relation between these good qualities and advancement from grade to grade. Opportunities—external factors—influence the progress of individuals from subprofessional to exalted technical rank. A large number of engineering graduates, regardless of their qualities, are destined to remain routineers simply because there is not enough room at the top for all of them.

Some engineers are beginning to be cynical about "professional status." Despite their degrees, graduates spend years in a kind of no-man's-land—not members of any trade, yet denied professional status by their own license laws. Appealing to engineers, disowned by the profession, the unions have convinced a great many of them that "professional status" is a myth, and "professional ethics" a fetish.

There are more practical objections which the unions find it harder to dismiss. Engineers have become identified with too many different unions. They change jobs frequently, and a new position may entail a complete change in union affiliation. It is not easy, therefore, to convince engineers that it is worthwhile to build a strong union—to pay substantial dues, to demand clauses in union contracts which strengthen the union itself and fight for these more resolutely than for clauses which insure direct and immediate benefits to the members. Although the craft and industrial unions are still absorbing subprofessional engineers (and even preprofessional and professional engineers), the major unions have recognized the disadvantage of this fragmentation, and they are building "white collar unions" in which, apparently, they hope to integrate clerical and "professional" workers.

Those who hope to retain these subprofessionals and routineers as members of the profession, must study the structure of the profession. If the chances of reaching the top are limited, some way must be discovered to offset this disadvantage and to insure pay for the subprofessionals commensurate with their training and services. Their salary schedules must bear such relation to wages of skilled and unskilled labor that they will not find it necessary to identify themselves with these groups in order to protect their interests.

On the other hand, if the profession were to renounce its claim to subprofessionals, eliminating from the engineering curriculum those courses which qualify students to perform subprofessional duties, it must be with full understanding of the effect of that decision.

First, the unions can be expected to set up "trade schools" and systems of apprenticeship such as they now maintain for operating engineers, for plumbers and decorators, and other trades. There will be a corresponding decrease in the number of students who enter engineering schools. Engineers cannot expect to continue half trade and half semiprofessional. If a large proportion of subprofessionals obtain their training in technical high schools and union trade schools, then by collective action establish high rates of pay, and through

seniority clauses insure continuity of employment and automatic promotions, four-year courses leading to similar jobs will be less and less attractive.

Second, if the unions, rather than the professions, decide what constitutes "professional status"—if they draw the engineer's boundary lines for him—it may not be subprofessionals alone who will be absorbed. Just above the subprofessionals who perform mechanical operations subsidiary to, but not a part of, engineering, there are the "preprofessionals." These men, under close supervision, implement the plans of professional engineers. They need greater knowledge of engineering fundamentals; they participate intelligently in creative work; but they do not exercise independent judgment and, as engineering becomes more and more standardized, their jobs are correspondingly more and more routine. There is no assurance that these men will not also secede from the profession. If the unions gain control of "preprofessional" as well as subprofessional engineers, the usual routes by which graduates progress to "responsible charge" will be closed to those who are reluctant to join unions. Perhaps some institution, like the intermediate schools in Germany, will develop to equip "preprofessionals" with the knowledge of engineering fundamentals required in these routine jobs, like the short courses offered in the United States during World War II.

Eventually there will be left to the engineering schools only those students who have demonstrated a capacity for creative work or administrative service. Relatively few institutions of higher learning would be needed to "process" the number of engineers of this category that industry can absorb. It would be necessary for industry to accept the product of these schools as trainees, or understudies, instead of developing them gradually in subprofessional and preprofessional capacities.

The effect of this shrinkage upon engineering societies and upon employer-employee relations must be given careful consideration. If, by professional definition or by their own secession, a preponderance of subprofessional and preprofessional engineers are definitely separated from the profession, the structure of the societies will be changed as much as the structure of the profession. Engineers will not support both unions and societies. As long as they have a tenuous claim on professional status—indicated by such evasive designations as "preprofessional" engineers, or "engineers-in-training" or "engineering aides"—they may remain loyal. If through any act of the profession, or on their own volition, they become definitely recognized as nonmembers—outsiders—they can hardly be expected to remain in the societies.

Certainly the relation between engineer-employers and engineer-employees will be changed if a great majority of employee engineers in subprofessional and preprofessional ranks organize in the pattern of, and identify themselves with, skilled and unskilled labor. These organizations will be in a position to control the "processing" of men who will join their ranks just as they now control apprenticeship and training for the trades.

To the writer it seems Mr. Baker's plea for a thorough investigation, by engineering educators and technical societies, of the composition and structure of the engineering profession should be heeded. It should be acted upon before other agencies have decided, for the profession, that crucial question—"Who

shall be members of the engineering profession?" This is the essence of professional freedom. It is a right, cherished by all other professions, which is given to a professional man in exchange for the service he renders to society, in order that he may not be impeded in such service. If it is not too late, the writer would strongly advise the profession to follow Mr. Baker's urgent recommendation. The present composition and structure of the engineering profession should be investigated thoroughly, and standards of qualification for membership should be redefined—new boundary lines for regulating entrance to the profession. Then let educators plan to "process" engineers so defined in engineering schools for utmost usefulness to industry and society.

M. E. McIver.[22]—Mr. Baker has urged that engineering educators and the technical societies examine carefully: (1) The composition and structure of the engineering profession, (2) the conditions encountered by engineering graduates in actual practice of engineering, and (3) the factors that govern the marketability of their services. He has recommended that the societies utilize the vast amount of authentic source material accumulated in their own files—the case histories of members, and the records of the employment service jointly sponsored by the societies.

Even now the Engineers Joint Council (EJC) is engaged in investigations along the lines suggested by Mr. Baker. The EJC, however, seems to be relying on the questionnaire method of obtaining data, instead of using the treasure-trove of facts stored in the files of the societies represented on the EJC.

American Association of Engineers (AAE) has tested the technique of investigation recommended by Mr. Baker and found it far more satisfactory than the questionnaire method of collecting data pertinent to the social and economic problems of the profession.

The disadvantages of the questionnaire method are:

1. Abuse of the device by commercial agencies has reduced its effectiveness. The promotional purpose of such agencies is thinly disguised by the pseudo-scientific veneer of their inquiries;

2. Employed engineers, unless they have been markedly successful, are reluctant to chronicle their careers for their societies and alma maters;

3. In answering questionnaires, employers and employees are inclined to report facts in a manner that reflects credit on themselves and their organizations; and

4. Sheer negligence and procrastination account, in part, for the necessity of repeated follow-ups to secure an adequate volume of replies.

For all these reasons, AAE has found the questionnaire method a slow, costly, energy-consuming process of collecting information. Its committees are inclined, moreover, to discount the accuracy of voluntary replies to inquiries that individuals may consider unwarrantably personal or intrusive. Whenever this device is necessary the questions are composed in such a way that the individual receiving the questionnaire will be intrigued or "needled" into replying.

[22] National Secretary, Am. Assn. of Engrs., Chicago, Ill.

Sources of Authentic Data.—The AAE employment service is its most dependable source of information concerning the social and economic status of engineers, the conditions that prevail in actual practice, and the market for engineering services. It is also the most vital contact with employers of engineers. Case histories of applicants, placement records, job orders, etc., are assembled by the employment service as routine; and AAE committees thus have more accurate information than could be obtained by a questionnaire. All their energies can be expended on organization and interpretation of data, because this system eliminates the arduous preliminary effort of collecting information by questionnaire. Fundamental steps in the procedure recommended by Mr. Baker are demonstrated in an AAE study published in June, 1946.[23]

Corroboration of Evidence in Mr. Baker's Paper.—Nowhere in Mr. Baker's paper is there any suggestion of authoritarianism. The evidence he has introduced in support of his convictions for the revision of engineering curricula is offered, not as conclusive proof of these recommendations, but to demonstrate the need of a more thorough investigation of the conditions indicated by these data and to suggest desirable lines of investigation. Various studies made by AAE committees support Mr. Baker's basic recommendations and corroborate evidence that he has cited.[24,25,26,27] Like Mr. Baker, the writer is prepared to demonstrate the absolute truth of these propositions. Nevertheless, the findings from investigations, although limited in scope, are interestingly parallel to, or supplement, the facts and findings recorded by the author.

Overspecialization.—From engineers and from their employers, the writer has gained the impression that engineering education is overspecialized. Employees exhibit a certain timidity that is attributable to overspecialization. It engenders a reluctance to accept engineering assignments outside a very restricted technical area in which they have specialized.

Electrical engineers, for example, thoroughly grounded in the theory of fractional horsepower motors, consider themselves competent to handle only the specialized phase of design of household appliances. They refuse to accept responsibility in the production of these devices because they lack knowledge of mechanical engineering principles, or the metallurgy involved in a production assignment.

In their job orders, manufacturers of electrical appliances manifest the same skepticism; they demand "mechanical engineers with experience in electrical lines," instead of electrical engineers for production jobs. Employers have greater confidence in specialized experience than in specialized education.

These are impressions—some exploratory work has been done by AAE to test the theory, but, as yet, nothing is conclusive. A study of the effect of specialization on the careers of ex-service men reveals that they fall into four definable units.

First, there are the men whose technological education was derived exclusively from special courses given by some branch of the armed forces, and who expect to continue this line of work in civilian employment. Second, there are

[23] "Before and After VJ-Day," *Professional Engineer*, June, 1946, p. 5.
[24] *Professional Engineer*, November, 1940, p. 35.
[25] "The Engineer as His Employer Sees Him," *ibid.*, February, 1928, p. 5.
[26] "Nation-Wide Survey of Engineering Civic Status," *ibid.*, December, 1939, p. 2.
[27] "Survey of the Market for Engineering Services," *ibid.*, November, 1940, p. 3.

the men whose academic training was interrupted by induction into the armed forces. The third unit is made up of men who, although they had completed four-year courses and received degrees in some branch of engineering, were inducted before they had sufficient experience to qualify for a position in responsible charge of work. Finally, there is the group that, having attained full professional stature, entered the armed forces as technical specialists.

Taking care to secure evidence from all four types of ex-service men, AAE asks the subjects to answer a questionnaire, which supplements their experience records, and which is obviously designed to aid the placement counselors in their special problems. Unobtrusively, a series of questions is woven into this questionnaire which, considered in relation to each other and to the applicant's complete vocational history, will provide a body of interesting facts concerning the effect of academic specialization on engineering careers.

The questionnaire asks, not only about the degree of specialization, but about the circumstances that prompted the candidate to concentrate upon a special phase of engineering in college. The relation of his subsequent experience to this specialization is investigated, measuring the well-known effect of the economic depression on candidates for employment who during the 1930's took any available job, regardless of specialization. The aim is also to measure the effect of rapid technological change during the 1940's upon the employability of highly specialized graduates who have not been engaged in engineering during the war. Finally, the objective is to ascertain the effect of wartime experience on the career plans of men who, if the war had not interrupted those plans, would have followed a very narrow path of specialization.

This line of investigation is one that the EJC might profitably pursue, expanding the exploratory study begun by AAE into a thorough, full-scale investigation. For obvious reasons, ex-service men (representing all four groups) are the best possible subjects for a study of specialization. Questions that concern the subject personally are emphasized in the AAE questionnaire: Rapid changes in technology during his period of military service that may, in some degree, have outmoded his academic training or experience; "GI" rights to reemployment and educational subsidies; salary modifications that take into account his maturity and wartime experience. This illustrates the technique for overcoming the inertia, reluctance, or actual hostility that makes the questionnaire method generally unsatisfactory.

Some of the early replies to the AAE questionnaire support incidental findings of other committees. Several of the subjects have shown that they were strongly influenced by parents or faculty advisers in choosing specialties, and that they are about to "write off" that theoretical asset as a loss. They ascribe various reasons for changing career plans. Some of them find a particular line of specialization not as lucrative as they had hoped; some report the field overcrowded; others complain that the specialty entails confining work; a few have come to regard the line of work for which they prepared as "socially unimportant" in comparison with other projects with which they were associated in wartime.

The most casual examination of these documents reveals that these men confirm the opinions of employers of engineers that were reported by AAE in 1928.[25] Employers intimated that, under a system of academic specialization,

young engineers have made this crucial choice when they lacked maturity to insure good judgment; they made it, moreover, without adequate knowledge of the conditions governing practice, or of the market for such services. Employers declared, rather than intimated, that the product of engineering schools was precocious in its knowledge of advanced engineering theory but deficient in appreciation of the business side of engineering, and that overspecialization was achieved at the cost of essential training in engineering economics.

At the same time, employers noted that a considerable proportion of students' time was spent in acquiring elementary skills and learning to use engineering or scientific tools and instruments; this, also, was at the expense of sound training in fundamentals throughout the broad field of engineering. This condition, employers reported, accounted for the low rates of compensation received by a large segment of engineering graduates, who, using only these elementary skills and tools, compete with subprofessionals whose competence is based entirely on practical rather than academic training. The 1940 "Survey of the Market for Engineering Services" to which Mr. Baker has referred,[24] reports evidence in "job orders" which corroborates the testimony of employers quoted in the 1928 report.[25]

It is only undergraduate specialization, obtained at the expense of broader training in engineering fundamentals, that is decried by employers. Engineers need these advanced courses after they have discovered their shortcomings in actual practice, or when opportunity for advancement depends on additional study. They are insatiable in their quest for scientific knowledge; it is this fact that explains the multiplicity of technical societies, and the sectional and cross-sectional pattern of organization within the societies. Mr. Baker might have argued that engineers, in this pattern of organization, demonstrate a potential responsiveness to systematic extension courses that may be offered by the schools. Undergraduate specialization is highly opportunistic. Postgraduate specialization is purposeful. If the schools offered well-planned, practical extension courses, engineers who have already embarked upon careers, who know the market for certain specialties, and who recognize their own limitations, should certainly be expected to avail themselves of such facilities quite as eagerly as they now seek advanced training in theory and practice from technical society meetings and technical society journals.

Mr. Baker's Analysis of the Engineering Profession.—No psychological tests and no scientific methods have been devised by AAE, that enable its committees to report authoritatively the mental quirks of engineers, or to trace tendencies toward an engineering education. The author has accurately reported certain general indications noted by AAE committees. A synthesis of employers' opinions, as expressed in job orders, presented in the 1940 survey[24] demonstrated that employers believe engineers' principal weaknesses are: Blindness to intangible phases of their work; inarticulateness; inability to sell their own capabilities; and an indifference to, or lack of, understanding of the "profit motive" involved in engineering projects. The same criticism was found in the earlier 1928 survey,[25] and to some extent in the 1939 survey.[26]

The 1946 study[23] leads one to conclude that, since 1941, there has been a marked increase in employer demand for engineers who can "count the cost."

It seems to be an outgrowth of the change-over from "cost-plus" systems of production of war goods to normal, competitive methods of producing civilian goods. There are other reasons.

Fearing inflation, and confronted by increased pay schedules for skilled and unskilled labor, business needs engineers who can get maximum returns from this more expensive labor force and so hold down unit costs of production, thereby averting an increase in prices of finished products. Dollar-conscious engineers are needed also to keep engineering costs in line with economy programs designed to offset high taxes.

Manufacturers need engineering executives who can understand and insure conformity with all manner of government regulations—for example, those of the Securities Exchange Commission, the Internal Revenue Department, and others which impose highly technical rules and require complex and meticulous records in which technological operations are a factor.

Finally, business needs expert engineering guidance in order to arrive at, and conform to, satisfactory collective bargaining contracts. Labor unions are represented by experts in negotiations for contracts and in grievance procedures; the employer must have business administration experts who understand engineering, or engineers who grasp the fundamentals of business administration in order to deal satisfactorily with the unions in setting up job classifications and specifications, wage and incentive systems, etc., and in living up to the very letter of agreements with the unions.

Mr. Baker omitted only one of the insistent demands made by employers in reporting the findings of the 1940 survey.[24] This was the growing demand for engineers of "pleasing appearance." Perhaps the author felt that this particular problem is the responsibility of the individual, not the schools. A number of AAE committees have suggested (and the point was made in the 1940 survey) that the schools may have rather overemphasized "ruggedness." Some misapprehension may have caused the students to confuse virility with untidiness. At one time, a committee requested the writer to check, casually, the rather prideful references published in engineering school journals to engineering students as "campus roughnecks." There was some corroboration of that theory, but it was not sufficient to warrant examining a great number of these journals.

For the 1940 survey, however, employer specifications were checked closely as to "appearance" of candidates. Of the job orders filed with AAE between 1927 and 1929, 1.6% stated that appearance would be a factor in evaluating candidates for jobs, and in 1939 and 1940, 13.6% of the orders made a similar requirement.

Census Bureau Statistics Quoted by Mr. Baker.—Mr. Baker has reproduced three interesting tables compiled by the U. S. Census Bureau, showing the distribution of technical engineers on the basis of educational attainments, age, and salaries. The author does not argue that these tables are necessarily representative of the entire profession. He does suggest that they are interesting, as they pertain to a substantial segment of cross section of the profession.

The 1940 survey included an analysis of data concerning 573 engineers who, at that time, made up the "active file" of registrants in the AAE employment

service.[28] Segregating those qualified for responsible charge of work in each category, the distribution was as shown in Table 10. These groups were analyzed from the standpoint of educational qualifications, age, and salary ratings; but the AAE experiments are not exactly parallel to those made by the Census Bureau and reported by the author. For instance, AAE dealt exclusively with "employee" engineers, whereas the Census Bureau group included an unstated percentage of engineers engaged in private practice. In analyzing educational attainments and salary levels the AAE procedure was not precisely that of the Census Bureau. Certain findings are reported in Table 10 only because they bear a striking similarity to those of the Census Bureau.

For example, Table 3(*a*) can be compared with Table 10, which shows the distribution of the 573 engineers whose registration cards were the basis of the 1940 study.[29]

For civil and electrical engineers, the data in Table 10(*a*) are not greatly at variance with those in Table 3(*a*). A smaller percentage of the mechanical engineers, included in the Table 10(*a*) study, held degrees than did the corresponding group analyzed by the Census Bureau.

TABLE 10.—SIGNIFICANT FINDINGS IN THE 1940 SURVEY OF THE MARKET FOR ENGINEERING SERVICES

Description	Civil and construction	Electrical	Mechanical and industrial	Total
Number of records	249	88	236	573
Responsible charge of work (%)	59	60	65	62
(*a*) EDUCATIONAL ATTAINMENTS (PERCENTAGE OF TOTAL NUMBER)				
Degree in engineering	61.0	67.0	36.0	....
Some technical education	22.5	21.5	33.0	....
Trade and correspondence school	6.0	4.5	8.5	....
High school only	10.0	6.0	22.5	....
(*b*) AGE DISTRIBUTION (PERCENTAGE OF TOTAL NUMBER)				
Younger than 31 years	36.5	52.0	38.5	39.0
Younger than 40 years	69.5	81.0	69.0	70.0
Older than 45 years	18.5	12.5	19.0	18.0

Considering all registrants in Table 10 (573), and comparing their educational attainments with the Census Bureau data for "all technical engineers" (Table 3(*a*), Col. 6), the AAE group corresponds very closely to that studied by the Census Bureau. Of the 573 engineers, 52% were graduates, and an additional 26% had one or more years of technical school training (not including trade or correspondence school work). The total 78% practically tallies with the Census Bureau total of 78.8%, adding lines 1 and 2 of Col. 6 in Table 3(*a*).

[28] *Professional Engineer*, November, 1940, p. 26.
[29] *Ibid.*, Group II, p. 29.

Table 3(*b*) indicates that 36.2% of "all technical engineers" (Col. 6, line 11) are older than 45. Only 18% of the engineers covered by the AAE study were in that age group. This is natural, because all the 573 engineers were applicants for employment, whereas, the Census Bureau studied both employee engineers and those engaged in private practice. Only 12% of the men placed by the AAE service in 1940 were older than 45.[30] In analyzing job orders it was found that one third of all employers filing such orders made a preliminary requirement as to age, and that only 1% of them expressed a willingness to hire men older than 45.

Although age restrictions were relaxed during World War II, the 1946 study[23] indicates that they have "tightened up" rapidly since the end of the war. The report of placements for 1939–1940 given in the 1940 survey,[30] shows an interesting resemblance to data quoted in Table 3(*c*) (Col. 6, lines 16 to 23). The annual salary ratings of engineers can be studied by segregating the entire sample into three groups of equal numbers; thus, one third of the engineers placed by AAE in 1939 and 1940 received annual salaries of: Less than \$1,500; \$1,500 to \$2,400; and \$2,400 to \$4,200, respectively.

The 1940 study cites only the rate at which these men were placed, not the actual earnings for the year. The Census Bureau quoted actual and total earnings for 1939, which may have accrued from less than a year of employment, some of the men reported having worked only intermittently but at monthly rates higher than total earnings for the year seem to indicate. Although no real parallelism exists, a comparison of the AAE data with the Census Bureau's report that 21% of all technical engineers earned less than \$1,600 in 1939, whereas another 29.8% earned between \$1,600 and \$2,500, produces no startling contradictions. In Col. 6, Table 3(*c*), adding lines 16 to 19, inclusive, indicates that 21.1% of all technical engineers earned less than \$1,600.

Professional Registration.—Among the 573 engineers whose experience records were analyzed in Table 10, only forty four were registered as professional engineers, that is, 7½%. Of the 573, there were 355 who had experience in design or higher grades of practice that should have entitled them to register. Of this 355, only 12% were registered. Of twenty-two construction superintendents, only seven were registered. Only two of nineteen electrical engineers with experience in responsible charge were registered; among the mechanicals only one of ten who had served as chief engineers in industry was registered, and he was the only man in this category who had had no academic training. Employers' indifference to registration was evidenced by the fact that only one of several thousand job orders specified that registration was requisite. This is as true in 1946 as it was in 1940. In the 1946 study of job orders[23] only one employer stipulated that candidates must be registered architects, and not one employer asked for a registered engineer.

Summary.—The foregoing comment is presented on the personal responsibility of the writer and does not necessarily reflect the official views of the AAE. The intent has been to report data compiled by AAE that should be useful in the appraisal of the paper by Mr. Baker. As stated, some of the AAE committees have followed the very line of investigation recommended by the author

[30] "Survey of the Market for Engineering Services," *Professional Engineer*, November, 1940, p. 48.

and have used the technique that he suggests to the schools and professional societies. The findings reported by AAE bear a striking resemblance to those that resulted from Mr. Baker's independent investigations; and the inferences from the findings conform rather closely to Mr. Baker's recommendations that:

(1) Undergraduate education should be confined to engineering fundamentals and that it should cover the entire field of engineering rather than a single branch or specialty; and

(2) The schools should assume responsibility for specialization through systematic extension courses as well as postgraduate study in residence.

SCOTT B. LILLY,[31] M. ASCE.—This presentation of the views of a consulting engineer on engineering education is most timely. If changes in the curriculum are due, they should be made now while the effects of World War II are being felt; while every school is faced with changes in personnel; and while the first-hand experience with teaching skills and techniques gained from the instruction of great numbers of men during the war period is available. The writer agrees with the main thesis of the paper, that engineering education should emphasize fundamental principles, and that postgraduate education should be designed to prepare for a career involving administrative, executive, and managerial activities. There are certain phases of the problem of instruction, however, to which the writer would like to call particular attention.

Essentially, engineering is planning. It consists in meeting and solving problems involved in the design of a particular structure, machine, or business activity, before an investment is made. For its successful practice, the engineer must have a sound background, not only in science, but in experience. In fact, he must have the sound judgment based on experience if he is to create any enterprise that is successful. Under any type of government, investments must satisfy social needs if they are to be justified.

If, then, the great need of the successful engineer is judgment based on experience, why should a man go to college to study engineering? Why not revert to the old apprentice system? Certainly the details of practice can be learned more quickly and more thoroughly on the job than in the classroom. What can a college education give a man that he cannot get on the job? Just this: Unless a man has a theoretical background, he has no way of classifying and evaluating his experience. He has no knowledge of the limitations imposed by nature, no realization that, although a law may hold under certain conditions, abrupt changes may be encountered if its use is extended beyond certain definite limits.

If basic science is to provide this framework, it must be taught so that a greater proportion of students find it usable. Mathematics must be so thoroughly taught and learned that general principles expressed in symbols are readily understood; but these principles must be so thoroughly comprehended that the student realizes that they are useless unless he can get from them the answer to the concrete problem to be solved. The physical sciences must be so thoroughly mastered that a knowledge of theory will make the

[31] Prof., Civ. Eng., and Chairman, Div. of Eng., Swarthmore College, Swarthmore, Pa.

engineer able to predict the limit of what any approach can be expected to yield, together with a clear idea of the limits of the theory.

The heart of this suggestion is that the amount of material taught should be limited to the ability of the students to comprehend clearly what is presented. Nothing is so useless as a knowledge of facts so poorly digested as to be incapable of use. The author states that too many engineers are "narrow." There is nothing inherent in engineering which makes education in that field "narrow." From the reports that are coming out of the liberal arts colleges, it appears that English, history, political science, and many others of the so-called humanities, are being taught so that the end product is narrow. Quoting from Alfred North Whitehead:[32]

> "In the teaching of science, the art of thought should be taught; namely, the art of forming clear conceptions applying to first-hand experience, the art of divining the general truths which apply, the art of testing divinations, and the art of utilizing general truths by reasoning to more particular cases of peculiar importance. Furthermore, a power of scientific exposition is necessary, so that the relevant issues, from a confused mass of ideas, can be stated clearly, with due emphasis on important points."

Engineering is being taught in this way in some engineering schools. A man who has been exposed to this discipline for four years cannot be called "narrow" or uneducated. Every thoughtful teacher in every course should be striving for the objectives stated in the quotation from Mr. Whitehead, whether the subject be mathematics, English, or history.

When he graduates, the student must realize that he has merely learned the vocabulary in college and that he must educate himself on the job. The interest that comes from immediate use, the joy of accomplishment that is experienced when, by reason of study the night before, a man is able to have the right answer at the right moment, gives the urge which may make such study a lifelong habit.

What has been said applies to the technical side of a man's life. Education should prepare a man for his leisure hours as well as his working hours. There is a real adventure involved in the meeting of great minds in books, in making friends with these authors, in the feeling that they are always there on the shelf, where they can be consulted. This type of companionship is waiting for those men who know how to read ideas and not words. It comes to those men who have been under the influence of teachers and friends whose joy is in introducing young men to these pleasures. The teachers who do this must be men endowed with enthusiasm, as well as with knowledge and taste. Is this too much to ask of those who present literature, psychology, and philosophy?

This is not an idle dream. Such teachers can be had if society wants them. Salaries can be made attractive enough to bring able, well-rounded men into teaching. However, men of the type desired crave recognition of the importance of their job even more than they crave money. They must feel that there is wide realization of the great difficulties involved in teaching; of the hours of study necessary; in general, that teaching demands the best that a man has, or can become, if he is to have real success; and that the ends sought justify such efforts.

[32] "Aims of Education, and Other Essays," by Alfred North Whitehead, p. 81.

Such teachers would produce students with a professional attitude. They would be conscious of the fact that they have an obligation to extend the frontiers of knowledge in their own fields. More than that, they would have a knowledge of the impact of their activities on society. They would feel a responsibility toward society; with the background they had received from contact with active minds, with cultivated imaginations, they would be able and willing to engage in public affairs; and the problem of professional recognition for engineers would disappear.

With the help of industry, the teacher can do much to improve his condition. Let him spend some time each summer in industry; let him become familiar with current problems. If he knows these problems, the teacher's salary must rise or he will stay in industry. There is nothing like competition, not only to increase salaries, but to develop the teacher. Teachers must be alert, keen, broadminded, and well informed, if they are to be equal to today's needs.

There is no easy simple solution to this complicated problem. It is not one that can be solved by changing curricula, or studying in college five or six years instead of four. It is quality of instruction that is needed; it is the true professional attitude toward all activities that must be inculcated, that will finally win the battle; and quality in the student must come from quality in the faculty. What can be done to bring into teaching the best minds in the profession? That is the question to be solved. What can the members of the Society do to bring this about?

WILLIAM A. CONWELL,[33] M. ASCE.—The kind of material about which practicing engineers often talk but seldom write is contained in this paper. The topics, of course, have been treated at length by engineering educators in the rôle of scholars discussing their specialities. Such dissertations lack the freshness and exhilaration which are likely to characterize the probings of an intelligent man in a field in which, although he is not a specialist, he is highly interested. Such are the characteristics of this paper. The thoughts and musings are the type which might be heard in an informal discussion of the subject by engineers. In this instance, however, the ideas are supplemented by well-arranged data which give them force and weight ordinarily absent in informal discussion.

It is interesting to examine the proposed revisions to the methods of engineering education in the light of the functions of those concerned—the individual, the school, and the employer.

Under the system generally employed prior to World War II, the individual followed a course of instruction which was largely technical. He was left principally to his own resources in developing the nontechnical requirements of his profession, and of his cultural background. The school outlined courses and taught subjects which were technical or which barely skirted the fringes of the nontechnical requirements. Employers did one of two things, depending upon their needs. With the confidence that the logical thought processes induced by an engineering education would be of value to him whatever his business, one type of employer hired graduating engineers regardless of their specialties; acquainted them with his organization by a course of indoctrina-

[33] Gen. Engr., Structural Eng. and Design Dept., Duquesne Light Co., Pittsburgh, Pa.

tion; and then used them to solve his problems, whether in the field of engineering or not. It was this type of employer who voiced opposition to excessive specialization according to the 1940 analysis of the American Association of Engineers.[2] The other type of employer hired the graduate as a technologist and put him to work immediately on the solution of engineering problems. In the latter instance, the engineer's experience, gained in the solution of practice problems as a student, was indispensable.

Under the plan of education proposed by the paper the individual would pursue a more general course and thus not be required to devote as much of his extracurricular activities to self-development. The school would offer the general course stressing fundamentals in technical subjects, eliminating practice problems, and including considerable nontechnical and probably cultural matter. Needless to say, the school would have to "sell" such a course to the embryo engineers who normally look askance at any subject that lacks the quality of being immediately and practically applicable in professional practice. The school would further expand opportunities for the employed graduate to continue his studies, a commendable proposal under any system of education, past, present, or future. If the employer is of the first type, interested in men trained as engineers regardless of branch, the suggested plan suits him admirably. All engineering graduates would be eligible for his indoctrination course. The second type of employer, who wants a technologist whom he can put to work on engineering problems, will find no graduate with the requisite experience in practical problem solution. He, too, must institute some kind of training. To borrow from Hardy Cross, M. ASCE, he must take the young engineer who has "hitched his wagon to a star" and induce him to get "his feet on the ground."[34]

In this comparison of the former and the proposed methods of education, one can discern the definite shift of responsibility from the individual to the school, and from the school to the employer. The school takes over the student's former responsibilities in the nontechnical field, and the employer, unless he confines his employees to men with advanced degrees, assumes the responsibility of the school for training in practice problems. This trend may be thought of as consistent with that in many other fields and as accompanying the higher degree of socialization which we shall continually find in our civilization; but it could hardly be said to enhance the engineer's individuality, at present one of his most precious possessions.

The writer is in hearty agreement with the author's premise that, in his undergraduate training, the student should be imbued with a sense of the importance of professional progress after graduation. Real progress is demonstrated, of course, by the engineer's performance of increasingly difficult work as his career develops; but this progress is often reflected in, and enhanced by, activities in three fields—advanced degrees, registration, and advanced grades of membership in engineering societies.

Appreciation of the value of the master's and the doctor's degrees is mounting as time goes on and there can be little doubt of their eventual attainment of

[34] *Transactions*, ASCE, Vol. 96, p. 140.

the respect due them in the engineering world. The same cannot be said of the professional degree which is sought by relatively few graduates. The attitude toward this degree is surprising in view of the fact that its essence is recognition of experience, a most valuable asset of the practicing engineer.

The trend in the field of registration for license to practice is "all to the good." The time should not be far off when all professional engineers will recognize the full value of registration.

Appreciation of membership and advanced grades in engineering societies is lacking in many engineers. As against the author's opinion, it is the writer's firm conviction that failure of an engineer to obtain membership in the engineering societies and to advance his grade consistently lies in his apathy rather than in his not having had opportunity to perform work which would entitle him to recognition.

It is the writer's belief, contrary to that of the author, that the economic depression of the 1930's had a profound effect upon the stability of Junior Members of that period.

There is some question as to whether an anomaly is not presented by the author's proposed revision of courses which excludes some subjects and adds others. One of the author's arguments for elimination of practice problems is that the graduate must wait eight or ten years before he has an opportunity to apply what he has learned (a premise with which the writer cannot wholly agree). At the same time the author recommends courses in "men," "money," and "management" for inclusion in undergraduate curricula; but in tracing the professional progress of the engineer, the author envisages his dealing first with "matter," next with "men," then with "money," and finally, at the height of his career, with "management." If the reason for eliminating practice problems is valid, it would seem that a similar reason would hold for eliminating the last three "M's" from the undergraduate work. These thoughts are presented in the belief that the author, in his closing discussion, might like to clarify an apparent inconsistency. They are not meant to imply that courses, particularly those dealing with "men," are out of place before graduation. Ability to get along with one's fellowmen is of paramount importance; and, if a student's home or early school training has failed to develop him in this direction, something should be done about it in college.

The writer questions how effective a five-year or ten-year forecast of the market for engineers can be. It is unlikely, for instance, that the great demand for radio engineers in the 1920's could have been predicted. On what basis could there have been foretold the need in the early 1940's for army engineers with training in "men" and "management" far beyond their years and experience? Flexibility in training, the second alternative suggested by the author, would seem to be the solution to this problem; but the goal of flexibility does not necessarily (in the opinion of the writer) require the elimination of practice problems in undergraduate work.

If the prewar graduate was "primarily a trained, rather than an educated person," his successor, under the proposed revisions, would probably continue to be so. Although certain technical training would be eliminated and more emphasis would be placed on purely educational subjects, the suggested courses

in speaking, writing, business, etc., would be in the field of training rather than education.

A. AMIRIKIAN,[35] M. ASCE.—If the success of the present-day engineering education is to be gaged by the success of its product, as suggested by the author, the statistical data presented in the paper do not reflect a favorable condition in so far as the great majority of the members of the profession is concerned. This is unfortunately true whether success is measured by the rate of the young engineer's progress in the profession, his attained standing and prestige in the community, the recognition of his contribution, or the compensation for his services.

Causes contributory to this unhappy situation are many and complex. Although some of these causes may be traceable to certain deficiencies in engineering education and training, most of them in reality are related to engineering practice. As observed by the author, engineering is no longer practiced as a free profession, but is conducted along lines similar to a business enterprise. The change is not new; it has been taking place during the past several decades. As a result, the individual practitioner, the true representative of the free profession, is practically nonexistent today. He is forced either to seek employment with large engineering and architectural organizations or to join forces with other engineers to form an engineering firm, and thus become either an employer or an employee.

Various reasons are advanced for the evolution of engineering practice from a free profession to a competitive business enterprise. According to the opinion of some, this change is due to modern trends of industrial development with corresponding growth in engineering projects requiring the services of large engineering organizations for their execution. Others think it is due to a keen competition predicated on present-day business methods and practices. Regardless of what the real reasons may have been to cause this change, the important fact is that it has occurred. From an educational viewpoint, the only thing that can be done to improve the lot of the young engineer is to give him a training adaptable to the requirements of current practice.

An examination of engineering curricula will reveal that during the first half of the twentieth century no significant changes have been made in either programs of instruction or methods of training. The institutions are still engaged in the task of producing the finished product—the professional engineer. In this work, efforts are being made to equip the candidate with the necessary knowledge and training to practice engineering in the same way that students are being trained to practice medicine and law. At first approach, the program may appear as proper and its objective as logical; but a closer study of the means utilized in the program and the problem of professional practice of the finished product will bring out serious doubts concerning both the adequacy of the means as well as the propriety of the objective.

The first point of the argument needs little elaboration. It is generally admitted that a four-year engineering course is too short a period for the re-

[35] Head Engr., Bureau of Yards and Docks, Navy Dept., Washington, D. C.

quired training. The disparity between the set objective and the allocated time will be more apparent when comparison is made of the seven-year to eight-year training period prescribed by the legal and medical professions. The inadequacy of the means is further illustrated by the fact that there are few, indeed, if any, institutions which are equipped to give the specialized training required by present-day engineering practice.

The other considerations concern the practical problem of placement of the finished product. Since the young engineer cannot open an office and practice his profession, as would a lawyer and a physician, after graduation there still remains the difficult task of securing a proper position. Strange as it may seem, his specialized training—even when assuming that he was able to obtain it—not only would be of little help in securing employment, but, in most cases, would prove a handicap. This is due to the fact that a young graduate is seldom able to find a position that will correspond to his particular specialization in school. Under normal circumstances, he has but little choice for employment, and usually he accepts the first job that comes along. Furthermore, because of his lack of experience, the organization that offers him employment considers him as a mere recruit who must go through the "grind"—regardless of his specialization or particular qualifications. Stated more frankly, his acceptance into the profession does not materially differ from that of an apprentice into a trade. The course of his later progress is equally discouraging—even more so than that of an apprentice. As a result, after surviving his initial disappointment, the young engineer keeps on changing his place of employment at frequent intervals, trying to adapt himself to the conditions, and, finally, he either becomes reconciled with the situation or he leaves the profession.

Unfortunately, little attention is focused on the latter phase of the problem. The statistical data presented in the paper concerning change in employment and abandonment of the profession reveal an alarming condition. According to the data, the turnover runs as high as 60%, and as many as 50% eventually leave the profession. Essentially, this is a condition suggestive of both maladjustment and malcontentment. Obviously, no changes in the educational system can appreciably affect the latter factor, since it is due entirely to current methods of engineering practice. The only thing that engineering institutions can do in this respect is to take the glamour out of engineering education and present a clear and realistic picture of the profession. Such a warning will, at least partly, obviate future disappointments and disillusionments on the part of the student. On the other hand, conditions of maladjustment can be greatly improved by introducing certain necessary changes in the educational system to provide the needed flexibility of adaptation. Briefly, these changes would consist of the following:

(*a*) *Undergraduate Work.*—Confine undergraduate instruction to courses in liberal arts and general engineering only. Assuming a four-year curriculum, the first two years would be devoted to liberal arts and the latter two years to engineering. The courses in the former period would consist primarily of social and cultural subjects; in the latter period, the main subjects would consist of three important "Ms" which form the backbone of any branch of engineering—

namely, mathematics, mechanics, and materials. There would be no specialized courses, and only simple and elementary applications of the fundamentals to a particular branch of engineering.

The advantages of such a combined undergraduate course are many. From the administrative standpoint, optimum use would be made of the institution's facilities and staff, and there would be little conflict or confusion in the arrangement of the curricula. From the point of view of the student, the derived benefits would be still more important: (1) His liberal education would provide a cultural background that would aid him in later life regardless of what line of endeavor he might eventually follow; (2) there would be ample time for a more considerate choice of a profession and an opportunity for a desired change at relatively later stages of instruction; and (3) the placement and adjustment problems after graduation would be greatly facilitated because of the general nature of the training.

(b) *Graduate Work.*—Confine postgraduate work to specialized courses in various branches and subbranches of engineering. The main purpose of these courses would be to provide up-to-date professional training required in current engineering practice. To be eligible for admission, the candidate should have completed undergraduate training and, in addition, should have had a minimum of five years of engineering experience. The importance of the latter requirement cannot be overemphasized. During such a trial period the young engineer would have had a good taste of the methods and practice of the profession for making his final decision; also, he probably would have located the particular line of engineering for which he is best suited.

The courses may be arranged on the basis of both resident and nonresident instruction. In most cases, however, the latter arrangement would prove to be the most satisfactory, since it would assure the practicability of the system. The duration of the period may vary from one to three years, in accordance with the requirements and the complexity of the specialization, and the training would culminate with the granting of a professional degree. As for the necessary instruction staff, the faculty would consist mostly of practicing engineers engaged on a part-time basis—leading specialists in the various fields of engineering. In this connection, it is to be noted that, unlike the medical and law schools, little or no attempt is made by engineering schools to utilize such talent.

(c) *Research Work.*—Supplement graduate courses with research work. There are many problems in the various fields of engineering which need elaborate research and experimentation. Most of these problems are directly related to the work of the practicing engineer. As a matter of fact, such problems constantly arise in devising new techniques to make more advantageous use of materials, or to improve the methods of applying an existing technique. If satisfactory arrangements could be made by the engineering schools, it would be possible for the research-minded engineer to bring his problems to the institution and work out a solution by utilizing its aid and facilities. Engineering research conducted on this basis would yield more practical and valuable results than are obtained from the present system of graduate work by which research is incidental and serves primarily as a vehicle for the inexperienced engineering graduate in his effort to obtain an advanced degree.

C. A. DYKSTRA,[36] ESQ.—During the past few years, the writer has given some thought to engineering education, and has discussed the problem with many engineers and with members of engineering faculties. He agrees with the author that engineering training should be broad and fundamental and that it should place some emphasis on what is being called "general education." An engineer well grounded in mathematics and the necessary sciences who has some knowledge of the background of civilization, a reasonable mastery of the English language both spoken and written, and a speaking acquaintance with the fields of psychology and economics will have a better chance to advance in his profession than the one who too early acquaints himself with techniques and specialities in the field of engineering. These specialities can be mastered if and when the need for them arises. The mastery of a speciality will come with experience on the job, through special courses given by industry, and through the opportunities for advanced work either in residence or through extension courses in engineering schools.

Also there is need for the training of the imagination of engineers. Such education comes out of wide reading in the fields of literature and from the discussion of controversial issues; it comes from contact with other engineers and with those who practice other professions. It is time to begin to use the words, "engineering education," instead of the phrase, "engineering training." If the so-called training could be superimposed upon the education of the individual, wiser men would be developed in the profession. In modern technological civilization there is great need for the technicians called engineers, but, to master this mechanical civilization, technical men must be aware of the implications of modern life and they must feel at home in a changing world. A structural engineer should know more than how to build a bridge. He should be able to state whether a bridge is necessary, what will happen if it is built, and perhaps be able to suggest an alternate solution to what is traditionally thought of as a bridge problem.

Therefore, it is gratifying that the author is interested in the educational aspects of the engineering world and it is to be hoped he will continue to call attention to the fact that a study of engineers as well as a study of engineering is needed. After all, engineering schools are in the business of educating men, some of whom will be engineers for the remainder of their lives, and some of whom will find themselves with shifting and varying responsibilities which may be quite tangential to what is familiarly called the engineering profession. If, as it may happen, engineers are called much more frequently into management or into public life, the character and quality of their education becomes of real importance to the social structure.

LOUIS BALOG,[37] ESQ.—The major purpose of this inquiry as stated in the "Introduction" is: "* * * to evoke discussion of the subject of engineering education by the users of its product." The point of view of "the users of the product" does not necessarily coincide with public interest and with the professional interest of the individual. In fact the statistical data included in the

[36] Provost of the University, Univ. of California at Los Angeles, Los Angeles, Calif.
[37] Cons. Engr., New York, N. Y.

paper indicate that these interests are quite divergent. The opinion expressed in the paper—that the assumption of administrative duties by an engineer constitutes professional advancement when he begins "depending on his subordinates more and more for technical results and opinions"—misrepresents the value of engineering science. It would appear reasonable that work involving technical science should be rated above all other activities, and that superior technical knowledge should enable the engineer to assign subordinates to the nontechnical duties of the managerial position. Educational institutions and professional organizations should not create men prepared to prosper on the knowledge of subordinate engineers; rather, they should produce engineers who will have reasonable hope of improving their conditions by professional, and not by business, efforts.

A profession is a vocation that requires a learned education. A uniform educational standard, therefore, is a necessary requirement for creating a profession. This was well recognized in the 1920's by the American Medical Association in rating medical schools and in undertaking a relentless effort for the immediate closure of third-rate and, for the gradual elimination of all second-rate, institutions of medical instruction. As long as uniform educational requirements for the designation "engineer" are not established, the group classification of "engineering profession" remains meaningless. The divided authority of the university, the state registration board, and the engineering society in declaring individuals engineers, cannot result in a true professional status for the engineer, similar to that of medical men. The latter, upon complying with precisely defined scholastic requirements, are declared to be doctors of medicine on the strength of the authority of the university and become full-fledged members of their profession.

From statistical data, Mr. Baker concludes that the engineer at present cannot achieve professional status by education (see heading, "The Practice of Engineering: Rate of Advancement"):

> "* * * the average engineer—at least if he follows civil engineering—does not attain a position in which he is called on * * * to assume engineering responsibility for anything except work of the simplest character, until at least from eight to ten years after he has graduated; and many do not attain such a position within that time."

Under the heading, "Prewar Engineering Education," Mr. Baker states also that at the university the student: "* * * grappled with problems of a character that he would never meet, or at least would not have to solve, on his own responsibility for from at least twenty to twenty-five years after graduation." In striking contrast to the foregoing statements, Arthur J. Boase, M. ASCE, in reporting on the advanced stage of development of reinforced-concrete design in South American countries, observes that the leading designers of those countries are young men, the ages ranging from twenty-five to thirty-five years.[38] None of these highly educated, able designers (who have developed a reinforced-concrete design practice far superior to that of the level achieved in the United States) could satisfy Mr. Baker's criterion for engi-

[38] "South American Building Is Challenging," by Arthur J. Boase, *Engineering News-Record*, Vol. 133, 1944, p. 121.

neering responsibility or be classified as able to design. This is an indication of something fundamentally wrong in the guiding principles that underlie his opinions concerning the purposes of civil engineering education and professional organization.

Effecting that professional education and technical knowledge, so that it will be to the best advantage of the individual and the community, is the foremost duty of any group of men engaged in the same occupation. The engineering society has been ineffective in these professional objectives primarily because it is not a group of persons engaged in the same occupation and interest. According to Mr. Baker's statistics (Table 4), 43% of its corporate membership is not engaged in engineering; and a closer scrutiny of the actual activity of those in the grade of member, by Arthur Wardel Consoer, M. ASCE, reveals that "* * * only a pitifully small group * * * can really consider themselves to be practicing engineering as a profession."[39] In demonstrating similar facts (Fig. 1), the author arrives at the conclusion that engineering education should emphasize only the fundamental principles of engineering and should include executive and managerial training. At the convention of the American Society for Engineering Education in June, 1946, the recommendation was made that civil engineering education should emphasize fundamentals and that design "can be better learned in practice." Such recommendations are not to the best interests of the civil engineer. If South American engineers, credited with outstanding accomplishments at the age of twenty-five years[38] had received the education advocated by Mr. Baker and the American Society for Engineering Education, they could never have achieved real engineering prominence; a few may have become managers of some mass-production organization "twenty to twenty-five years after graduation." . Why should the young men of the United States be denied an education that would equip them for independent accomplishment as civil engineers?

In discussing the "Organization and Structure of the Engineering Profession" under the heading, "The Engineering Profession," Mr. Baker states: "The current practice of engineering, except by those who serve in advisory or consulting capacities, is a mass-production activity * * *." Critical examination of this correct observation reveals, however, that this condition involves all the disadvantages and none of the advantages of mass production, and that it is detrimental to the professional interest of the civil engineer. Engineering structures are not produced by mass-production methods, and nature seldom provides the same conditions twice. A structure that fits perfectly into its location always represents saving to balance the insignificant cost of a good design. Mass-production principles manifest themselves in standardization, and standardized designs are the most effective means of hindering progress. They minimize the value of talent in design and hinder the useful employment of engineers. The application of mass production to design has created the highly valued executive, but it has degraded the designer, and eliminated competitive design and, with it, the proper recognition of individual accomplishments, which is the prime requisite for professional existence.

[39] "The Professional Status of Civil Engineers," by Arthur Wardel Consoer, *Civil Engineering*, November, 1939, p. 673.

The management of engineering organizations, at present, may be a purely parasitic activity in which mere trader's cunning, or certain dexterity in the use of technical terms, is sufficient qualification for a position above the engineer. The slight technical knowledge that is required for this form of management is demonstrated by the fact that most heads of engineering organizations advanced to their positions through salesmanship or assumed executive duties. The emphasis placed on management and organization, at the expense of technical knowledge, has lowered the designer to the status of a laborer. The user of the product, whose advice Mr. Baker seeks in an effort to improve engineering education, paid the highly educated designer (the true representative of the civil engineering profession) less than the wages of unskilled labor, and terminated his employment immediately upon completion of the work. These practices have forced designers to use the methods of union labor in their struggle for existence, a disgrace that removed from the civil engineer even the semblance of belonging to a learned profession. Mr. Baker accepts this as an unalterable situation and recommends that the student of engineering be advised as to what he is "getting into." According to Mr. Baker (under the heading, "Postwar Engineering Education"):

> "The student should also receive a realistic picture of the profession which he has chosen for a life career—not the glorified aspect usually presented by older alumni or distinguished engineers who address upper classmen at meetings."

It is of even greater importance to the student to know that the distinguished engineers are purposely not telling the truth. The incredibly cynical admissions of this appalling fact, in private conversation, show the prevailing conditions in the civil engineering profession to be based on the betrayal of morality on which all human relations should rest.

The author's recommendations that the experience records of engineers be studied in order to discover needed educational improvements and the demand for engineering services can yield no useful results. Such records do not show the actual accomplishments or the capabilities of anyone; and the demand for engineering services is never revealed by such records.

Examination of engineering structures will indicate educational and professional conditions; it will indicate needed educational improvements and wasted opportunities for the employment of engineering services. The professional biographies of the engineers, enumerating their engagements, will indicate nothing. Anywhere and everywhere, structures can be observed which disclose the need for engineering services—instances where the use of expert engineering talent would have resulted in savings, improved appearance, and increased engineering employment.

Mr. Baker's analysis of the advancement of engineers in the qualification grades of the engineering society, therefore, cannot be accepted as a suitable guide for the improvement of engineering education or professional organization. On the contrary, the misleading conclusions that result indicate that the rejection of his basic principles is a necessary requirement for the achievement of actual improvements.

The classification of engineers by interested private individuals, as "juniors," "associates," and "members," that postpones recognition of design ability until after a person has passed the prime of life, [40,41] and that declares any one older than thirty-five years able to design, irrespective of his actual occupation, is incompatible with the conception of a learned profession. The growth of technical sciences has resulted in the evolution of educational institutions that actually eliminate the system of apprenticeship established by this antiquated and wholly unjust classification of engineers by the engineering society. If this were not an artificially created situation, the university as an institution for educating civil engineers could be regarded as a complete failure. The inadequacy of the university is a direct result of the influence exerted by the controlling ideas in the existing organization of the civil engineering profesision.

The engineer will attain professional status when a properly constituted university has become recognized as the sole authority for qualifying an individual, upon completion of specified studies and examinations. Since the rights of individuals are guaranteed by the authority of the state, the state should establish the educational requirements leading to those rights and should be represented by its properly constituted registration board in the final examinations of engineers at the university. Such an arrangement eliminates duplication of effort. It eliminates the system of dependence on personal recommendations; it guarantees that engineers will be able to begin practicing their profession at a reasonable age and succeed according to their ability.

A professional man is necessarily a lifelong student whose knowledge should increase steadily. The admission to a profession, however, should be based on a precisely defined, formal education which preferably should include the entire educational period. The scholastic level of high schools in the United States is lower than that of preparatory schools of other countries of the world by at least two years of study.[42,43] A more efficient secondary education is of great interest to the engineer. He should be given the possibility of acquiring a proper cultural and basic scientific education and the formation of mental habits that result in self-dependence and maturity, before entering the university at the age of eighteen. Experience in education indicates that this can be achieved and a professional organization of engineers should influence the establishment of such an educational procedure.

It is rational to spend the first two years at the university with the basic and advanced theories now given as graduate study, the following two years with the application of theories to design, and the fifth year with specialized technical studies and courses in economics and statistics. This university program of five years should be based on at least 40 hours each week in lectures, laboratory, and design work. Upon completion of this work, and the examina-

[43] "Secondary Education in the United States," by William A. Smith, The Macmillan Co., New York, N. Y., 1932, p. 108.

tions, the candidate should prepare a thesis and pass a written and oral examination in his three principal engineering subjects before a board comprising members of the university and federal registration authorities. This joint board should declare the successful candidate an engineer, and he should be acknowledged a full-fledged member of the profession at the age of twenty-four.

The academic prestige of the engineer's diploma should be the same as that of the doctor of medicine. Courses that do not require compulsory work and specific examinations by a duly formed combination of university and registration boards should be disqualified in appraising candidates for the degree of engineer. It is a truism that taking courses does not mean that the individual has any knowledge of the subjects involved.

The graduate engineer, upon presentation of a paper which is rated satisfactory by a special board of the university, and upon passing an oral examination, should be able to obtain the academic degree of doctor from the university. This degree, however, should not give rights in addition to those acquired with his diploma. The degrees of Bachelor of Science and Master of Science, in engineering, should not exist. All oral examinations should be public.

The sequence of studies described in this discussion is psychologically more sound for the development of the proper sense of values than the prevailing reversed procedure. Observation indicates that an elementary structural education, followed by the study of the theories of elasticity and stability, often results in an attitude that misjudges the rôle and value of mathematical procedures in creating structures. The layout determines the cost, quality, and appearance of a structure. The performance is ascertained by analysis only; but analysis can never improve upon a structure if the layout is faulty. All the knowledge contained in the curricula is necessary in structural design. The subjects of design, therefore, must follow the mastering of advanced theories.

Mr. Baker's idea of transforming engineers into managers by the study of such a miscellany of subjects as "human nature," "institutions," and "business practice" should be rejected. Only superior technical knowledge should be the qualification for leading positions in engineering. The only nontechnical subjects required of the engineer should be economics and statistics. The analysis of scientifically classified collections of fact relating to national and world economy is a suitable method of interpreting conditions and values by technically trained minds.

As executive training or experience does not make one a designer, teaching experience does not make one a professor. Thorough technical knowledge of the subjects involved is the fundamental requirement in both cases. A thousand students would rather listen to the lectures of an outstanding teacher than groups of fifty, to men of limited knowledge and faulty point of view. Personal contact between lecturer and students is not necessary. Self-dependence is essential for the development of the student. The professor should not be required to expend more time than that required for lectures and examinations.

During the first two years at the university, since the emphasis is on analysis, the engineer is trained by men who are primarily theorists. After the second year, the lectures should be given by practicing engineers. Lecturers should be required, concurrently, to engage in research or design, keep abreast of all progress in their respective lines, and modify their lectures every year. The compensation of lecturers and their assistants should be so high that everyone would strive to attain the knowledge that qualifies men for a position at the university.

The educational and qualifying procedures outlined in this discussion, and the establishment of free competition in design, are the only means for establishing the civil engineer in his proper professional status. A suggestion that, in order to succeed, the engineer should be a politician, an orator, an executive, a salesman, or anything but a person who applies technical science in his work, is an implicit admission that technical knowledge is of no value. This condition follows from the prevailing system of qualifying engineers through personal recommendations, by which means anyone can be made a great engineer or a lifelong slave. As long as it is possible to declare every technical function a matter of detail—as long as it is possible to accord credit for the work of others to anyone whose advancement is the personal interest of a user of the product—the existence of a civil engineering profession will remain a mere illusion.

Henry B. Lynch,[44] M. ASCE.—A well-considered, thoughtful statement of a problem of greatest importance to the engineering profession has been presented by Mr. Baker. In the past few years it has become increasingly necessary that the time devoted to preparation for an engineering career be scheduled with precision. More subjects should not be crowded into the college curriculum. In fact, there is criticism in some places that too much is attempted already. It has become necessary either to extend the time devoted to educating the engineer or to jettison some of the material formerly taught, to make room for new material that cannot be omitted. The author has suggested a good working basis for extending courses.

In appraising engineering education, in listing the subjects that can be discarded or curtailed, and in naming courses that could be given greater weight, the views and experiences of mature practicing engineers throw as much light as do those of engineering educators.

For many years it has seemed to the writer that the most important duty imposed upon the engineering college is that, first of all, the graduate be a broadly educated man. The aim of the curriculum should have been to impart judgment rather than skill, knowledge rather than training. He should have a broad knowledge—even though not a detailed knowledge—of history, English, and literature. He should be well grounded in mathematics and science and such foreign language as seems proper, without forgetting that he is being educated to become an engineer.

These objectives cannot all be accomplished unless there is a sharp curtailment in the time now devoted to subprofessional training. In an education leading to an engineering degree, much of the shopwork should be eliminated

[44] Cons. Engr., Los Angeles, Calif.

and such courses as surveying and mechanical drawing should be greatly shortened. Even so, provision should be made in some such manner as that proposed by the author, for extension courses preparing for further degrees.

These objectives cannot be attained through the college alone. Considerable groundwork must be done in the preparatory schools. For this purpose a much sharper distinction should be made between education that ends in the high schools and that which leads to a college degree. In preparing the engineering student, the high schools could well reduce greatly the elective subjects permitted, with a view to giving a thorough grounding in those subjects which a broadly educated person must have, so that the colleges may devote more time to the necessary engineering subjects.

ALFRED R. GOLZÉ,[45] ASSOC. M. ASCE.—The experience of the Bureau of Reclamation shows a need for greater appreciation by the engineering schools of the fields of endeavor into which graduates will advance. This experience supports Mr. Baker's conclusions that engineering education should emphasize fundamental principles in subjects throughout the broad field of engineering and that a graduate engineer should be able to undertake a career leading to administrative, executive, or managerial responsibilities. The unusual conditions affecting educational institutions during and following World War II provide an unexcelled opportunity for possible curriculum adjustments to meet extreme weaknesses.

The Bureau of Reclamation is considered primarily an engineering organization. Its accomplishments in the fields of civil, electrical, and mechanical engineering are well known; yet of its present staff of approximately 15,000 employees less than 30% are engineers devoting their time exclusively to strictly engineering phases of planning, design, and operation processes. The other employees—legal, clerical, and skilled labor—are engaged in multitudinous tasks of administration. Since the work of planning, building, and operating reclamation projects is essentially engineering in character, it follows that men with engineering training would seem to be the most logical group to advance to administrative and supervisory positions. It has been the Bureau's experience, however, that engineers, regardless of the excellent technical education they receive in the colleges, are not as well equipped to move into supervisory and administrative positions where employees of all professions and trades come under their direction, as are men who have received their basic education in fields with broader perspectives. For instance, men in charge of operating reclamation projects must be versatile creatures. They must excel at public relations in dealing with both water users and their innumerable requests, and with labor, both organized and unorganized. They must be good accountants to recover the construction and operating costs assessed against a project; they must write an endless number of brief, concise reports of every description; and they must operate and maintain massive dams and miles of canals, laterals, and drains, and direct the operation of fleets of equipment.

---

[45] Asst. Director, Branch of Operation and Maintenance, Bureau of Reclamation, Washington, D. C.

The Branch of Operation and Maintenance of the Bureau of Reclamation has the responsibility for the operation of completed irrigation facilities. There is a woeful lack of qualified men to fill developing vacancies in the field. On the older irrigation projects the officials in charge are reaching retirement age. New projects requiring complete staffs of competent men are being brought to completion. In both cases the Bureau has no source of trained material from which to draw to fill the key positions on operating projects. This condition is caused not only by the failure of the Bureau to appreciate its own needs and to provide a proper training program, but also by a feeling on the part of most men who elect to stay with the civil engineering profession that the field of construction is the one to follow.

With the college curriculums in civil engineering shaped as they are in most schools, it is only natural that the graduate should judge that the sole professional opportunities are in construction. The lack of interest in the operation of completed engineering facilities—which is only one example—seems to be due to two factors: (1) A failure on the graduate's part to appreciate the engineering importance of these facilities to the continued welfare of the community and of the United States; and (2) the mercenary aspects of low salary scales.

With respect to factor (1), if Mr. Baker's engineering course, alternative I, were adopted, it would be of great assistance. In regard to factor (2), the Bureau of Reclamation, together with other federal agencies, pays the same salaries for operation and maintenance duties as those given to construction and planning engineers, largely eliminating the salary differential as a reason for keeping young engineers out of this field.

Seeking to determine the situation in the western universities, the writer has recently completed a trip through California and the Southwest where he visited some of the major universities giving courses in engineering and irrigation agriculture. In nearly every case, although the faculties appreciated the need for emphasizing the part that engineers can play in western development, the colleges were making no particular effort in that direction. In other words, the standard four-year engineering courses are about the same as the courses given in the universities of the Middle West and the East. Most colleges consider four years academically too short a time to provide an engineering student with other than the technical tools with which to begin his career. Such activities as public speaking, administration, western resource development, and national economics are seldom considered.

Resorting again to the Bureau of Reclamation as an illustration, it has expended more than $1,000,000,000 in providing a high standard of living to secure agriculture for the people of the West. It has on its books nearly another billion dollars of authorized work and ahead are more years of billion dollar expenditures. In thirty years the men who are now in colleges will be in charge of this vast investment. It is self-evident that the universities, particularly those of the West, carry a major responsibility in properly training men for this difficult and important work.

A promising aspect of the situation at most western schools is the evident desire of the faculty members to widen the scope of the engineering training and to increase the consciousness of students to their future responsibilities in

developing and administering the natural resources of their part of the United States. Shortcomings in public relations and report writing are well understood. Formerly several of the western schools were leaders in these fields and their staff members have become nationally known for their contributions to irrigation engineering. With the passage of years, however, there has been a slowing down of the leadership because of age and turnover so that institutions which formerly led the field are having difficulty in maintaining their rank. If other schools were coming to the front this would be a healthy development injecting new blood and new ideas in the field of engineering education, but there is little indication that a broader engineering education adapted to the needs of the consumer is becoming available.

Although the situation appears gloomy, the spark of self-improvement does exist in most of the schools visited by the writer, and presumably it exists elsewhere. Once the peak of the present high enrolment of returning veterans has been passed, a number of western schools should seek to motivate engineering curriculums to reflect the needs of the nation, and particularly those of the western states, by arousing in the neophyte engineer a consciousness of the responsibilities attending his profession in the broad fields of economics, public relations, and administration. If the users of engineers, as well as the producers of engineers, will accept Mr. Baker's challenge, this objective ultimately should be forthcoming.

DONALD M. BAKER,[46] M. ASCE.—In reading the discussions of this paper, one is reminded of the old Hindu story about the blind men who were taken to visit an elephant, and afterward asked to describe the animal. The man who felt the elephant's legs stated that an elephant was like a tree, the one who had felt his trunk described the animal as being like a huge snake, while the one who had felt his tail likened him to a thick rope.

Each discusser—practicing engineer, educator, or layman—discusses engineers, the practice of engineering, and engineering education from his contacts with them. Some have been wide and varied, have involved large numbers of engineers practicing many specialties in varied locations, while others, although extending over considerable periods of time, have been with limited groups and sometimes within limited areas.

Most of the engineering educators appear to have had in mind recent graduates, seeking employment following graduation or during the early years of their practice, or possibly to be thinking of the employers endeavoring to recruit young graduates to fill subprofessional or preprofessional positions in their organizations. Professor Brinker talks about maintaining student interest in courses and about preparing civil engineering graduates so that, following commencement, they may secure positions as instrumentmen rather than as rodmen, as draftsmen rather than as tracers. Professor Carpenter feels, and rightly so, that employers of young graduates should be convinced of the value of viewing such graduates as professionally trained men, and of affording them an opportunity to rise from subprofessional to professional status.

On the other hand, practicing engineers and others seem to have in mind the engineer in his more mature years, when he is practicing as a specialist or as a

[46] Partner, Ruscardon Engrs., Los Angeles, Calif.

"routineer," an engineering executive or administrator, a business man, or merely as a contented and worthwhile citizen.

Mr. Balog, when he sees the "highly educated designer" as a true representative of the civil engineering profession, apparently has in mind those young South American structural designers—twenty-five to thirty-five years old—who, he states, have developed a reinforced concrete design practice far superior to that of the level achieved in this country. In this assertion he ignores the efforts of those civil engineers, young and old, whose endeavors, in many instances involving more or less routine design, have resulted in many huge dams; water supply, flood control, irrigation, and power projects; highways; railroads; airfields; and port facilities; that in turn have done so much to establish the high standard of living prevalent in the United States. Perhaps Mr. Balog has in mind a definition of "design" which involves merely the use of formulas and charts to determine the dimensions of various members of a structure. Should not this word "design" include the conception, planning, arrangement, location, dimensions, use, and general economics of a structure or utility.

Mr. Wagner and Miss McIver, from their long and intimate experience with engineers of all ages, kinds, and capacities, and with large numbers of employers of engineers, have probably achieved a broader and deeper contact with these than is the case with most of the other discussers. It is significant, in view of this, that Mr. Wagner poses these extremely pertinent questions: "What is engineering?" "What is the engineering profession?" and "What is its scope?" When the answers to these questions are known with a reasonable degree of certainty, engineering societies and engineering educators will have a far sounder basis for their activities than they now have.

The writer throughout his paper and this discussion has referred to engineering as a profession, although for some considerable time there has been a question in his mind as to whether the practice of engineering involves the practice of a profession, or whether it involves a business in which a professional man is engaged. No attempt is made herein to answer this question; it is one which merits serious consideration by engineers, engineering societies, and engineering educators.

The statistical material used in this paper to present the composition and structure of the engineering profession, and the conditions that govern and prevail in actual practice, embrace, on a nationwide scale, a very large and representative segment of the engineering profession. Where derived data are based on sampling, the samples were of a size adequate to produce results of a quality sufficient to meet the purposes of this paper. Conclusions reached were substantially in agreement with independent studies made by Mr. Thomas and Miss McIver. This does not mean, however, that further work of this character is unnecessary. On the other hand, it is urgently needed, and the author would be the first to admit the inadequacy of his basic data. He submits, however, that the statistical material presented all points in the same direction, and, furthermore, conclusions reached coincide with experience.

National engineering societies during recent years have given far more attention to engineers, as against engineering, than was given in the past. This

may be due, in part, to the large additions of younger men to their membership and the demand by these younger engineers for a display of such interest. Activity along these lines can be expected to continue to increase, if for no other reason than that changed conditions growing out of wartime employment will require it. These activities, however, cannot be carried on with the highest degree of effectiveness until more knowledge is obtained concerning the answers to the three questions posed by Mr. Wagner. An expenditure by national engineering societies of the order of $500,000 in this field over a five-year period would yield handsome returns to their members, to industry, and to the nation at large.

The paper, although by its title pertaining to the broad field of engineering education, was limited primarily to a discussion of the engineering profession, the practice of engineering, educational curricula, and course content. The writer also made recommendations as to modification or changes in these last two for the purpose of producing young engineers who, as time goes on, can more adequately meet the demand for engineering services in the postwar market. Had the paper fully covered the subject, it should have included a discussion of engineering instructors, engineering instruction, and the problem, strongly and properly emphasized by Mr. Boalich, of how better to control the admission to engineering courses of students who possess those tempermental and other personal characteristics which fit them to follow engineering and to be content in its practice.

Mr. Lynch suggests that preparation for collegiate training in engineering should commence in high school. This suggestion has a great deal of merit, although it probably will not be adopted until such time as engineering schools, societies, and state registration boards have come to work more closely together toward a common objective. Although there still exists a widespread feeling among engineers that professional status may be obtained without a formal engineering education—due probably to the still large number of men claiming such status without holding a degree—the next generation of engineers will have a far smaller percentage of men within its ranks who have not had a formal engineering education. This situation has already occurred in medicine, dentistry, accounting, and law. The young man who makes up his mind in high school to follow professional engineering and begins then to shape his course and plans for the "long pull" will be the one who attains professional status in the highest sense of the words.

A number of discussers refer to the desirability of developing imagination in students. Mr. Oesterblom talks about the "creative urge," and very rightly decries the tendency to "train a flexible mind into a rigid form." Imagination and vision are personal traits. Some persons possess them in a greater degree than do others, but even in those who inherently lack them, they can be cultivated by inspirational instruction. This latter is extremely difficult to secure; and only too often those instructors who possess the ability to give it either leave teaching or are advanced rapidly to positions on the faculty where their contacts are with older students.

Professor Lilly has pointed out the crux of this problem in his statement, "* * * quality in the student must come from quality in the faculty."

It is customary in developing faculties in engineering, as well as in other schools of collegiate grade, to assign as instructors in freshman subjects recent graduates, if possible men who have achieved scholastic honors. If and when these younger instructors attain experience and seniority, they are assigned to sophomore courses and, ultimately, with greater seniority and possibly with increasing reputation derived from research and writing, may arrive at teaching junior and senior courses.

Freshman and sophomore students from eighteen to twenty years old are passing through the most impressionable and idealistic period of their adult life. Seldom do they know just why they enrolled in an engineering course, although many of them may think they do. During these formative first two years, their contact is almost entirely with immature and inexperienced instructors; and it is upon such instructors that the responsibility largely rests of providing inspired instruction at the time when it is most needed and most effective. Even after the student has reached his junior year, his contacts are seldom with instructors who have had experience in the practice of engineering in a responsible capacity and who are familiar with problems commonly met in engineering practice. With only such contacts as described, how is the student, during the first two years, to determine whether he is fitted to, or will want to follow, engineering as a career and be happy in so doing.

Perhaps the lack of student interest during the first two years of the engineering course referred to by Professor Brinker and others is due more to uninteresting instructors and unimpressive instruction than to course content. Inspirational instruction is as much a matter of the personality of the instructor as it is of his reputation in or knowledge of his subject. It is also more a matter of the manner in which he presents his subject than the content of his lectures. The writer recalls his course in descriptive geometry, a subject usually disliked by most students. The instructor had never taught the course before, and had but a casual knowledge of the subject. He managed, however, to keep several pages ahead of the class in text, so they did not discover the shallowness of his knowledge. He had an engaging personality, and managed so to arouse the interest of his students in the subject and in himself that every student acquired a deep interest in the course, and a thorough knowledge of this normally dry and uninteresting, although valuable, subject. He also recalls a course in hydraulic machinery given by an instructor who was an outstanding authority, a man who had done much pioneering work in the design and development of pumping machinery and turbines. This instructor, however, droned through his lecture and filled the blackboard with formulas and mathematical developments of theory. Few in this class acquired much knowledge of the subject by the end of the course.

Were it possible to develop a faculty that had as one fourth to one third of its members engineers who had from fifteen to twenty years of experience in the practice of engineering, at least one half of which time was in a fairly responsible capacity, and if freshman and sophomore students were provided the opportunity to sit for three or four hours per week under some of these instructors, and under some of the older instructors who had achieved eminence in engineering—men to whom they could look with respect and even awe—

this lack of interest would not exist. Furthermore, if freshman and sophomore students were told—and they should be told repeatedly—just how their course had been developed, why each subject had been included therein, the interrelationship between all subjects in the course, and the relationship of the structure and pattern of the course to their future practice, they might within this two-year period gain a picture of what they were doing, why they were doing it, and the direction in which they were headed. In addition, it is believed that when the deans or department heads commenced to justify to themselves the courses given, prior to presenting such justification to the younger students, the conclusion might be reached that some of these courses could not be justified and they might be eliminated. It might also be discovered that other courses could only be justified because Professor Soandso, who has been giving a certain course for years, objected to teaching any other subject.

Mr. Perry states that the need of salesmanship by every man is but a partly true statement. A number of discussers decry the need of salesmanship by engineers, and question whether it can be taught. Salesmanship involves a knowledge of the product sold, of people, and the faculty of clear and logical expression, verbal and written. One never completes his education in these subjects any more than he does in engineering subjects, but the student is entitled to be told, with emphasis, of the importance to him of salesmanship. He should, at a minimum, be able to make out an effective application for employment, although only one graduate out of ten can do this. He should be able to write a clear and effective one-page letter, and to meet a prospective employer without stammering and stuttering. Few graduates can do these things. Criticism, by instructors, of the manner in which students recite and of the quality of expression found in their papers and reports will often prove as effective as formal courses in literature and expression.

The writer believes it requires salesmanship for a graduate to secure his first engagement, and that salesmanship is required in order for him to advance to higher positions. He has known and worked with many so-called financially successful and eminent engineers, and with many engineers who were far less successful financially and far less eminent, but who possessed equal ability and capacity. Too often it has been found that the only difference between men in the two groups is the amount of salesmanship practiced by the more financially succesful and more eminent engineers.

It is not so readily possible to determine the quality of engineering service as it is the quality of other professional service. A doctor loses or cures a patient. A lawyer wins or loses a case. Their successes or failures are soon known, and as these accumulate their professional reputation or standing is enhanced or disappears. Floods that wash out dams, earthquakes that destroy buildings, loadings that cause bridges to fail may not occur until years after the death of the engineer responsible for their design or construction. One engineer may develop an ore deposit in one manner and another develop it differently. In either case, the success or failure of the mine is usually credited to the character of the deposit, or to the market, not to the engineer. One engineer may plan, design, and construct a water supply project costing millions of dollars. This aids in making him successful and eminent, even though twenty

years after the project has been completed, it is found to have been greatly overdeveloped, and cannot meet interest on its bonds. Another engineer may develop a much smaller project costing thousands instead of millions, but which is very successful and able to pay off its bonds before maturity. This latter engineer is seldon heard of unless he possesses the quality of salesmanship.

It is admitted that engineers cannot advertise the value and worth of their services in the same manner as do makers of soap and laxatives, but the "better mouse trap" theory became obsolete with the advent of newspaper and periodical advertising. Some engineers have jobs seek them; but the writer is familiar with too many engineers and engineering organizations, public and private, large and small, who have their salesmen or contactmen, sometimes dignified by the title of public relations counsel, to believe that work well done is the only requirement for securing more and better work to perform. Engineers write papers and publish books for the purpose of giving the profession the benefit of their experience and knowledge, or for the purpose of advertising themselves, but usually for both purposes. They join organizations, civic, religious, fraternal, social, and professional, to make contacts. The better an engineer is known the greater the opportunity he will have to perform more interesting and more important work; and he can become known more quickly and effectively if he tells the world about himself in a dignified and ethical manner. Too many instructors fail to realize that it is a wasted effort to teach a student how to design a structure, a piece of machinery or equipment, if the student cannot convince a prospective employer or client that he is capable of doing such a job and, therefore, should be given an opportunity to do it.

There appears to be, on the part of most of the engineering educators who discussed this paper, a mistaken view of the writer's proposal that the current four-year engineering course be limited to fundamentals in the broad field of engineering, and broadened to include subjects in business, the humanities, and expression. This proposal constituted only a part of the program suggested, and was urged in view of prevailing opinion and experience over several decades that few engineering students will, for economic and other reasons, spend more than four years in residence at any engineering school to secure an engineering education. Attention is called to the statements under the heading, "Postwar Engineering Education," that the postwar market for engineering services can be expected to require:

> "(1) A longer period of study and training for engineers * * *; (2) the broader knowledge of a wide range of both technical and nontechnical subjects necessary to provide maturity of judgment; and (3) the greater demand * * * for executives and administrators who have had background and experience in engineering."

The requirements set forth under items (2) and (3) are pointedly emphasized in a survey released[47] in May 1947, which covered personnel placement bureaus in one hundred and one colleges and universities in the United States. This study finds a notable trend on the part of employers toward seeking

[47] "Twelfth Annual Survey of College Placement Experience," Northwestern National Life Insurance Co., Minneapolis, Minn., 1947.

college graduates with engineering degrees for positions in sales work, office administration, and other nontechnical lines. It also finds that employers, except when seeking men for research and design activities, lay far more stress upon a graduate's ability to "get on" with people, his personality, and his extracurricular activities while in school, than they do upon his scholastic record. It also states that most large concerns that have instituted training programs for entering employees who are graduates give little weight to any specialization which a graduate may have undertaken while in college, preferring to train these graduates themselves in specialized subjects. These findings confirm those in the study made by the American Association of Engineers in 1940, which were quoted by the writer.

To meet these requirements, a four-year course as outlined was suggested, to be followed by an opportunity for postgraduate study, either in residence or through extension or correspondence, in specialties or in nontechnical subjects, with the goal of a professional degree when a suitable amount of such study had been satisfactorily completed. These two items are the keys to the program suggested in the paper, and must be considered as being inseparable.

To effect such a program would not call for anything revolutionary. It would mean harder work for instructors during the time necessary to adapt existing courses to new conditions, and to develop new courses. It would also call for some education of, and cooperation and understanding by, personnel directors and employers in the realization that the graduates of the four-year courses they would then be employing would not be so highly trained in certain specialties, but would have a broader training in fundamentals, could be more flexibly used, and could be expected to secure their specialized training during the early years of their employment. A few years of experience with graduates of this type should soon convince employers of their increased value. The greatest burden would fall upon the graduate working for his professional degree at the same time he was earning a living, and also upon his wife and family if he acquires these during such period. These should realize, however, that the sacrifices called for will be compensated later.

The discussion by Mr. Wagner of the composition and structure of the engineering profession, and the information which he presents pertaining to German technical education prior to World War I are of extreme interest. Fig. 1 was presented to illustrate the statement that the practice of engineering is a mass activity—not mass production as mistakenly inferred by Mr. Balog—and that any product created by engineers is the work of many persons with varying kinds and degrees of technical training, experience, and ability. Mr. Wagner states that if engineering is considered as being pyramidal in shape, as against the cubical shape of other professions and trades, a large number of engineering graduates, regardless of their qualities or abilities, are doomed to remain in positions in the middle or lower sections of the pyramid, because there is not room for them at the top. This fact is true of any group activity of this character. An army is composed of a few generals, a substantially larger number of captains and lieutenants, a still larger number of noncommissioned officers, and a great number of privates. A private may advance to be a general, but only if he has outstanding ability and undergoes arduous training. All privates and

sergeants receive specialized training, but not that of a character provided for potential generals.

It may be, as Mr. Wagner states, that other forces and organizations will solve the problem of fitting engineering education to conditions prevailing in practice, without the aid of engineering schools or societies, and that this may develop a pattern somewhat similar to that existing in Germany before World War I, adapted, however, to American conditions. This does not remove from engineering schools or societies the responsibility of endeavoring to solve the problem. Naturally, however, until far more information is available as to the number of engineers required to perform technical duties in the various branches of engineering in each functional bracket (from nonprofessional up through subprofessional, and preprofessional, to professional), and the number of so-called "routineers" among the professional workers, and until more information is available upon which opinion can be developed as to future trends in these numbers, little more than an approach can be made to fitting the general pattern of engineering education to the requirements of the future market.

Adoption of the educational program suggested in this paper would undoubtedly decrease the number of those who embark upon an engineering course with the expectation of achieving full professional status, and would increase the number of those who will be satisfied to seek an education which will qualify them to perform subprofessional or routine professional duties. Mr. Perry questions the wisdom of decreasing the number of professional engineers without, at the same time, making plans to supply adequately the demands for a subprofessional group. He is correct in this view.

In medicine, as Mr. Wagner states, those who do not expect to achieve professional status are only required to follow an educational program equipping them for subprofessional work. Laboratory technicians, nurses, and pharmacists are not secured from the ranks of those who embark upon, but for some reason fail to complete, the entire medical course, or who, having secured their medical degree, lack certain qualities or characteristics necessary for professional practice, and fall back upon subprofessional work. Every person seeking to practice medicine knows at the outset of his premedical course, and usually in high school, that he must complete this course, his medical course, and a year or more of internship, and then submit to an extremely difficult and searching state examination before he can be admitted to practice. He also knows that he can specialize only after further and prolonged study. One does not hear of the need of providing undergraduate courses in medicine in order to maintain the interest of the student.

Professor Grinter agrees that courses in public speaking, English literature, technical writing, history, and public affairs, when given under cultured and stimulating teachers, would produce results in broadening students; but he questions how a student can study such courses in sufficient quantity and still "end up as a trained engineer." This raises the question, "Can a trained engineer be produced by having a student successfully pursue four years of study at an engineering school, even at a school of the highest caliber?" The answer is manifestly in the negative. The author believes, however, that if a student should follow a four-year course, such as is outlined in this paper,

supplemented by graduate study of sufficient scope, character, and time to attain the professional degree, he will more closely approach the status of a trained engineer than will the graduate of current four-year courses after he has practiced from six to ten years.

Mr. Williams states that engineering education consists of cultivating the "growth" of the faculties to observe, to think, and to express thoughts, and of the personal attributes essential to citizenship and a full life. This is a most worthy objective, but if the writer's contacts—with thousands of graduates of all ages, in all branches of the profession, and holding all degrees of responsibility—are a guide, such objectives have been attained in an extremely small percentage of engineering graduates.

Professor Dougherty suggests that the writer has overlooked many changes that have taken place in engineering education. A review of courses offered in a considerable number of engineering schools; discussions with younger graduates; and a reading of news items in technical journals pertaining to engineering faculty additions, to improvements in school facilities and equipment, and to changes in courses, give the impression that there has not been any material change in engineering education since the period prior to World War I, beyond that of keeping well abreast of technical developments and practices.

Professor Dougherty also suggests that Fig. 1 be presented with professional age as the ordinate. This might be accomplished by use of material presented in Table 3(*b*), but it would serve little purpose. The presentation of Fig. 1, which was not drawn to scale, was, as heretofore stated, to indicate the fact that, as the relative amount of engineering work performed and the degree of responsibility attached to such work increased, the number of engineers required materially decreased. There is, of course, some degree of correlation between age, on the one hand, and the importance of work performed and the responsibility assumed, on the other, but no data are readily available, by which such correlation could be developed. The research suggested by the writer would involve the collection of analysis and interpretation of this type of data; but, until such research has been conducted, a great deal of the activities carried on to improve the profession technically, socially, and economically will be performed in the dark, or at least in the twilight.

Professor Lilly with much truth states that "Education should prepare a man for his leisure hours as well as his working hours." Miss McIver has pointed out that it is not now the fashion to portray engineers as "roughnecks," and that more and more stress is being placed by employers upon appearance. If engineering education is to provide a vocabulary, as mentioned by Professor Lilly, and also to provide for leisure hours, it would seem that the students should have an opportunity to acquire a nontechnical vocabulary; for many of his contacts following graduation will include those who do not possess or understand a technical vocabulary and with whom communication must be had in nontechnical terms. Furthermore, if the student has never been given even a taste or a glimpse of good literature, of music, history, or art, how will he know that these exist, or where to turn to gain an acquaintance with them. Even a course offering contact with these things and involving one hour a week during four years, where no problem sets were assigned and no grades given

except for attendance, would develop an interest on the part of many graduates which would greatly help them in preparing their leisure hours in later years.

Mr. Conwell indicates that the program suggested in this paper shifts the responsibility for developing nontechnical requirements of the engineering profession and for the cultural background of the student from the latter to the school, and shifts some of the responsibility for obtaining technical knowledge from the school to the employer. The writer agrees with this, and believes that it is proper. Under current practice, the student, an immature youth of seventeen or eighteen, presents himself to an engineering school and says "I want to be an engineer. Will you please make one out of me." The school proceeds to work on, and sometimes with, him for four years, filling him with technical theories and practice. At the end of the four years' time it takes those who have survived, the school gives each an engraved piece of parchment with his name on it, and tells him,

> "We have done what we could. We know that you can hold down the first job you are offered, and we hope that you can progress to higher and more responsible positions. We know that some of our graduates have done so, although we have not heard from most of the others."

The employer greets the graduate with open arms, and with high hopes that he has hired a future chief engineer, manager, or even president, and then, in most cases, promptly forgets him, although continuing to grouse about the inadequacies of engineering schools. The world seems very cold to the graduate, except for the opportunity sometimes provided once a month, if he resides in a fair-sized community, of attending the meeting of the local engineers' club or of the local section of a national engineering society. At such meetings he may sit next to his boss at dinner, talk about something else besides his daily tasks, and may also listen to some older fellow engineer "advertise" himself by telling about work he has recently performed. The graduate is on his own. His alma mater and his employer, as well as his profession, do have a responsibility toward him which they have, to a great degree, left unfulfilled.

Mr. Amirikian emphasizes the "practical problem of placement of the finished product," referring to graduates in law, medicine, and engineering. The engineering graduate is accepted by most employers as an apprentice in a trade, with the difference that he has acquired a familiarity with some of the tools which he will use in his trade, and is able to use a few of the simpler ones in minor operations. A further difference in this analogy, however, is that a plumber's apprentice can only become a plumber and not a bricklayer, whereas a civil engineering graduate may, and frequently is, apprenticed in mechanical, electrical, mining, or chemical engineering, and is then required to learn the use of a new type of tools.

The discussion by Mr. Thomas illustrates what can be developed concerning engineers and the practice of engineering from existing basic data. Table 7, showing that since 1929 the Society has taken three new members to gain one, serves to raise some extremely pertinent questions, among which is included, "How many engineers must be graduated from the current engineering courses to produce one professional engineer successfully practicing at the

age of, say, forty seven?" An analysis of the relation of losses in Society membership to total membership, other than from death, shows that the high loss ratio was not due to the depression of the 1930's. Table 8 indicates that one half the number of engineers who were practicing their profession at the age of thirty had left their profession fifteen years later, or by the time they were forty five, and that such loss ratio increases for engineers over thirty years old. Although the basic data upon which these conclusions rest may not be a strictly representative sample, nevertheless, the conclusions are interesting and significant, and involve a sample of sufficient size to warrant their being given serious consideration. Mr. Thomas' study resulting in Fig. 2, which shows the increase of employment of younger civil engineers in public service, might well be extended to other branches of engineering. Fig. 2 shows the deterioration of private practice in civil engineering as a field of opportunity for younger engineers. Such trend commenced long before the depression, so it cannot be charged to conditions created thereby.

Miss McIver's discussion of the methods and source of material used by the American Association of Engineers in its studies of engineers and of the practice of engineering indicates what can be accomplished through the use of existing data. The writer is in thorough agreement with her conclusions as to the disadvantages of the use of questionnaires to which voluntary replies are requested, and as to the unreliability of results secured where basic data are collected by this method. The unreliability of these results was established in a dramatic manner by a poll of the 1936 presidential election. Such polls had been taken a number of times previously and showed a high degree of accuracy with election results, but the sampling in the 1936 poll was apparently very unrepresentative.

Past studies of engineering compensation, based on voluntary replies to questionnaires, bear no resemblance to the material presented in Table 3(*c*), which is based on the salaries of every technical engineer in the country. Those receiving income disproportionately low compared to their age, length of experience, or position held, either do not reply or give higher than actual figures, while recipients of high income always proudly answer. The results, therefore, are heavily weighted by replies from those receiving higher incomes. Even if sampling by this method is truly representative, there is no way of determining this fact. Polls compiled by George Gallup and by the magazine *Fortune*, based on samples carefully selected so as to be representative, although extremely small in number compared to the universe sampled, are statistically sound and have been proved to be highly accurate. Furthermore, sampling, whether it be on the basis of voluntary replies to questionnaires, or through personally interrogating the respective sample, only gives current views, attitudes, and facts. Trends can best be determined by utilization of existing basic data.

Experience records of engineers as a source of basic data in the study of the composition and structure of the engineering profession were suggested as the best available information. These records include the type and kind of work performed by engineers, the extent of responsibility which was placed upon them, the relative importance of the work which they were performing at various stages of their careers, the general rate of progress which they have made

in their profession, the changes from one branch or specialty to another, and the changes from one location or employer to another. They were not suggested, as Mr. Balog has assumed, as a source of information as to the accomplishments or capabilities of engineers. The writer agrees with Mr. Balog in his statement that:

> "Anywhere and everywhere, structures can be observed which disclose the need for engineering services—instances where the use of expert engineering talent would have resulted in savings, improved appearance, and increased engineering employment."

If engineers were better salesmen this statement would not be true. Agreement is not possible, however, with Mr. Balog's statement that:

> "The management of engineering organizations, at present, may be a purely parasitic activity in which mere trader's cunning, or certain dexterity in the use of technical terms, is sufficient qualification for a position above the engineer."

The writer's statement—

> "The current practice of engineering, except by those who serve in advisory or consulting capacities, is a mass-production activity, in which each individual serves as a cog in a machine and performs his specific duties as a unit of a much larger group"

—was not quoted in its entirety by Mr. Balog. The creations of engineers, particularly when they involve structures or facilities, are not those of mass production, but are those of an organized group of technical men working with others. Before a large engineering structure can be designed and built, its location, site, income possibilities, and many other features must be studied. Alternate preliminary plans and designs must be prepared, the economics of each plan and design investigated. Final plans are then prepared and a cost estimate made. The structure then must be built, and working plans prepared, foundation conditions explored, and changes made in the design during construction.

Tracers, draftsmen, designers—structural, mechanical, electrical, and others—rodmen, instrumentmen, chiefs of party, laboratory technicians, concrete technologists, resident engineers, inspectors, and a multitude of other personnel are required, some performing perfunctory duties, some routine work, and others technical work requiring extremely high skill, knowledge, and judgment. The designer is but one member of the team—an important one it is true, but no more important than many others. At the top is the manager. He coordinates, plans, drives, and pushes, makes the important decisions, or confirms those made by others. If he devoted his time primarily to the engineering phases of the operation which he was managing and, as Mr. Balog suggests, "assigns subordinates to the nontechnical duties of the managerial position," one wonders if the job would ever be completed, and if so at what cost.

Again, the questions posed by Mr. Wagner arise. Was the chief engineer of the Golden Gate Bridge (San Francisco, Calif.) practicing engineering only during the times when he stopped in the drafting room to discuss with his chief

designer the arrangement, size, and thickness of plates to be used in the design of the towers, and the unit stresses of steel to be allowed in the cables of this, the longest suspension bridge in the world? Or was he practicing engineering during the entire period from the time such bridge was conceived and determined in his mind to be feasible until the time it was completed and opened to traffic?

Mr. Golzé well expresses the viewpoint of the engineering employer when he speaks of the need of the U. S. Bureau of Reclamation, a large public engineering organization, which is passing into the stage of operating the engineering projects it has built, and clearly foresees the need for engineers who can administer and operate these projects, as well as design and build them.

Mr. Dykstra gives an excellent description of the type of engineer whose services will be required in coming years when he states,

> "In modern technological civilization there is great need for the technicians called engineers, but, to master this mechanical civilization, technical men must be aware of the implications of modern life and they must feel at home in a changing world. A structural engineer should know more than how to build a bridge. He should be able to state whether a bridge is necessary, what will happen if it is built, and, perhaps, be able to suggest an alternate solution for what is traditionally thought of as a bridge problem."

During the fall of 1946, the writer encountered an article[48] from which the following excerpts are quoted:

> "Because the engineering schools have always made it their chief aim to impart the technical information needed in industrial production, and because both scientific knowledge and industrial practice have grown so rapidly, the attention of technical schools has been focused chiefly upon keeping up to date in science and practice. The university emphasis on research in natural science has also tended to magnify the importance of technique and to minimize the importance of personality * * *. Therefor it seems necessary to consider the question whether this emphasis on technique is producing a new and higher type of engineer, or whether the engineering profession still stakes its faith on the fundamental thesis that personal character is, after all, the real foundation for achievement * * *."
>
> "Progress is being made towards the conception that there is really but one profession of engineering, in spite of its apparent division into the several well known branches. War conditions have not only hastened public recognition of the engineer as an expert in applied science and fostered solidarity in the profession, they have also opened to him new fields of activity * * *."
>
> "Hence there has arisen a pressing demand for men who can deal with labor and with business administration in the engineering spirit * * *."
>
> "These new opportunities for the engineer have been gradually developing for a number of years, but the profession as a whole has been slow to discern them. The war has focused attention on them and precipitated a general recognition of them. It is also evident that the mastery of these new activities depends in greater measure than does mastery of the traditional types of engineering on the personality of the man * * *. Therefor as engineering expands into new fields now opening before it, the conception that character, judgment, efficiency, and the understanding of men are no less necessary than technical knowledge and skill will become more and more impelling, and it will become more and more essential that schools of engineering pay greater attention to the effect of their work on the personal development of students * * *."

[48] *Engineering News-Record*, October 24, 1918, p. 742.

"The net result is that curricula and methods of instruction that were devised to supply the intellectual element in production by imparting knowledge of natural science must be reorganized to meet the new industrial demand for engineering administrators and the larger professional demand for men of strong personality * * *."

It should be noted that these excerpts appeared in an article published in October, 1918, and are quotations from the report on the three-year study of engineering education made by Charles R. Mann, under the joint auspices of the Carnegie Foundation for the Advancement of Teaching and the Joint Committee on Engineering Education of the national engineering societies.

The writer feels that Mr. Mann's statements, made less than a month prior to Armistice Day of World War I, are even more pertinent today.

Paper No. 2313

MOMENT-STIFFNESS RELATIONS IN CONTINUOUS FRAMES WITH PRISMATIC MEMBERS

By George H. Dell,[1] Assoc. M. ASCE

With Discussion by Messrs. I. Oesterblom, William A. Conwell, and George H. Dell.

Synopsis

The design of a continuous frame usually involves a process of successive revisions and analyses, starting with an estimate of the stiffnesses of the various members. On the basis of the stresses obtained from an analysis of this structure, a preliminary design is made. The preliminary design is next analyzed, and it is usually found that some of the members are unnecessarily strong and some are deficient in strength. The designer then makes whatever changes seem appropriate in those members and reanalyzes the structure. This process may have to be repeated several times before the design and the analysis are in agreement.

When the stiffness of one or more members is changed, the moments in all the members are affected. Since the moment at a given section in a continuous structure is a function of the stiffnesses of the various members, the differential of the moment (or moment differential) is a function of the differential changes in the stiffnesses. The resulting relation between the differential of the moment and the differentials of the stiffnesses is designated a "moment-stiffness relation." In some types of structures composed of prismatic members, the analytical part of the design procedure may be facilitated by the use of such moment-stiffness relations. Moment-stiffness relations may also be used in connection with studies aimed at improving the economy of an existing design.

A method of determining the moment-stiffness relations, using moments created by unit couples applied at the several joints, and by unit horizontal forces at the joints in cases involving sideway, is presented in this paper. The numerical values of the moments resulting from these unit couples and from unit horizontal forces are available for use in obtaining the stresses pro-

Note.—Published in May, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Asst. Prof., Civ. Eng., Univ. of Illinois, Urbana, Ill.

duced in the original structure by the various combinations of dead load and live load.

The paper also includes a description and illustration of a procedure whereby the moment-stiffness relations can be used to bring the design from the preliminary stage to the final stage.

Since the shears, reactions, and deflections may be obtained from the moments, the differential changes in these quantities may likewise be calculated from the differential changes in the moments, if desired.

The types of structures discussed are those in which the members, assumed to be prismatic, are subjected to bending and shearing forces in a single plane and which may be analyzed from a consideration of the equilibrium of moments and horizontal forces at the various joints—for example, continuous beams, rectangular bents of one or more stories, and saw-tooth bents such as those shown subsequently in Figs. 1(*a*), 2(*a*), 3(*a*), and 5.

Experience indicates that moment-stiffness relations are a useful aid in the design of continuous framed structures composed of prismatic members, particularly in cases where the columns are subject to moments of considerable magnitude. These relations also provide a basis for the determination of possible improvements in an existing design.

As differential quantities are only approximate representations of the true changes, the relative stiffnesses upon which the moment-stiffness relations are based should be chosen with some care, or they should be determined from a preliminary design, and the final results should generally be checked by a direct analysis. It should be recognized that, in some instances, where large stiffness changes occur, the moment differentials will be subject to rather large errors and also that, where only minor changes in stiffness occur, the use of moment-stiffness relations is not particularly advantageous unless subsequent economy studies are to be made.

Conventions and Symbols

The sign convention used for moments is as follows: Tension on the upper side of a horizontal member corresponds to negative moment at the left end and positive moment at the right end; for vertical or inclined members, tension on the left face corresponds to negative moment at the lower end and positive moment at the upper end. Horizontal shears at the ends of vertical or inclined members are considered positive when acting toward the right. Letter symbols are defined where they first appear, and are assembled alphabetically, for convenience of reference, in Appendix 1.

Moment-Stiffness Relations

A general expression for the moment-stiffness relation (that is, the relation between the moment differential and the changes in the stiffnesses of the various members) may be derived by analogy with the analytical process used in the determination of the moments. With the general expression as a guide

(see Eq. 7), the moment-stiffness relations for a particular structure may be evaluated most conveniently by moment-distribution procedures.

A brief description of the types of structures dealt with herein has been given in the "Synopsis." With regard to any typical member, AB (horizontal, vertical, or inclined), in such structures, the moment at point A is the sum of C_{AB}, the fixed-end moment due to loads between points A and B, and M'_{AB}, the elastic moment or "M'-moment." The latter (M'_{AB}) is equal to the flexural stiffness $\left(K = \frac{E\,I}{L}\right)$ of the member, times a linear function, ψ, of the elastic deformations. The fixed-end moments being constant, the elastic deformations are functions of the stiffnesses of the various members. The following expression is thus obtained for M_{AB}:

$$M_{AB} = C_{AB} + K_{AB}\,\psi_{AB} \quad \text{.....................(1)}$$

The corresponding moment differential is $dM_{AB} = \psi_{AB}\,dK_{AB} + K_{AB}\,d\psi_{AB}$ which, by putting ψ_{AB} equal to M'_{AB}/K_{AB} and dK_{AB} equal to $i_{AB}\,K_{AB}$, becomes

$$dM_{AB} = M'_{AB}\,i_{AB} + K_{AB}\,d\psi_{AB} \quad \text{..................(2)}$$

In Eq. 2, i is the "stiffness-change ratio."

The horizontal shear at point G in a vertical or inclined member GH, denoted by H_{GH}, is the sum of the simple beam shear and the shear due to the end moments, M_{GH} and M_{HG}. The end moment is the sum of the fixed-end moment C and the M'-moment. Similarly, by defining the fixed-end shear, Q, as the sum of the simple beam shear and the shear created by the fixed-end moments, the horizontal end shear H may be defined as the sum of Q_{GH}, the fixed-end horizontal shear, and H'_{GH}, the horizontal shear due to the M'-moments. Shear H'_{GH} is then equal to the flexural stiffness, K_{GH}, times a linear function, ϕ_{GH}, of the elastic deformations. The following expression is thus obtained for H_{GH}:

$$H_{GH} = Q_{GH} + K_{GH}\,\phi_{GH} \quad \text{.....................(3)}$$

The corresponding shear differential is $dH_{GH} = \phi_{GH}\,dK_{GH} + K_{GH}\,d\phi_{GH}$, which, by making ϕ_{GH} equal to H'_{GH}/K_{GH} and dK_{GH} equal to $i_{GH}\,K_{GH}$, becomes

$$dH_{GH} = H'_{GH}\,i_{GH} + K_{GH}\,d\phi_{GH} \quad \text{..................(4)}$$

An analysis of the moments by either the slope-deflection method or moment-distribution procedures is equivalent to making ΣM equal to zero at the various joints and Σ(horizontal forces) equal to zero for each condition of sidesway or horizontal joint displacement, and solving for the M'-moments, which are then added to the fixed-end moments. Thus, there are two separate classes of equations or operations, which, for convenience, will be designated as "moment equations" and "shear equations." In the case of a moment equation for a given joint J, the constant term, or unbalanced moment, is ΣC_{J_n}—the sum of the fixed-end moments at that joint. In the case of a shear equation

for a given joint or section, the constant term, or unbalanced force, is ΣQ, the sum of the fixed-end horizontal shears, together with any external horizontal forces that may be acting on the joint or section in question.

The moments may be obtained by superposition. Let $m_{A,AB}$, $m_{B,AB}$, . . ., be the moments at joint A in the member AB due to unit couples applied at joints A, B, . . ., respectively; and let $m_{\Delta 1,AB}$, $m_{\Delta 2,AB}$, . . ., be the moments at joint A in the member AB due to unit horizontal shears, or joint forces, corresponding to conditions Nos. 1, 2, . . ., of sidesway or horizontal joint displacement. The following relations may then be stated:

A. The M'-moment at point A in member AB, due to an unbalanced moment of ΣC_{Jn} at joint J, is equal to $m_{J,AB}\,\Sigma C_{Jn}$.

B. The M'-moment at end A in member AB, due to an unbalanced horizontal force of ΣQ_1, is equal to $m_{\Delta 1,AB}\,\Sigma Q_1$.

The total value of M'_{AB} or $K_{AB}\,\psi_{AB}$, in Eq. 1, due to all the unbalanced moments and horizontal forces is thus given by the following expression:

$$M'_{AB} = m_{A,AB}\,\Sigma C_{An} + m_{B,AB}\,\Sigma C_{Bn} + \cdots + m_{\Delta 1,AB}\,\Sigma Q_1 + m_{\Delta 2,AB}\,\Sigma Q_2 + \cdots \quad (5a)$$

The moment M_{AB} may then be expressed as follows:

$$M_{AB} = m_{A,AB}\,\Sigma C_{An} + m_{B,AB}\,\Sigma C_{Bn} + \cdots + m_{\Delta 1,AB}\,\Sigma Q_1 + m_{\Delta 2,AB}\,\Sigma Q_2 + \cdots + C_{AB} \quad (5b)$$

The way is now paved for describing an analogous procedure of obtaining the moment differentials, or moment-stiffness relations. From a comparison of Eqs. 1 and 2, it is noted that the quantity $M'_{AB}\,i_{AB}$, in Eq. 2, corresponds to the fixed-end moment C_{AB}, in Eq. 1; and the quantity $K_{AB}\,d\psi_{AB}$, in Eq. 2, corresponds to the M'-moment, represented by the term $K_{AB}\,\psi_{AB}$, in Eq. 1. Likewise, from a comparison of Eqs. 3 and 4, it is seen that the quantity $H'_{GH}\,i_{GH}$, in Eq. 4, corresponds to the fixed-end shear Q_{GH}, in Eq. 3; and the quantity $K_{GH}\,d\phi_{GH}$, in Eq. 4, corresponds to H'_{GH}, or the term $K_{GH}\,\phi_{GH}$, in Eq. 3.

It can be shown that, just as the moments are obtainable by making ΣM equal to zero at the various joints, and Σ(horizontal forces) equal to zero for each condition of sidesway or horizontal joint displacement, the moment differentials are obtainable by making $\Sigma(dM)$ equal to zero and $\Sigma(dH)$ equal to zero for each moment equation and each shear equation, respectively. Corresponding to the moment equation for a given joint J, the unbalanced moment is $\Sigma(M'_{Jn}\,i_{Jn})$; and, corresponding to the shear equation for a given joint or section, the unbalanced shear is $\Sigma(H'\,i)$.

In connection with the determination of the moment differential dM_{AB} by the principle of superposition, the following relations may now be stated:

A'. The part of the quantity $K_{AB}\,d\psi_{AB}$ in Eq. 2, due to an unbalanced moment of $\Sigma(M'_{Jn}\,i_{Jn})$ at joint J, is equal to $m_{J,AB}\,\Sigma(M'_{Jn}\,i_{Jn})$.

B'. The part of the quantity $K_{AB}\,d\psi_{AB}$ in Eq. 2, due to an unbalanced horizontal shear of $\Sigma(H'_1\,i_1)$, is equal to $m_{\Delta 1,AB}\,\Sigma(H'_1\,i_1)$.

The total value of the quantity $K_{AB}\, d\psi_{AB}$ in Eq. 2, due to all the unbalanced differential moments and horizontal shears, is therefore:

$$K_{AB}\, d\psi_{AB} = m_{A,AB}\, \Sigma(M'_{An}\, i_{An}) + m_{B,AB}\, \Sigma(M'_{Bn}\, i_{Bn}) + \cdots$$
$$+ m_{\Delta 1,AB}\, \Sigma(H'_1\, i_1) + m_{\Delta 2,AB}\, \Sigma(H'_2\, i_2) + \cdots \ldots \ldots \ldots \ldots \quad (6)$$

In accordance with Eq.2, the total moment differential, or moment-stiffness relation, for M_{AB} is then as follows:

$$dM_{AB} = m_{A,AB}\, \Sigma(M'_{An}\, i_{An}) + m_{B,AB}\, \Sigma(M'_{Bn}\, i_{Bn}) + \cdots + m_{\Delta 1,AB}\, \Sigma(H'_1\, i_1)$$
$$+ m_{\Delta 2,AB}\, \Sigma(H'_2\, i_2) + \cdots + M'_{AB}\, i_{AB} \ldots \ldots \ldots \ldots \ldots \quad (7)$$

As a check, it should be noted that the sum of the coefficients of i in a complete moment-stiffness relation is theoretically equal to zero.

Referring to Eq. 7, the procedure for obtaining the moment-stiffness relation for a given monent M_{AB}, due to a particular arrangement of loading producing given M'-moments in the various members, will be clarified by the following rules:

1. Place a unit couple successively at joints A, B, . . ., N and distribute moments throughout the structure in each instance. This step provides the first class of m-moments for the ends of all members in the structure. In obtaining the moment-stiffness relation for M_{AB}, the particular values to be taken from this step are $m_{A,AB}$, $m_{B,AB}$, . . ., $m_{N,AB}$. If the structure is subject to sidesway, the correction for sidesway should be made in finding these m-moments.

(b)

FIG. 1.—SIMPLY-SUPPORTED CONTINUOUS BEAM

2. Place a unit horizontal force successively at appropriate joints of the structure, corresponding to the various conditions of sidesway or horizontal joint displacement to which the structure is subject, and find the moments thus produced throughout the structure in each instance, when the structure is in equilibrium. This step provides the second class of m-moments for the ends of all members in the structure. For obtaining the moment-stiffness relation for M_{AB}, the particular values to be taken from this step are $m_{\Delta 1,AB}$, $m_{\Delta 2,AB}$, etc.

3. At joint A take the product of $m_{A,AB}$ (see step 1) times the sum of the quantities $M'\, i$ for the various members connecting at that joint; similarly, take products for each joint of the structure that is required to be balanced.

4. Corresponding to each condition of sidesway or horizontal joint displacement to which the structure is subject, take the product of $m_{\Delta, AB}$ (see step 2) times the sum of the quantities $H' i$ for the various members entering into the given sidesway condition.

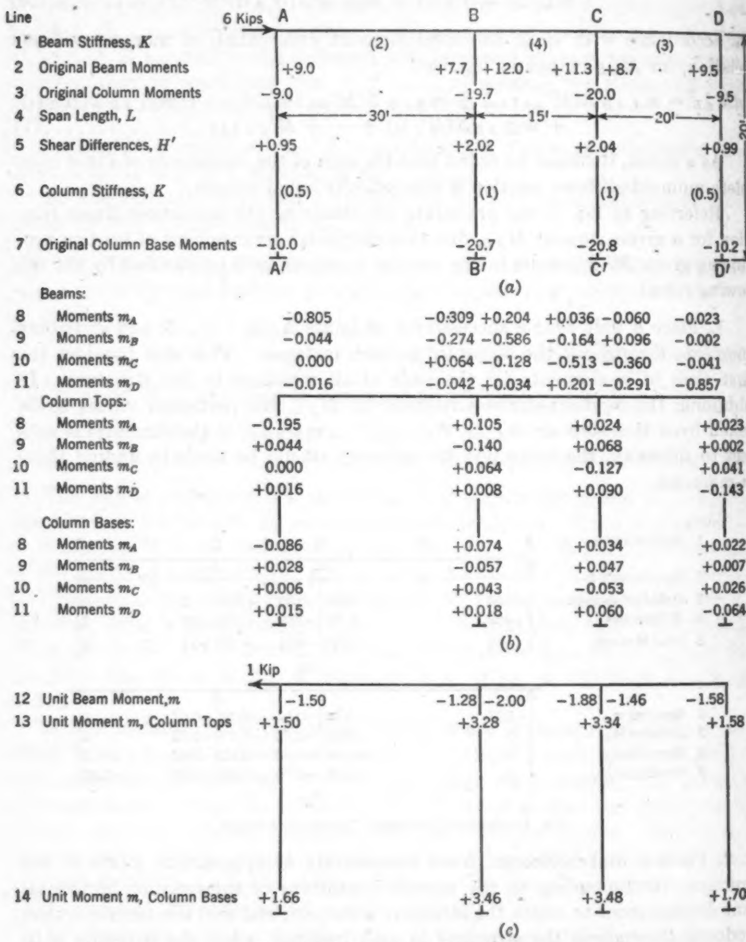

FIG. 2.—RECTANGULAR RIGID FRAME

5. To the sum of all the terms in steps 3 and 4 add the term $M'_{AB}\, i_{AB}$, and place the resulting expression equal to dM_{AB}. A check is obtained by the sum of the coefficients of i, which is theoretically equal to zero.

The application of the foregoing steps to a variety of structures is explained in the following examples, after which the use of moment-stiffness relations in connection with design will be explained and illustrated.

Example 1. Simply-Supported Continuous Beam.—In this problem it is required to calculate the moment-stiffness relation for M_{BA} in Fig. 1(*a*) if the spans AB and BC carry a uniformly distributed load of $5\frac{1}{3}$ kips per ft. Fig. 1(*a*) shows the fixed-end moments, the M'-moments, and the total moments. The relative stiffnesses are shown in parentheses (line 1, Fig. 1(*a*)). The *m*-moments in Fig. 1(*b*) were obtained by placing a unit counterclockwise couple at successive joints. In accordance with Eq. 7, the required moment-stiffness relation is: $dM_{BA} = -0.34\ (400\ i_{AB}) - 0.30\ (56\ i_{AB} - 356\ i_{BC}) + 0.10\ (-133\ i_{BC} + 33\ i_{CD}) - 0.05\ (0\ i_{CD}) + 56\ i_{AB}$; or $dM_{BA} = -96.8\ i_{AB} + 93.5\ i_{BC} + 3.3\ i_{CD}$. As a check: $-96.8 + 93.5 + 3.3 = 0$.

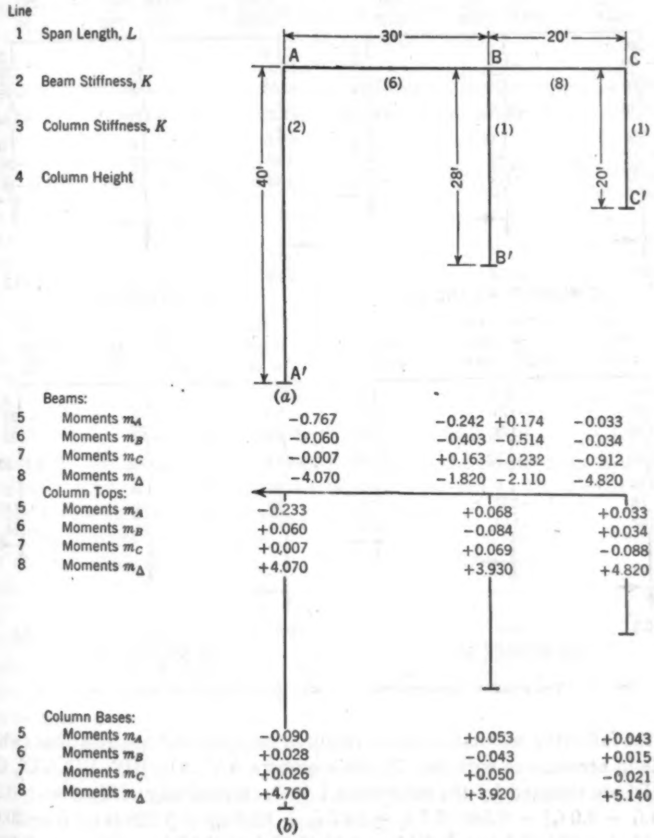

FIG. 3.—RIGID FRAME WITH UNEQUAL LEGS

Example 2. Rectangular Rigid Frame.—This problem requires the computation of the moment-stiffness relations for M_{BC} and $M_{A'A}$ for the loading arrangement in Fig. 2(*a*). The moments produced in the original structure by the horizontal force of 6 kips are shown in Fig. 2(*a*). All the moments in

Fig. 2(*a*) are also M'-moments. The fixed-end moments C are all zero, since there are no intermediate loads. The values of H' at the tops of the columns are written in line 5, Fig. 2(*a*).

The m-moments due to a unit couple at joints A, B, C, and D, respectively, are shown in Fig. 2(*b*). These moments have been corrected for sidesway. Fig. 2(*c*) gives the m-moments due to a unit horizontal force at the top of column AA'.

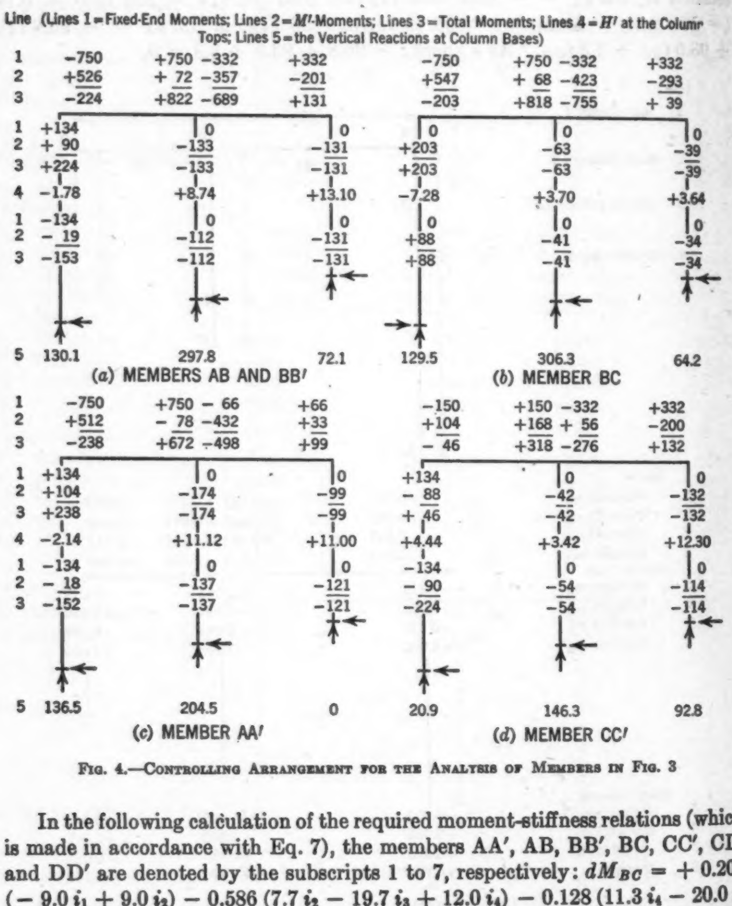

FIG. 4.—CONTROLLING ARRANGEMENT FOR THE ANALYSIS OF MEMBERS IN FIG. 3

In the following calculation of the required moment-stiffness relations (which is made in accordance with Eq. 7), the members AA', AB, BB', BC, CC', CD, and DD' are denoted by the subscripts 1 to 7, respectively: $dM_{BC} = +\,0.204\,(-\,9.0\,i_1 + 9.0\,i_2) - 0.586\,(7.7\,i_2 - 19.7\,i_3 + 12.0\,i_4) - 0.128\,(11.3\,i_4 - 20.0\,i_5 + 8.7\,i_6) + 0.034\,(9.5\,i_6 - 9.5\,i_7) - 2.00\,(0.95\,i_1 + 2.02\,i_3 + 2.04\,i_5 + 0.99\,i_7) + 12.0\,i_4$. Simplifying:

$$dM_{BC} = -\,3.7\,i_1 - 2.7\,i_2 + 7.5\,i_3 + 3.6\,i_4 - 1.5\,i_5 - 0.8\,i_6 - 2.3\,i_7 \quad \text{(8a)}$$

As a check: $-3.7 - 2.7 + 7.5 + 3.6 - 1.5 - 0.8 - 2.3 = +0.1$. Similarly:

$dM_{A'A} = -0.086\,(-9.0\,i_1 + 9.0\,i_2) + 0.028\,(7.7\,i_2 - 19.7\,i_3 + 12.0\,i_4) + 0.006\,(11.3\,i_4 - 20.0\,i_5 + 8.7\,i_6) + 0.015\,(9.5\,i_6 - 9.5\,i_7) + 1.66\,(0.95\,i_1 + 2.02\,i_3 + 2.04\,i_5 + 0.99\,i_7) - 10.0\,i_1$. Simplifying:

$$dM_{A'A} = -7.6\,i_1 - 0.6\,i_2 + 2.7\,i_3 + 0.4\,i_4 + 3.3\,i_5 + 0.2\,i_6 + 1.5\,i_7 \quad \text{..(8b)}$$

As a check to Eq. 8b: $-7.6 - 0.6 + 2.7 + 0.4 + 3.3 + 0.2 + 1.5 = -0.1$.

Example 3. Rigid Frame with Unequal Legs.—In Fig. 3(*a*), showing a bent with three legs of unequal length, it is required to calculate the moment-stiffness relation for M_{BA} when both spans carry a uniform dead load of 2 kips per ft and a uniform live load of 8 kips per ft, and the column AA′ (Fig. 3(*a*)) is subjected to uniform live load of 1 kip per ft.

Fig. 4(*a*) shows the fixed-end moments (lines 1), the M'-moments (lines 2), and the total moments (lines 3) and also the values of H' at the tops of the columns (lines 4). The *m*-moments, m_A, m_B, m_C, and m_Δ, are given in Fig. 3(*b*).

In the following calculation of the required moment-stiffness relation, by Eq. 7, the members AA′, AB, BB′, BC, and CC′ are denoted by the subscripts 1 to 5, respectively: $dM_{BA} = -0.242\,(90\,i_1 + 526\,i_2) - 0.403\,(72\,i_2 - 133\,i_3 - 357\,i_4) + 0.163\,(-201\,i_4 - 131\,i_5) - 1.82\,(-1.78\,i_1 + 8.74\,i_3 + 13.10\,i_5) + 72\,i_2$; which, simplified, becomes

$$dM_{BA} = -18.6\,i_1 - 84.4\,i_2 + 37.4\,i_3 + 110.8\,i_4 - 45.2\,i_5 \quad \text{........(9)}$$

As a check: $-18.6 - 84.4 + 37.4 + 110.8 - 45.2 = 0$.

The moment-stiffness relation in Eq. 9 is shown in tabular form in the first line of Table 1.

Example 4. Two-Span, Saw-Tooth Bent.—Calculate the moment-stiffness relations for M_{AB} and $M_{CC'}$, in Fig. 5(*a*), when the spans carry a uniformly distributed load of 1 kip per ft of horizontal projection. The analyses shown in Figs. 5 were obtained by alternate distributions of moments and shears. The procedure is briefly described in Appendix 2. Fig. 5(*a*) shows the fixed-end moments (lines 2), the M'-moments (lines 3), and the total moments (lines 4). The *m*-moments due to unit couples at joints A, B, C, D, and E are shown in Fig. 5(*b*), lines 5, 6, 7, 8, and 9, respectively. Fig. 5(*c*) gives the *m*-moments due to unit horizontal forces at points A, C, and E, indicated by $m_{\Delta A}$, $m_{\Delta C}$, and $m_{\Delta E}$ in lines 10, 11, and 12, respectively.

TABLE 1.—MOMENT-STIFFNESS RELATIONS

Moment	i_1	i_2	i_3	i_4	i_5
M_{BA}......	−18.6	− 84.4	+37.4	+110.8	−45.2
M_{BC}......	+50.8	+ 60.2	+24.6	−137.6	+ 1.4
$M_{AA'}$......	+71.0	−123.8	+34.8	− 25.8	+44.2
$M_{BB'}$......	− 0.8	+ 29.8	−87.4	+ 16.2	+42.4
$M_{CC'}$......	+18.4	+ 9.0	+15.0	+ 19.4	−61.2

The members AA′, AB, BC, CC′, CD, DE, and EE′ will be denoted by the subscripts 1 to 7, respectively. In the application of Eq. 7 to the structure of Fig. 5, the terms indicated by $\Sigma(H'_1\,i_1)\,\Sigma(H'_2\,i_2)$, etc., require particular attention. The horizontal end shears at joints A, C, and E must be kept in

(c) m-MOMENTS RESULTING FROM UNIT HORIZONTAL FORCES

FIG. 5.—TWO-SPAN, RIGID FRAME WITH A UNIFORMLY DISTRIBUTED LOAD OF 1 KIP PER FOOT ON SPANS

equilibrium: hence, at point A—

$$\Sigma(H'\,i) = -\frac{M'_{AA'} + M'_{A'A}}{h_1}\,i_1 + \frac{M'_{AB} + M'_{BA}}{h'_2}\,i_2 - \frac{M'_{BC} + M'_{CB}}{h'_3}\,i_3 \,.\,.\,(10a)$$

at point C—

$$\Sigma(H'\,i) = -\frac{M'_{AB} + M'_{BA}}{h'_2}\,i_2 + \frac{M'_{BC} + M'_{CB}}{h'_3}\,i_3 - \frac{M'_{CC'} + M'_{C'C}}{h_4}\,i_4 + \frac{M'_{CD} + M'_{DC}}{h'_5}\,i_5 - \frac{M'_{DE} + M'_{ED}}{h'_6}\,i_6 \ldots\ldots\ldots\ldots (10b)$$

and, at point E—

$$\Sigma(H'\,i) = -\frac{M'_{CD} + M'_{DC}}{h'_5}\,i_5 + \frac{M'_{DE} + M'_{ED}}{h'_6}\,i_6 - \frac{M'_{EE'} + M'_{E'E}}{h_7}\,i_7 \,.\,.\,(10c)$$

In Eqs. 10, h_1, h_4, and h_7 are the heights of the columns AA′, CC′, and EE′, respectively. The meanings of h'_2 and h'_3 are illustrated in Fig. 6; h'_5 and h'_6 in the right-hand span are analogous to h'_2 and h'_3 in the left-hand span, respectively. In Fig. 5, $h'_2 = h'_5 = 22.5$ ft, and $h'_3 = h'_6 = 45$ ft. The required moment-stiffness relations are then as follows: $dM_{AB} = -0.477\,(156\,i_1 - 123\,i_2) - 0.057\,(-101\,i_2 + 201\,i_3) - 0.089\,(92\,i_3 - 26\,i_4 - 166\,i_5) + 0.024\,(-98\,i_5 + 198\,i_6) - 0.030\,(34\,i_6 - 167\,i_7) - 6.24\,(-10.2\,i_1 - 10.0\,i_2 - 6.50\,i_3) - 1.31\,(10.0\,i_2 + 6.50\,i_3 + 0.83\,i_4 - 11.7\,i_5 - 5.17\,i_6) - 1.39\,(11.7\,i_5 + 5.17\,i_6 + 9.67\,i_7) - 123\,i_2$. Simplifying:

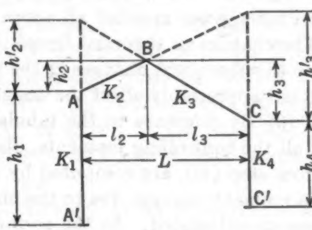

FIG. 6

$$dM_{AB} = -10.8\,i_1 - 9.3\,i_2 + 12.5\,i_3 + 1.2\,i_4 + 11.6\,i_5 + 3.3\,i_6 - 8.4\,i_7 \,.\,.\,(11a)$$

As a check: $-10.8 - 9.3 + 12.5 + 1.2 + 11.6 + 3.3 - 8.4 = +0.1$. Also, $dM_{CC'} = +0.221\,(156\,i_1 - 123\,i_2) + 0.063\,(-101\,i_2 + 201\,i_3) - 0.300\,(92\,i_3 - 26\,i_4 - 166\,i_5) - 0.004\,(-98\,i_5 + 198\,i_6) + 0.156\,(34\,i_6 - 167\,i_7) + 3.98\,(-10.2\,i_1 - 10.0\,i_2 - 6.50\,i_3) + 8.11\,(10.0\,i_2 + 6.50\,i_3 + 0.83\,i_4 - 11.7\,i_5 - 5.17\,i_6) + 4.01\,(11.7\,i_5 + 5.17\,i_6 + 9.67\,i_7) - 26\,i_4$. Again simplifying:

$$dM_{CC'} = -6.1\,i_1 + 7.7\,i_2 + 11.9\,i_3 - 11.5\,i_4 + 2.1\,i_5 - 16.8\,i_6 + 12.7\,i_7 \,.\,(11b)$$

As a check: $-6.1 + 7.7 + 11.9 - 11.5 + 2.1 - 16.8 + 12.7 = 0$.

APPLICATION TO DESIGN

The following outline, although subject to variation, should serve as a general guide in designing with the aid of moment-stiffness relations:

(1) The relative stiffnesses upon which the moment-stiffness relations are to be based are chosen carefully, or they are determined from a preliminary design. The structure thus obtained is called the "basic structure."

(2) The basic structure is analyzed to determine (a) the m-moments due to unit couples placed at successive joints; and (b) the m-moments due to unit

horizontal forces or shears corresponding to the various sidesway conditions existing in the structure. If sidesway conditions are present, correction for sidesway should be made in finding the former group of m-moments.

(3) Analyses of the basic structure are made to determine (*a*) the loading arrangements controlling the design of the various members; (*b*) the values of the corresponding controlling moments and axial forces; and (*c*) the M'-moments and values of H' needed for the evaluation of the moment-stiffness relations. The performance of these analyses is expedited by the use of the m-moments obtained in step (2).

(4) The members are designed for the controlling stresses obtained in step (3). The resulting stiffnesses of the members will be different, in general, from those of the basic structure. The stiffness-change ratio, i, or the change in stiffness divided by the stiffness assumed in the basic structure, is calculated for each member.

(5) Moment-stiffness relations corresponding to the various controlling moments are calculated, and are tabulated in such a way that the coefficients of i for a given member all appear in the same column, as shown in Table 1. (The changes in the axial forces in vertical or inclined compression members, due to subsequent changes in the stiffnesses of the various members, generally do not appreciably affect the design and therefore may usually be disregarded.)

(6) By reference to the tabulated moment-stiffness relations, the changes in all the controlling moments, due to a change of stiffness in a given member (from step (4)), are computed by a single setting of the slide rule. Similarly, the moment changes due to the changes in stiffness of the various other members are calculated. In the performance of this step the designer is rewarded for the labor of obtaining the moment-stiffness relations. With their aid, he is able not only to calculate, rapidly, the effects of any number of consecutive revisions in the design, but to form an advance estimate of the effects of contemplated revisions.

(7) The members are redesigned in accordance with the revised moments obtained in step (6), and the moment changes thus produced are again computed, as in step (6). This process is continued until no further changes in design are required. The stiffness-change ratios are always based upon the stiffnesses assumed in the basic structure.

Example 5.—The bent outlined in Fig. 3(*a*) is to be designed in steel in accordance with the 1936 specifications of the American Institute of Steel Construction (AISC) revised in 1941. The horizontal members carry a dead load of 2 kips per ft and a live load of 8 kips per ft. Provision is also to be made for a live load of 1 kip per ft applied uniformly to the side of column AA′. The weight of the columns will be neglected. The unsupported lengths of the columns are: AA′, 13½ ft; BB′, 14 ft; and CC′, 20 ft.

A description of the design procedure conforming to steps (1) to (7) is as follows:

(1) The basic structure and assumed stiffnesses are as shown in Fig. 3(*a*).

(2) The m-moments, m_A, m_B, m_C, and m_Δ are shown in Fig. 3(*b*).

(3a) Figs. 4 contain the analyses corresponding to the loading arrangements that were found to control the design of the members. In Fig. 4(a), the loading, which controls the design of members AB and BB′, consists of dead load plus live load on both spans, and lateral live load. In Fig. 4(b), the loading that controls the design of member BC consists of dead load plus live load on both spans, but no lateral live load. The loading in Fig. 4(c) consists of dead load plus live load on the left span, dead load on the right span, and lateral live load. This loading controls the design of member AA′. The loading in Fig. 4(d) consists of dead load on the left span, dead load plus live load on the right span, and lateral live load. This loading controls the design of member CC′.

(3b) and (3c) Figs. 4 show the fixed-end moments, the M'-moments, and the total moments, in the order named. These analyses were made with the aid of the m-moments shown in Fig. 3(b), utilizing relations A and B which were stated in connection with the development of Eq. 5b. The values of H' at the tops of the columns are entered in lines 4 in Figs. 4.

The controlling moments (M) and axial forces (F) are as follows: For member AB, $M = 822$ ft-kips (line 3); for member BB′, $M = 133$ ft-kips (line 3) and $F = 297.8$ kips (line 5), as shown in Fig. 4(a); for member BC, $M = 755$ ft-kips (line 3), as shown in Fig. 4(b); for member AA′, $M = 238$ ft-kips (line 3) and $F = 136.5$ kips (line 5), as shown in Fig. 4(c); and for member CC′, $M = 132$ ft-kips (line 3) and $F = 92.8$ kips (line 5), as shown in Fig. 4(d).

(4) The design calculations corresponding to step (4) are shown in the first cycle of Table 2. The data for the design of girders, Table 2(a), include: M, the required S, $K\,L$, I_o, I, i, the section selected, and the actual S. For member AB, the required S is $\frac{822 \times 12}{20} = 493$, which is provided by a 36-in. WF at 150 lb, with $S = 503$ and $I = 9{,}012$. For member BC, the required S is $\frac{755 \times 12}{20} = 453$, which is likewise provided by a 36-in. WF at 150 lb. For member AB, $I_o = I = 9{,}012$; hence, $i = 0$. The inertia moment I_o for the remaining members is found by multiplying this value of I_o by the ratio of the value of $K\,L$ for the member in question to the value of $K_{AB}\,L_{AB}$. Thus, for member BC, $I_o = \frac{160}{180}(9{,}012) = 8{,}011$; and therefore $i = \frac{9{,}012 - 8{,}011}{8{,}011} = +\,0.125$.

The data for the design of columns, Table 2(b), include F, M, $K\,L$, A_c, A_b, the total of $A_c + A_b$, A'_c, A'_b, the total of $A'_c + A'_b$, I_o, I, i, $L'/\bar{r}$, L'/b, the section selected, s_c, s_b, and the area provided. The columns are designed to resist, in addition to the axial force, (I) the moment at the top or bottom, or (II) 70% of the moment in case (I). In case (I), the required area is $A_c + A_b$. With allowable stresses of 17 kips per sq in. and 20 kips per sq in. for axial compression and bending, respectively, $A_c = \frac{F}{17}$ and $A_b = \frac{0.6\,M\,c}{\bar{r}^2_b}$. In case

(II), the required area is $A'_c + A'_b$, where $A'_c = \frac{F}{s_c}$ and $A'_b = \frac{14}{s_b} A_b$. Case (I) was found to control in each instance.

In the design of the columns some effort was made to conform with the relative stiffnesses assumed in Fig. 3(a), but the immediate objective was to obtain a design in which the area agreed closely with that required. With

reference to Table 2(*b*) (first cycle), for column AA′ the required area = 29.8 sq in.; $I_o = \frac{80}{180}$ (9,012) = 4,006; the area provided (18-in. WF at 105 lb) = 30.9 sq in.; I = 1,852; and $i = \frac{1{,}852 - 4{,}006}{4{,}006} = -0.54$. For column BB′, the required area = 29.7 sq in.; $I_o = \frac{28}{180}$ (9,012) = 1,400; the area provided (18-in. WF at 105 lb) = 30.9 sq in.; I = 1,852; and $i = \frac{1{,}852 - 1{,}400}{1{,}400}$ $= +0.323$. For column CC′, the required area = 20.5 sq in.; $I_o = \frac{20}{180}$ (9,012) = 1,001; the area provided (14-in. WF at 74 lb) = 21.7 sq in.; I = 797; and $i = \frac{797 - 1{,}001}{1{,}001} = -0.204$.

If subscripts 1 to 5 are used to refer to members AA′, AB, BB′, BC, and CC′, respectively, the stiffness-change ratios resulting from the first cycle of design are as follows: $i_1 = -0.54$; $i_2 = 0$; $i_3 = +0.323$; $i_4 = +0.125$; and $i_5 = -0.204$.

(5) Moment-stiffness relations are required: For M_{BA} and $M_{BB'}$, using values of M' and H' in Fig. 4(*a*); for M_{BC}, using values of M' and H' in Fig. 4(*b*); for $M_{AA'}$, using values of M' and H' in Fig. 4(*c*); and, for $M_{CC'}$, using values of M' and H' in Fig. 4(*d*). The calculation of the moment-stiffness relation for M_{BA} has already been explained in detail (see Example 3). The moment-stiffness relations for M_{BC}, $M_{AA'}$, $M_{BB'}$, and $M_{CC'}$ are calculated in a similar manner as shown in Table 1, together with the moment-stiffness relation for M_{BA}.

TABLE 3.—MOMENT CHANGES

(6) The calculated changes in the controlling moments are shown in Table 3. The original values of the moments are shown in Col. 1. Col. 2 contains the moment changes due to decreasing the stiffness of member AA′ by 54%

($i_1 = -0.54$). These moment changes were obtained by multiplying the coefficients of i_1, in Table 1, by -0.54. Cols. 3, 4, and 5, Table 3, which were calculated in a similar manner, show the remaining moment changes resulting from the first cycle of design, and Col. 6 shows the revised values of the moments. The values of F were assumed to remain essentially unchanged.

(7) In the second cycle of design, for which the calculations are shown in Table 2, the moments were revised after each change in section. For member AB, $M = 867.1$ ft-kips (Col. 6, Table 3), requiring a 36-in. WF at 160 lb, with $i_2 = +0.08$, which resulted in the moment changes and revised moments shown in Cols. 7 and 8, Table 3. For member BC, $M = 787.1$ ft-kips, and no change in design was required. For member AA′, $M = 188.6$ ft-kips, requiring an 18-in. WF at 96 lb, with $i_1 = -0.044$, which produced the moment changes and revised moments shown in Cols. 9 and 10, Table 3. For member BB′, $M = 165.0$ ft-kips, requiring an 18-in. WF at 114 lb, with $i_3 = +0.13$, and producing the moment changes and revised moments given in Cols. 11 and 12, Table 3. For member CC′, $M = 120.4$ ft-kips, requiring a 14-in. WF at 68 lb, with $i_5 = -0.073$, and producing the moment changes and revised moments given in Cols. 13 and 14 of Table 3.

Calculations for a third cycle of design, shown in Table 2, indicate that no additional changes were required.

For comparison with the values of F and M shown in the third cycle of Table 2, and in Col. 14, Table 3, the results of a direct final analysis were found to be as follows:

Member	F	M
AB	....	867
BC	....	796
AA′	133.7	184
BB′	302.7	176
CC′	93.6	113

Economy Studies

In the course of the foregoing design, alternate selections were available which, if adopted, would have resulted in a final design differing somewhat from that shown. Furthermore, it is to be expected that several designers, although adhering closely to the procedure herein described, but each starting with a different set of assumed stiffnesses, would obtain designs differing more or less from each other. In connection with an existing design there arises, therefore, the question of whether, by changing the stiffnesses of certain members, a saving can be effected in the total amount of main material. Such a saving may occur in two principal ways: First, a change in stiffness due to the substitution of a lighter member may be accompanied by a change in moment such that the resulting unit stresses in the lighter member may meet the requirements of the specifications, without producing overstress in the remaining members; and, second, it may be found possible to reduce the stresses in a given member (and thus to use a lighter member) by changing the stiffness of adjacent members, in addition to that of the member to be made lighter.

In the latter case, sometimes the weight per foot of a long member may be decreased with the aid of an increase in the weight per foot of an adjacent, shorter, member, with a resultant saving in total weight.

The writer's experience indicates that, in one or both of these ways, a saving of from approximately 3% to 6% of the total weight can frequently be obtained.

It does not appear practicable to formulate a fixed procedure for such investigations, except to state that it is essentially a matter of trial. Moment-stiffness relations are well suited to a rapid determination of the effects of various changes aimed at securing increased economy. In the foregoing example it is found, with the aid of the moment-stiffness relations in Table 1, that the member AA′ can be designed with a 24-in. WF section at 80 lb, with a saving of 640 lb, or about 4% of the total weight of the main members in the bent.

Conclusion

Experience indicates that moment-stiffness relations are useful aids in the design of continuous framed structures composed of prismatic members, particularly in cases where the columns are subject to moments of considerable magnitude. These relations also provide a basis for the determination of possible improvements in an existing design.

As differential quantities are only approximate representations of the true changes, the relative stiffnesses upon which the moment-stiffness relations are based should be chosen with some care, or determined from a preliminary design; and the final results should generally be checked by a direct analysis. It should be recognized that, in some instances, where large stiffness changes occur, the moment differentials will be subject to rather large errors; also, that, where only minor changes in stiffness occur, the use of moment-stiffness relations is not particularly advantageous unless subsequent economy studies are to be made.

APPENDIX 1. NOTATION

The following letter symbols, used in this paper and in its discussions, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials (ASA—Z10a—1932), prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932.

A = section area required for given design conditions:

- A_b = area for bending at a section with lateral support;
- A_c = area for axial compression at a section with lateral support (see Table 2);
- A'_b = area for bending at an unsupported section;
- A'_c = area for axial compression at an unsupported section;

b = width of a section;
C = fixed-end moment caused by loads between the ends of a member;
c = distance from the gravity axis of a member to the outer fiber in bending;
E = modulus of elasticity;
F = axial force that controls the design of a member;
H = horizontal shear at the end of a vertical or inclined member:
  H' = the difference between H and the fixed-end shear, Q (that is, $H' = H - Q$);
  H'' = horizontal shear correction resulting from a distribution of shears;
h = column heights; the length of the vertical projection of an inclined member; h' = the vertical distance from the bottom of one inclined member to the prolongation of the other inclined member in the same span (see Fig. 6);
I = rectangular moment of inertia of a member as designed; I_e = the moment of inertia of a member corresponding to the stiffness assumed in the basic structure (that is, I_e is proportional to $K\,L$);
i = the stiffness-change ratio of a member = $\frac{dK}{K}$;
K = the relative flexural stiffness, or the $\frac{E\,I}{L}$-value of a member, as assumed in the basic structure;
L = length of a given member:
  L' = unsupported length of a member;
  dL = relative horizontal displacement of the opposite ends of a given span;
l = length of the horizontal projection of an inclined member;
M = moment; moment at the end of a member that controls its design:
  M' = difference between M and C (that is, $M' = M - C$);
  M'' = the fixed-end moments created by horizontal displacements of column tops, visualized in balancing horizontal shears;
  δM = a change in moment resulting from the distribution of moments;
m = moment created by a unit couple applied at a place whose location is given by a subscript; that is, m_A is the moment caused by a unit couple at joint A and m_Δ is the moment created by a unit horizontal force that produces sidesway;
P = concentrated loads applied to various members of a structure;
Q = fixed-end horizontal shear due to loads between the ends of a vertical or inclined member, or the sum of the simple beam shear and the shear created by fixed-end moments; ΣQ is the sum of the fixed-end horizontal shears on a given joint or section and any external horizontal forces that may be acting on it;
$\bar{r}$ = least radius of gyration; $\bar{r}_b$ = radius of gyration in the plane of bending;

S = section modulus, I/c;
s = allowable unit stress at an unsupported section:
s_b = bending stress;
s_c = compressive stress;
V = vertical shear;
x = lever arm of a vertical load P from left support; x' = lever arm from right support (see Fig. 8);
y = vertical distance to a horizontal load P;
γ = side-thrust stiffness;
Δ = sidesway or displacement produced by a unit horizontal force; horizontal displacement of the top of a column;
κ = average rate of convergence;
ϕ = a linear function of the elastic deformations, given by the relation $H' = K\phi$; and
ψ = a linear function of the elastic deformations, given by the relation $M' = K\psi$.

APPENDIX 2. ANALYSIS OF MULTIPLE-SPAN PEAKED BENTS

Multiple-span, peaked, or saw-tooth bents may be analyzed with a fair degree of accuracy and facility by alternate distributions of moments and horizontal shears. (The distribution of joint forces was suggested by Hardy Cross, M. ASCE, in 1926, in a mimeographed treatise entitled "Statically Indeterminate Structures.") The procedure involves the following steps:

1. Compute fixed-end moments at all joints and balance by moment distribution, assuming that the joints are not displaced.
2. Compute the horizontal shears at the tops of the columns and at the ends of the spans and balance them by distribution to the columns and adjoining spans in proportion to the side-thrust stiffness of these units; by addition, find the resulting shear corrections.
3. Compute the fixed-end moments due to the shear corrections and displacements occurring in the preceding distribution of horizontal shears and balance by moment distribution, as before.
4. From the changes in the moments resulting from the preceding distribution of moments, compute the parts of the horizontal shears remaining to be balanced and balance them by horizontal shear distribution, as before.
5. Repeat steps 3 and 4 until the solution converges. Horizontal displacements and horizontal end shears are considered positive to the right.

The side-thrust stiffness of a column is defined as the horizontal force or shear which, applied at the top of the column, will produce a unit horizontal displacement, without rotation, of the top of the column. The side-thrust stiffness of a span (consisting of two inclined members) is defined as the horizontal force or shear required to produce unit relative horizontal displacement

of the ends of the span without rotation of the ends or of the peak joint. In other words, if the ends of the span are denoted by the letters A and C, and the peak joint by the letter B, the side-thrust stiffness of the span is the value of of one of the two equal and opposite horizontal forces or shears which, applied at points A and C, will produce a unit change in the length of the span, without rotation of the joints A, B, and C, and without any vertical movement of joints A and C.

The similarities between moment distribution and horizontal shear distribution as applied to multiple-span peaked bents are apparent from the following brief description of the two processes:

Item	Moment distribution	Horizontal shear distribution
1.	The joints are balanced consecutively with regard to moments.	The joints at the tops of the columns are balanced consecutively with regard to horizontal shears.
2.	In balancing a given joint the only joint movement permitted is the rotation of the joint in question.	In balancing the joints at the tops of columns the only joint movements permitted are a horizontal displacement of the joint in question, and a vertical and horizontal displacement of the peak joints in adjacent spans. The joints are not permitted to rotate.
3.	The unbalanced moment is distributed to the connecting members in proportion to their flexural stiffness or resistance to rotation.	The unbalanced horizontal shear is distributed to the column and adjacent spans in proportion to their side-thrust stiffness, or resistance to horizontal displacement.
4.	The balancing of the moments produces fixed-end moments, or carry-over moments, at the opposite ends of the members; hence, whenever the joints are all balanced individually, a new set of unbalanced moments arises from the carry-over moments.	The balancing of the horizontal shears produces horizontal shears, or carry-over shears, at the opposite ends of the adjoining spans; hence, whenever the joints at the tops of the columns are all balanced individually, a new set of unbalanced horizontal shears arises from the carry-over shears. (A shear correction applied at one end of a span produces an equal and opposite shear at the other end of the span.)
5.	To obtain a complete distribution the process of balancing and carrying over must be continued until the corrections become negligible.	To obtain a complete distribution the process of balancing and carrying over must be continued until the corrections become negligible. This process may be expedited by the summation of a series.

Item	Moment distribution	Horizontal shear distribution
6.	Before the second, or any subsequent, distribution of moments can be made it is necessary to compute the fixed-end moments produced by the displacements occurring in connection with a corresponding distribution of horizontal shears.	Before a distribution of horizontal shears can be made it is necessary to compute the horizontal shears, or parts of them, which are required to be balanced.
7.	These fixed-end moments (item 6) are computed by simple formulas obtained from a consideration of the elastic deformations (see Eqs. 19, 23*a*, and 23*b*, derived subsequently).	These quantities (item 6) are obtainable by statics (see Eqs. 12, 14, 15*a*, and 15*b*, derived subsequently).

In the computation of items 1 to 7, numerical subscripts are used to designate the various members; for example, in Fig. 6, the column AA′ is designated by the subscript 1; and members AB and BC, by the subscripts 2 and 3, respectively.

The horizontal shears required in the first distribution of shears are obtained (by statics) from the loads on the structure and from the moments resulting from the first distribution of moments. The horizontal shear at the top of a column AA′ is as follows (see Figs. 6 and 7):

$$H_{AA'} = -\frac{M_{AA'} + M_{A'A} + \Sigma(P\,y')}{h_1} \quad \ldots .(12)$$

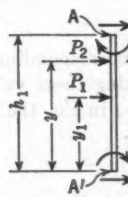

FIG. 7

Expressions for the horizontal shears at the lower ends of the inclined members are obtained by combining the equations of statics pertaining to the separate members and eliminating the unwanted horizontal and vertical forces. Thus, in Fig. 8 (involving vertical loads), by taking moments about points A and C:

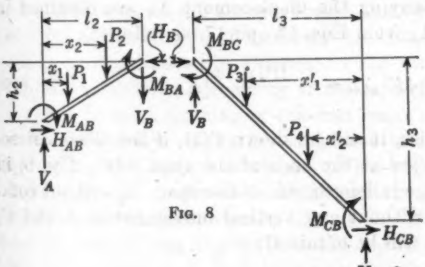

FIG. 8

$$M_{AB} + M_{BA} + V_B\,l_2 - H_B\,h_2 + \Sigma(P\,x) = 0 \quad ..(13a)$$

and

$$M_{BC} + M_{CB} + V_B\,l_3 + H_B\,h_3 - \Sigma(P\,x') = 0 \quad ..(13b)$$

Elimination of V_B and substitution from the relations $H_{AB} = -H_{CB} = H_B$ result in the following expression for the desired end shears:

$$H_{AB} = -H_{CB} = \frac{M_{AB} + M_{BA} + \Sigma(P\,x)}{h'_2} - \frac{M_{BC} + M_{CB} - \Sigma(P\,x')}{h'_3} \quad ..(14)$$

in which $h'_2 = h_2 + \frac{l_2}{l_3}\,h_3$ and $h'_3 = h_3 + \frac{l_3}{l_2}\,h_2$ (see Fig. 6).

Equations for the calculation of the parts of the horizontal shears required to be balanced in subsequent distributions of horizontal shears are obtained in a similar manner; then, however, the quantities $\Sigma(P\,y)$, $\Sigma(P\,x)$, and $\Sigma(P\,x')$ are zero. Therefore, the horizontal shears which require balancing at the end of the second, or of a subsequent, distribution of moments are given by:

$$H_{AA'} = -\frac{\delta M_{AA'} + \delta M_{A'A}}{h_1} \qquad \text{(15a)}$$

and

$$H_{AB} = -H_{CB} = \frac{\delta M_{AB} + \delta M_{BA}}{h'_2} - \frac{\delta M_{BC} + \delta M_{CB}}{h'_3} \qquad \text{(15b)}$$

in which $\delta M_{AA'}$, $\delta M_{A'A}$, δM_{AB}, etc., are the changes in moment resulting from the distribution of moments.

Consider now the side-thrust stiffnesses and the fixed-end moments produced by the displacements occurring in the distribution of shears. The fixed-end moments of the column in Fig. 7, produced by the displacement Δ_A, are

$$M''_{AA'} = M''_{A'A} = -\frac{6\,K_1}{h_1}\,\Delta_A \qquad \text{(16)}$$

The corresponding shear correction, denoted by $H''_{AA'}$, is obtained by substituting these values of $M''_{AA'}$ and $M''_{A'A}$ (Eq. 16) in place of $\delta M_{AA'}$ and $\delta M_{A'A}$ in Eq. 15a:

$$H''_{AA'} = \frac{12\,K_1}{h^2_1}\,\Delta_A \qquad \text{(17)}$$

The side-thrust stiffness of column AA′, found by placing $\Delta_A = 1$ in Eq. 17, is, therefore:

$$\gamma_{AA'} = \frac{12\,K_1}{h^2_1} \qquad \text{(18)}$$

The fixed-end moments accompanying the displacement Δ_A are obtained in terms of $H''_{AA'}$ by eliminating Δ_A from Eqs. 16 and 17, as follows:

$$M''_{AA'} = M''_{A'A} = -\frac{H''_{AA'}\,h_1}{2} \qquad \text{(19)}$$

By moment areas, or otherwise, it can be shown that, if the shear corrections, H''_{AB} and H''_{CB}, are applied at the ends of the span ABC, Fig. 6, in such a way as to produce a change in length, dL, of the span, L, without rotation of the joints A, B, C, and without any vertical movement of A and C, the following fixed-end moments will be obtained:

$$M''_{AB} = M''_{BA} = -\frac{6\,K_2}{h'_2}\,dL \qquad \text{(20a)}$$

and

$$M''_{BC} = M''_{CB} = +\frac{6\,K_3}{h'_3}\,dL \qquad \text{(20b)}$$

The corresponding shear corrections are obtained by substitution of these

values of M'' (Eqs. 20) in place of the values of δM in Eq. 15*b*:

$$H''_{AB} = -12\left[\frac{K_2}{(h'_2)^2} + \frac{K_3}{(h'_3)^2}\right] dL \qquad (21a)$$

and

$$H''_{CB} = +12\left[\frac{K_2}{(h'_2)^2} + \frac{K_3}{(h'_3)^2}\right] dL \qquad (21b)$$

The side-thrust stiffness of span ABC may be obtained by placing $dL = -1$ in Eq. 21*a* or by placing $dL = +1$ in Eq. 21*b*, giving

$$\gamma_{AC} = 12\left[\frac{K_2}{(h'_2)^2} + \frac{K_3}{(h'_3)^2}\right] \qquad (22)$$

The fixed-end moments accompanying the displacement dL are obtained in terms of the shear corrections, in the case of the member AB, by eliminating dL from Eqs. 20*a* and 21*a*, and, in the case of the member BC, by eliminating dL from Eqs. 20*b* and 21*b*, as follows:

$$M''_{AB} = M''_{BA} = \frac{H''_{BA}}{2}\,\frac{\dfrac{K_2}{h'_2}}{\dfrac{K_2}{(h'_2)^2} + \dfrac{K_3}{(h'_3)^2}} \qquad (23a)$$

and

$$M''_{BC} = M''_{CB} = \frac{H''_{CB}}{2}\,\frac{\dfrac{K_3}{h'_3}}{\dfrac{K_2}{(h'_2)^2} + \dfrac{K_3}{(h'_3)^2}} \qquad (23b)$$

Example 6.—Determine the bending moments at the ends of the members of the structure illustrated in Figs. 5(*a*) and 9(*a*), the loading consisting of 1 kip per ft of horizontal projection, uniformly distributed over both spans.

The relative flexural stiffnesses are shown in Fig. 9(*a*), and the relative side-thrust stiffnesses of the three columns and two spans are shown in Fig. 9(*b*). The fixed-end moments of members AB, BC, CD, and DE, due to the given loading, are distributed in Fig. 9(*a*).

The horizontal shears acting at the tops of the columns and at the ends of the spans at the beginning of the first shear distribution are shown in parentheses in Fig. 9(*b*). They are calculated in accordance with Eqs. 12 and 14. The unbalanced horizontal shears, or the algebraic sums of the quantities in parentheses, are written above the various joints in Fig. 9(*b*). The joints were balanced in the order A, E, and C. In the first cycle, the unbalanced shear of +29.54 kips at joint A is distributed to the column AA′ and the span ABC in proportion to their side-thrust stiffnesses—namely, 1.00 and 2.67—the corrections being −8.05 and −21.49, respectively. The unbalanced shear of −24.75 kips at joint E is distributed to the column EE′ and the span EDC in a like manner, the corrections being +6.74 and +18.01, respectively. Corrections assigned at one end of a given span are carried over to the other end with a change in sign; hence, at joint C, the unbalanced shear is + 0.28 + 21.49 − 18.01 = + 3.76 kips. This quantity is distributed to column CC′ and the

spans CBA and CDE in the proportions of 1.00, 2.67, and 2.67—the corrections being −0.59, −1.58, and −1.59, respectively. After the last two corrections are carried over to joints A and C, respectively, with change in sign, the second and third cycles of shear distribution are performed. The corrections

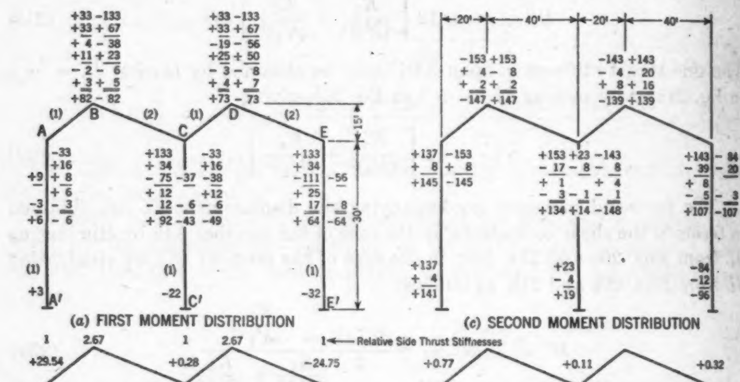

FIG. 9.—ANALYSIS OF MULTIPLE-SPAN PEAKED BENTS

now form geometric series, converging at approximately equal rates at the various joints. As the convergence is rather slow, a considerable saving in arithmetic may be made if the remainders are calculated.

The average rate of convergence, κ, may be found with sufficient precision by dividing the sum of the unbalanced shears (taken without regard to sign)

in the third cycle by the sum of the unbalanced shears in the second cycle. Hence, in the example, $\kappa = \dfrac{098 + 1.42 + 0.97}{1.58 + 2.31 + 1.59} = 0.613$. The remainders are summed by multiplying the results of the third cycle of distributions by $\dfrac{\kappa}{1 - \kappa} = \dfrac{0.613}{0.387} = 1.58$, and are designated by Σ in Fig. 9(*b*).

The total horizontal shear corrections are next found, by addition of each column of figures, exclusive of the quantities in parentheses; they are designated by H'' in Fig. 9(*b*). As a check on the shear distribution, the sum of values of H'' at a given joint should be equal and opposite to the original unbalanced shear. The sums in question are -29.54, -0.29, and $+24.75$. The fixed-end moments arising from the balancing of the horizontal shears are marked M'' in Fig. 9(*b*); they are calculated in accordance with Eqs. 19, 23*a*, and 23*b*.

The M''-values obtained in Fig. 9(*b*) are written as fixed-end moments in Fig. 9(*c*), and the joints are again balanced by moment distribution. The unbalanced horizontal shears are then calculated from the changes in the moments of Fig. 9(*c*), in accordance with Eqs. 15*a* and 15*b*, and are written in parentheses in Fig. 9(*d*). The calculations are as follows:

$$H_{AA'} = \frac{-12}{30} = -0.40 \text{ kip}; \quad H_{CC'} = \frac{+13}{30} = +0.43 \text{ kip};$$

$$H_{BB'} = \frac{+35}{30} = +1.17 \text{ kips};$$

$$H_{AB} = \frac{8+6}{22.5} - \frac{-6-19}{45} = +1.17 \text{ kips}; \quad H_{CB} = -1.17 \text{ kips};$$

$$H_{CD} = \frac{-5+4}{22.5} - \frac{-4-36}{45} = +0.85 \text{ kip}; \quad H_{ED} = -0.85 \text{ kip}.$$

The second shear distribution is shown in Fig. 9(*d*); the computations were made in the same way as those for the first shear distribution. The resulting fixed-end moments, marked M'' in Fig. 9(*d*), are balanced by moment distribution in Fig. 9(*e*). The solution is summarized in Fig. 9(*f*), the moments shown being the sums of the quantities appearing in Figs. 9(*a*), 9(*c*), and 9(*e*).

DISCUSSION

I. OESTERBLOM,[2] M. ASCE.—The idea expressed in the title of this paper is excellent; and the author promises a development that is much needed for a quick adjustment of moment schedules of a framework to which changes are made—particularly, in industrial construction where loads so often must be shifted and sections changed. It remains to be demonstrated that the paper fulfils that promise. The third paragraph of the "Synopsis" and the examples that follow it suggest that the author may have a broader scope in mind: A universal method as a convenient substitute for the Hardy Cross relaxation method.

An important truth appears in the statement (second paragraph of the "Synopsis") that

> "Since the moment at a given section in a continuous structure is a function of the stiffnesses of the various members, the differential of the moment (or moment differential) is a function of the differential changes in the stiffnesses."

but this statement will not help very much unless the functional relation between the moment and all the sections (or the functional relations between one section and all the moments) can be given a very simple and true expression. In view of this fact, both the culminating Eq. 7 and the first sentence of paragraph three in the "Synopsis" seem incongruous. The complex appearance of Eq. 7 is most repellent; and to establish the moment-stiffness relation independently would mean the application of a few cycles of relaxation to the entire frame for each unit couple or unit force. How utterly impossible this task is—in a commercial sense—is not apparent from the paper, which demonstrates only primitive frames; and it is seldom that an engineer is given such simple tasks. This is true for all the examples except the bents in the "Appendix."

Not only is Eq. 7 unattractive, but the question may also be asked: Is it correct? Professor Dell declares cautiously (last paragraph of the "Synopsis") that the "* * * differential quantities are only approximate representations of the true changes." If it is correct, is it useful? Possibly it is useful for design but not for the correction of moments. The basic formula, Eq. 1, was differentiated to the form

$$dM_{AB} = \Psi_{AB}\, dK_{AB} + K_{AB}\, d\Psi_{AB} \qquad (24)$$

—leading to Eq. 2. This differentiation is permissible only if the curves of the slowly changing values of K_{AB} and Ψ_{AB} can be given a functional expression in relation to one another or to a fourth variable. What Professor Dell has in mind, seemingly, is not this condition but a rather violent quantum variation of K_{AB}, and thus also of Ψ_{AB}; such a relation does not permit differentiation. It could be done, of course, if the functional relation had been expressed. The sequence of developments that follows, in the paper, is correspondingly suspect, and the superposition that leads to Eq. 7 is entirely out of order. Therefore,

[2] Engr., Carbide & Carbon Chemicals Corp., South Charleston, W. Va.

Eq. 7 represents mere approximation at best; and it may be seriously in error.

Assuming, however, that it is reasonably true; how useful is it? Can a moment at any point be found independently by taking advantage of the stiffness elements of the entire frame? Can moment corrections be applied at all points by the section adjustment at a few points? The profession will be grateful for Professor Dell's answer to this question, because it will have considerable economic significance.

An interesting challenge to test the paper would be its application to the example in Fig. 1, expanded to a three-span, seven-story frame with fixed foundations. Can the author write the moment-stiffness relations for all points of such a frame? This is the kind of frame an engineer encounters intermittently and quite often. Applying the Dell method, an analyst would have his choice (1) of computing all the nodal point moments (if this is what he needs in the design) or (2) of changing the size of three or more of the members in the frame (this is what often happens) and computing the changes to all the nodal point moments due to the change of size (if he prefers).

In the solution of any similar problem there is a fundamental difficulty. The moment at any point is not only an aggregate of superposed moment elements, but also—in a philosophical sense—a divergent series and a very unusual one, which is difficult to set up and quite impossible to integrate. It is fanlike and interwoven—fanlike, because it is a complex assortment of many subordinate series; and it is interwoven, because these subordinate series are intermittently associated with, and assisting, one another. At the same time each one converges separately toward zero.

Naturally, this concept is to be taken as a philosophical ideal only. It is doubtful if any one will ever be able to give definite mathematical expression to the accumulation of moments along their devious paths of approach; but the idea should be helpful nonetheless, both as a guide as to what still may be done and as a warning as to what should not be attempted. The history of kinetics is ample proof how true this is. The great pioneers—Clapeyron, Maxwell, Greene, Otto Mohr, Castigliano, Williot, Manderla, Fidler, Müller-Breslau, Ostenfeld—all made important contributions to theory and method; but they were limited in their applications to continuous beams or arches, and to simple frames.

A number of years ago, the writer had occasion to assign a similar problem to a colleague, distinguished for his grasp of all the advanced methods of structural analysis. The structure was a three-span, three-story, reinforced-concrete building with different spans and story heights and with concrete elements fully designed. There were different uniformly distributed floor loadings on each span, one load concentration on each of the three floors, and an applied wind load—in all possible combinations. The problem was to determine all the maximum dead-load and live-load moments at the nodal points and in the girders.

This colleague had the choice of any one of the classical methods available at that time (and he knew them all); but after three months of study he abandoned the problem as being beyond the reach of human effort.

It was only when the revolutionary method of relaxation was introduced by Hardy Cross,[3] M. ASCE, and R. V. Southwell[4] that one succeeded—with fair economy of labor and complete accuracy—in computing the moments in a really complicated modern frame. The reason why this method succeeded lies also in the underlying philosophy of the problem. By its progressive and alternate freezing and releasing of joints, the relaxation method superimposes a method that is synchronized to the difficulties of the problem; it is thus that the innumerable redundants, hidden in as many equations and set up in a hopeless matrix of determinants, are eliminated. There is only one of the earlier methods to which this does not apply: The graphical method by Fidler, later developed by Müller-Breslau for continuous beams and arches and by Strassner for continuous frames. This method also has given designers a device for mastering the difficulties, and it should be used more extensively.

The critical parts of this discussion are not directed to Professor Dell only; but to the many others who have tried to eclipse the Hardy Cross method by offering a better one. No doubt details of procedure can be improved upon; but until a definitely superior method is discovered, which fits the difficulties of the problem better than the relaxation method, it is mere waste of time and paper to try the impossible. Details of procedure can be improved: Many already have been offered and accepted by the profession. Those who aspire to be pioneers might be more successfully constructive if they worked along these lines and also with the comparatively unknown graphical solutions.

If Professor Dell merely intended to present a rough and approximate solution for simple frames the answer is that a one-cycle relaxation will do equally well; it will be just as rapid—if not more so. Two cycles will be required for heavy point loads only, especially if they are near the supports. Even the famous old equation offered by Clapeyron in 1857 would do as well; and in most such cases it would be better than Eq. 7 proposed by Professor Dell.

WILLIAM A. CONWELL,[5] M. ASCE.—The merit of this paper lies principally in the fact that it extends the theoretical horizon of moment distribution. Many engineers, faced with the prospect of repeated analyses of a problem by moment distribution, have cast about for a more direct method of obtaining results. Their search usually brought them into contact with a variety of equations which separated the designer's mind from the physical characteristics of the structure under consideration. Since "avoidance of such general equations was the object"[6] of moment distribution, the hunt usually ceased at the first encounter with algebra, and a quick retreat to moment-distribution fundamentals was effected. The author, however, was rewarded when he continued his probing after first discouragements. Although use of the moment-stiffness relations does involve formulas, these latter are intimately associated with the fundamental physical characteristic of the change in bending moments caused by a change in stiffness and, if only from this point of view, are worthy of study.

[5] Gen. Engr., Structural Eng. and Design Dept., Duquesne Light Co., Pittsburgh, Pa.

[6] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, *Transactions*, ASCE, Vol. 96, 1932, p. 141.

An inspection of Table 1 is enlightening in this regard. It will be noted, for instance, that a stiffness-change ratio, i_2, of 10% in member AB produces a change of -8.44 in M_{BA}; but an equal 10% stiffness-change ratio, i_4, in member BC produces a greater change, $+11.08$, in M_{BA}. Similarly, a 10% value of i_1 in member AA′ produces a change of $+7.10$ in $M_{AA'}$, which is less than the -12.38 change produced by a similar 10% value of i_2 in member AB. It is but another step to observe that the effect of a change in stiffness on a bending moment does not necessarily increase with the proximity of the member in which the stiffness change occurs. For example: A 10% value of i_1 in member AA′, the one most distant from member CC′, produces a change of $+1.84$ in $M_{CC'}$, which is almost as great as the $+1.94$ produced by a 10% value of i_4 in the adjacent member, BC. From the foregoing it may be readily concluded than a change in stiffness in one member cannot be made without the possibility of a profound effect on even the most distant members of the frame.

With a view to comparing a moment-stiffness analysis with a direct analysis, as regards amount of labor, rapidity of convergence, and other items, the writer designed the rigid frame of Examples 3 and 5, employing direct methods only. The third direct analysis—that is, the second after the original—produced the values given by the author in step (7), Example 5, as the results of his final direct analysis used to check the moment-stiffness method. The only variance of any significance in those data was in the 132.0 kips obtained for F in member AA′ as against 133.7 kips. Accordingly, in Table 4, the author's

TABLE 4.—COMPARISON OF RESULTS OF MOMENT-STIFFNESS AND DIRECT ANALYSES IN EXAMPLE 5

Type of Load	Member	First Cycle		Second Cycle				Third Cycle		
				Moment Stiffness		Direct		Moment Stiffness		Direct
		Value	Error, %	Value	Error, %	Value	Error, %	Value	Error, %	Value
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)
Axial	AA′	136.5	+2.1	136.5	+2.1	132	−1.3	136.5	+2.1	133.7
	BB′	297.8	−1.6	297.8	−1.6	303	−0.1	297.8	−1.6	302.7
	CC′	92.8	−0.9	92.8	−0.9	94	+0.4	92.8	−0.9	93.6
End moment	AB	822	−5.2	867.1	0	865	−0.2	869.3	+0.3	867
	BC	755	−5.1	787.1	−1.1	798	+0.3	786.2	−1.2	796
	AA′	238	+29.3	188.6	+2.5	192	+4.3	186.8	+1.5	184
	BB′	133	−24.4	165.0	−6.2	166	−5.7	179.4	+1.9	176
	CC′	132	+16.8	120.4	+6.5	120	+6.2	115.9	+2.6	113

values were used as the final correct figures, and the several stages of the two methods of analysis are compared with the final results. As may be seen, each successive cycle of the direct analysis steadily approaches the final figures. The second cycle of the moment-stiffness analysis compares favorably with that of the direct analysis; but the third cycle of the former is erratic, when compared to the complete conformance of the latter with the final results. The differences are, of course, small in magnitude, insufficient to produce changes in section, and easily explainable by the unusually great differences

between the stiffness of certain members in the final design and those in the basic structure.

As to the comparison of the amount of work, the direct method required four analyses for each cycle—one each for uniform loads on members AA', AB, and BC, and one for a horizontal load at the top of the frame—a total of twelve analyses. The moment-stiffness method initially requires four analyses, one each for moments m_A, m_B, m_C, and m_D. If the recommendation in the "Synopsis," that "the final results should generally be checked by direct analysis" is followed, four additional analyses will be required, making a total of eight. Between the initial and final analyses, the moment-stiffness method requires two series of substitutions in Eq. 7 for changes in the controlling moments in each member. A comparison of the methods in this instance would seem to indicate that the choice is between four direct analyses of the structure and ten substitutions in Eq. 7. Both methods require a certain amount of superposition and proportioning of analyses, but these would largely balance on the work ledger sheet. The decision as to method would probably be one of personal preference, since the labor involved appears to be about the same. Elimination of one condition of loading would throw the balance sharply in favor of the direct method as one less analysis would be required in each cycle, whereas the number of analyses for moment stiffness would remain the same. On the other hand, an additional condition of loading would not be as favorable to the moment-stiffness method since, in the direct method, use can be made of m_A, m_B, m_C, and m_D computed for each cycle and the number of analyses per cycle can be held to a maximum of four.

The second paragraph under step (4), Example 5, should be carefully followed in conjunction with Table 2 to be readily understood. However, the appreciation of designers is gained by calling attention to the check that the sum of coefficients of i in any expression for dM equals zero. Another valuable feature is the analysis of multiple-span peaked bents in "Appendix 2."

Finally, the author has exhibited a fine sense of balance in presenting the paper for what it is worth, allowing it to stand on its merits and making no claims that cannot be substantiated by a reading of the paper and practice in use of the methods.

GEORGE H. DELL,[7] ASSOC. M. ASCE.—Contrary to Mr. Oesterblom's inference, the moment-stiffness relations were not intended to provide a new method of analysis. They are but a means of calculating changes in the moments as the design is progressively modified and, therefore, are merely an auxiliary tool for use in connection with the moments obtained by one of the standard methods of analysis. In describing the use of moment-stiffness relations, the writer, far from trying to eclipse the Hardy Cross method by offering a better one, recommended and used the Cross method exclusively in the calculation of the moment-stiffness relations. A method cannot possibly be a "convenient substitute" for the Cross method when it relies on that method for its results.

[7] Asst. Prof., Civ. Eng., Univ. of Illinois, Urbana, Ill.

The use of moment-stiffness relations places no restrictions on the designer's choice of methods for analyzing the structure or for designing the members, but it does offer a means of calculating the moment changes with rapidity and with a degree of accuracy such that the resulting design is unlikely to contain errors of any consequence.

One of the advantages of using moment-stiffness relations, not previously mentioned, is that it is not necessary to calculate the revised moments in all parts of the structure for a given arrangement of loads, but only at points where the moments control the design of members. Another important advantage worthy of re-emphasis is that, in redesigning a given member, the effects of a proposed change in stiffness are immediately apparent from the moment-stiffness relation, and one is thus able to anticipate and obviate the danger that after the member is revised it will be more seriously stressed than before.

The true moment change that occurs as a result of revisions in the stiffnesses of any or all the members can be expressed in the form of a Taylor series. The writer doubts whether such an expression is what Mr. Oesterblom had in mind in stating that "It is doubtful if any one will ever be able to give definite mathematical expression to the accumulation of moments along their devious paths of approach * * *." It is more likely that he was referring to the problem of determining the maximum positive and negative moments in a structure, such as the three-story building described by him. Inasmuch as the paper (except for "Appendix 2") was not concerned primarily with methods of analysis, the introduction of this problem is beyond the scope of the paper. However, it seems evident that if separate analyses are made to determine the moments throughout the structure, as a result of loads applied to one member at a time, the signs will indicate which members should be loaded in order that the maximum moment may be obtained at a given point. A more difficult and equally pertinent problem is that of finding the particular combination of axial forces and moments that will produce the greatest stresses in the columns.

Mr. Oesterblom's difficulty in following the derivation of Eq. 7 may be clarified by reviewing the statement (in the paragraph containing Eq. 1) that ψ is a linear function of the elastic deformations, which, in turn, are functions of the stiffnesses of the various members. The moments can be determined uniquely by a system of linearly independent "slope-deflection" equations, regardless of the values of the stiffnesses, and hence the moment changes may be legitimately represented by a Taylor series development,[8] provided the series converges. Furthermore, since the independent variables (the K-values) occur linearly in the slope-deflection equations, it is entirely proper to apply the principle of superposition in the determination of the first-order moment changes, resulting from a series of successive changes in stiffness in the same member, or in different members. In addition, since the slope-deflection equations are linear, the moment changes of second, and higher, orders may similarly be obtained by superposition; that is, the terms of a higher order may be found by applying, to the basic structure, certain fixed-end moments obtained in solving for the terms of the preceding order. Thus, Eq. 2 can be rewritten as

[8] "The Effects of Errors or Variations in the Arbitrary Constants of Simultaneous Equations," by G. H. Dell, *Bulletin No. 309*, Univ. of Illinois Eng. Experiment Station, Urbana, Dec. 6, 1938, Sections 6, 7, and 18, and Appendix A.

follows:

$$dM_{AB} = M'_{AB}\, i_{AB} + \delta M'_{AB} \qquad (25)$$

Eq. 25 expresses the fact that the first-order moment changes are found by solving for the balancing moments, $\delta M'$, resulting from the fixed-end moments, $M'\, i$. It can be shown[9] that the second-order changes are given by:

$$\delta^2 M_{AB} = \delta M'_{AB}\, i_{AB} + \delta^2 M'_{AB} \qquad (26)$$

Eq. 26 expresses the fact that the second-order moment changes $\delta^2 M$ may be found by using the quantities $\delta M'\, i$ as fixed-end moments.

It does not appear feasible to establish a general criterion for the convergence of the series, and even if such a proof were available, it is necessary that the series converge rapidly in order that the moment change, given by Eq. 7, be reasonably accurate. For the purpose of indicating the rate of convergence of the series for a particular structure, the writer has computed the changes in the controlling moments of Example 5, up to and including the third-order increments, as shown in Table 5. It should be noted, in comparing these results with those of the final analysis as given originally, that there is a small uncertainty in the third or fourth significant figure in both instances, as a result of slide rule inaccuracies, differences in procedure, and small discrepancies in the values of the stiffnesses.

TABLE 5.—MOMENT CHANGES OF HIGHER ORDER, EXAMPLE 5

Symbol	Original moment	Moment Changes			Total moment
		First term	Second term	Third term	
M_{BA} ..	+822	+47.6	−2.59	−0.60	+866.4
M_{BC} ..	−755	−31.3	−7.90	−1.68	−795.9
$M_{AA'}$ ..	+238	−50.9	−2.76	−0.49	+183.8
$M_{BB'}$ ..	−133	−46.5	+4.06	−0.60	−176.1
$M_{CC'}$ ..	−132	+16.4	+0.76	+0.12	−114.7

Mr. Oesterblom asks: "Can a moment at any point be found independently by taking advantage of the stiffness elements of the entire frame?" It has been shown that the process of determining the moment changes by Eq. 7 is equivalent to performing an analysis of the basic structure to determine the moments resulting from the use of the $(M'\, i)$-quantities as fixed-end moments. From this it follows that all joints of the structure are balanced; in addition, all sidesway conditions are satisfied, so that, theoretically, all the moments are solved, although, as previously stated, it is necessary to compute only the ones that control the design of given members.

The next question—"Can moment corrections be applied at all points by the section adjustment at a few points?"—seems to indicate that Mr. Oesterblom has in mind a method of finding the changes in all the end moments due to a single stiffness change, rather than a method of finding the change in a particular moment because of changes in all the stiffnesses. The writer has treated such a method elsewhere;[9] it consists in applying to the basic structure the M'-moments of the member whose stiffness is changed, and finding the resulting moments throughout the structure. The latter values give the coefficients of the partial moment changes in the moment-stiffness relation.

[9] "Adjustments in the Design of Statically Indeterminate Structures," by G. H. Dell, thesis presented to the University of Illinois at Urbana, Ill., in May, 1943, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

Time and space do not permit a detailed description of the method in this closure; however, as it does not involve the use of m-moments, the procedure might be advantageous in the design of the three-span, seven-story structure which Mr. Oesterblom mentions in connection with the question, "Can the author write the moment-stiffness relations for all points of such a frame?" In further reply to the latter question, it should be noted: First, that there is seldom any need for the moment change at more than one point in a particular member; and, second, that Eq. 7, being perfectly general, will enable one to write the moment-stiffness relation for any of the end moments if the required moments, resulting from unit couples and unit horizontal forces, are known for the basic structure. Furthermore, if moment-stiffness relations are required for some intermediate point on the span, they may be obtained by a suitable combination of the moment-stiffness relations for the ends of the member.

It is regrettable that Mr. Oesterblom finds Eq. 7 complex, but it is not possible to formulate a general statement of the first-order moment changes without including all the factors involved. As a matter of fact, the complexity is a function, not of the equation, but of the structure itself. Doubtless, in an extensive structure, the magnitudes of a great many of the m-moments would be so small as to permit their omission from a particular moment-stiffness relation.

There is probably no advantage in using moment-stiffness relations in the design of continuous beams; the principal field for their application is in frames in which the columns are subjected to considerable moments and, consequently, where sidesway plays an important part. Therefore, the procedures recommended by Mr. Oesterblom as being superior (the application of one cycle of moment distribution, or the use of the equation of three moments) would be extremely inappropriate and inaccurate. In Example 5, the final moments (Table 3, Col. 14), in foot-kips, as given by one cycle of distribution are as follows: $M_{BA} = 817$; $M_{BC} = 803$; $M_{AA'} = 205$; $M_{BB'} = 46$; and $M_{CC'} = 25$. The errors are 5.7%, 0.9%, 11.4%, 74%, and 78%, respectively. By applying three cycles of distribution, which would be closely equivalent to using the equation of three moments, the corresponding moments are 821, 794, 231, 57, and 31, with errors of 5.3%, 0.2%, 25%, 67%, and 72%, respectively.

It is true that in cases where only minor revisions are involved in the design of a frame there is no need for moment-stiffness relations; however, it is not always possible to foretell whether a particular problem will involve difficulties. Where difficult situations do occur, moment-stiffness relations will be advantageous.

Mr. Conwell notes that in the frame of Example 5 a given end moment may be appreciably influenced by a change in stiffness of a remote member. This tendency would doubtless diminish in proportion to the number of spans and stories, so that terms with very small m-moments could be omitted from the moment-stiffness relations. He also calls attention to the value of the check afforded by the sum of the coefficients. In this connection, it is desirable that a proof be given of the statement that the sum of the coefficients in a complete moment-stiffness relation should be equal to zero. By making all the stiffness-

change ratios equal to a constant value, c, one obtains from Eq. 7:

$$dM_{AB} = c\,(m_{A,AB}\,\Sigma M'_{An} + m_{B,AB}\,\Sigma M'_{Bn} + \cdots + m_{\Delta 1,AB}\,\Sigma H'_1 + m_{\Delta 2,AB}\,\Sigma H'_2 + \cdots + M'_{AB}) \ldots\ldots (27a)$$

For equilibrium, at any point, J, $\Sigma C_{Jn} + \Sigma M'_{Jn} = 0$ and, for each sidesway condition, $\Sigma Q + \Sigma H' = 0$. The expression for dM_{AB} may then be written as follows:

$$dM_{AB} = -\,c\,(m_{A,AB}\,\Sigma C_{An} + m_{B,AB}\,\Sigma C_{Bn} + \cdots + m_{\Delta 1,AB}\,\Sigma Q_1 + m_{\Delta 2,AB}\,\Sigma Q_2 + \cdots - M'_{AB}) \ldots\ldots (27b)$$

By taking note of Eq. 5a it is seen that Eq. 27b thus reduces to:

$$dM_{AB} = -\,c\,(M'_{AB} - M'_{AB}) = 0 \ldots\ldots\ldots\ldots\ldots (27c)$$

The investigation reported by Mr. Conwell in Table 4, dealing with a comparison of designing by successive revisions and direct analyses and by use of moment-stiffness relations, constitutes a sincere and unprejudiced trial, for which the writer is duly appreciative. It tends to confirm the writer's view that, if a final check analysis is necessary, a very considerable length of time is required for frame analysis, whether moment-stiffness relations are used or not. If the final check analysis is omitted, the use of moment-stiffness relations should result in a material saving of time. It is the writer's opinion that moments obtained by means of moment-stiffness relations will seldom be in error by more than 5%. On the average, half the errors would be on the unsafe side and half, on the side of safety.

In the case of a column, whose required area depends on the direct stress as well as on the moment, the resulting percentage of error in cross section would be only a part of the error in the moment. In using rolled sections, excess area is usually provided; whereas, in concrete structures the sizes of the members are such that there may be considerable error involved in the usual practice of using the moment of inertia of a member all the way to the intersection of center lines. In view of these, and other, considerations it would appear that the omission of the final check analysis would have no serious consequences. In this connection, it may not be irrelevant to refer to the common practice of basing the design of members of a truss on the primary stresses, although secondary stresses of considerable magnitude are generally present, which are always additive to the effects of direct stress.

THRUST EXERTED BY EXPANDING ICE SHEET

BY EDWIN ROSE,[1] ESQ.

WITH DISCUSSION BY MESSRS. ERNEST BROWN, B. R. MCGRATH, ROBERT E. KENNEDY, AND EDWIN ROSE.

SYNOPSIS

Expansion of an ice sheet, as the result of a temperature rise after a cold wave, can develop considerable thrust against abutting structures. Design loads for this effect on dams and hydraulic structures have varied from no allowance to values of from 40 to 50 kips per lin ft. A study and analysis, conducted to obtain a rational procedure for estimating the magnitude of ice pressures, and a review of available material on the subject are presented in this paper.

By the application of experimentally determined ice temperature-pressure relationships, an analysis is made that yields the magnitude of pressures developed for the variables of ice thickness and the rate of rise of air temperature. The temperature rise that follows the absorption of solar radiation is considered in the study of pressures developed. The effect of conditions of restraint around the edges of the ice sheet is estimated. Thickness and buckling of ice sheets, extreme temperature variations occurring in nature, and field measurements of ice temperatures and pressures are discussed. An analysis is made, for comparison, of measured and computed pressures. Curves are given to provide a guide for the reduction in reservoir water elevation, allowing for the ice-thrust effect on existing dams subject to ice pressure but not designed for it.

It is concluded that design loads of from 40 to 50 kips per lin ft are too extreme and are not realized even under the most severe conditions. Results of analysis show pressures developed for the important factors of thickness, rate of increase in air temperature, lateral restraint, and solar energy absorption. These data are presented in graphical form to facilitate the selection and interpolation of values for design loads and indicate maximum probable ice thrusts for continental United States to range from 5 to 20 kips per lin ft.

NOTE.—Published in May, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

1. Introduction

In latitudes where severe winters prevail, a solid covering of ice forms on quiet surfaces of rivers and lakes. When such an ice sheet is subjected to a rise in temperature, the expansion of the ice causes the development of pressure against abutting structures. Able investigators (see Appendix) (1)(2)(3)(4)(5)(6)(7)[2] have conducted numerous difficult experiments and have obtained important data pertaining to the physical properties of ice, but the complexity of the problem is such that the magnitude of the thrust exerted by an expanding ice sheet cannot be predicted accurately. The variable nature of the load deformation and of the thermal expansion properties of ice makes this a difficult problem to analyze.

In the design of dams the consideration of ice pressure has varied from no allowance to values as high as 50 kips per lin ft (1)(2)(8). (The kip is 1 "kilo-pound"—that is, 1,000 lb.) The high estimates have been based on a crushing pressure of ice of about 400 lb per sq in. Assuming that this crushing pressure was realized at the upper surface and that no pressure was exerted at the lower surface, the total force developed, assuming linear variation within the ice sheet, was computed as 2,400 lb per in. of ice thickness per linear foot. For an 18-in. ice sheet, the thrust would amount to 43,200 lb per lin ft.

However, the peculiar plastic properties of ice, and the effects of incomplete restraint and limited temperature variations, make it seem unlikely that such high pressures would be realized, even under the most severe conditions. Experiments conducted by E. Brown and G. C. Clarke, M. ASCE (3), indicate that, because ice flows when it is loaded, considerable pressure can develop only if the temperature rise is rapid.

The simultaneous occurrence of critical conditions of the many variables required to produce any considerable ice pressure seems rather improbable. Nevertheless, experience has shown that such pressures can, and occasionally do, develop. The designer is interested in the maximum probable pressure likely to occur within the life of a particular structure, and the present study was conducted from this viewpoint. It is proposed to present a review and study of the material available on this subject and, by application of experimental data, to obtain a rational procedure for determining the magnitude of ice pressures on dams. Properties of ice are so variable and experimental and field data are so scarce that the results can be only an approximation of actual ice pressures.

The effect of expansion during the time that water is freezing is not considered, since it is not likely to be of practical importance. The thrust exerted by large fields of moving ice also is not discussed.

2. Plastic Properties of Ice

Ice is not an elastic solid; it behaves as a viscous solid, flowing under applied load—the extent of flow varying with time and temperature. The rate of yielding also changes with the structure of the ice and with the direction of loads according to the optical axes of the ice crystals. In the formation of an

[2] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (see Appendix).

ice sheet, the ice crystals are so oriented that the optical axes are normal to the freezing surface (4).

Values of the modulus of elasticity of ice have been determined by different investigators (1)(4)(6) and range from about 250 kips per sq in. to 1,400 kips per sq in. The variation in the time factor is the principal cause of the wide range of values. The maximum value cited (1,400) was determined by dynamic methods and is unaffected by progressive yielding (4). The modulus of elasticity is greater with lower temperatures and decreases as the applied load increases, and also as the loading time interval increases. Tests reported by the Joint Board of Engineers for the St. Lawrence Waterway (6) show plastic action under very small loads.

The applied load and the rate of applied load in the problem under consideration develop as a result of the rate of expansion of the ice sheet. Ice expands with increasing temperature and contracts with decreasing temperature. However, the coefficient of expansion of ice is also variable with different temperatures, increasing with increasing temperature. The mean linear coefficient of expansion is about 0.00003 per degree Fahrenheit.

The crushing strength of ice has generally been accepted as about 400 lb per sq in., but this also depends on the rate of loading and the temperature. The St. Lawrence Waterway tests (6) show a considerable increase in crushing strength as the temperature drops, values of 300, 693, and 811 lb per sq in. being recorded at temperatures of 28° F, 14° F, and 2° F, respectively.

3. Laboratory Data

In 1932 Messrs. Brown and Clarke presented (3) results of laboratory tests designed especially to secure data on pressures exerted by expanding ice. These were conducted on 3-in. cubical ice specimens placed between two loading blocks in a testing machine. The cube was oriented so that the pressures would act normal to the length, or optical axes, of crystals as under natural conditions. The specimens were subjected to controlled temperature changes and the force developed by the expanding ice was measured. From the results of the tests, Messrs. Brown and Clarke plotted a curve (3*a*) showing the nonlinear relation between the rate of change of temperature and the rate of change of pressure. Fig. 1 (mostly from data released by Messrs. Brown and Clarke (3)) shows that, as the rate of change of temperature increases, the rate of change of pressure increases at a greater than linear rate. The dotted part of the curve, indicating a slight extension beyond the Brown-Clarke experimental data, is based on results of tests on continuous

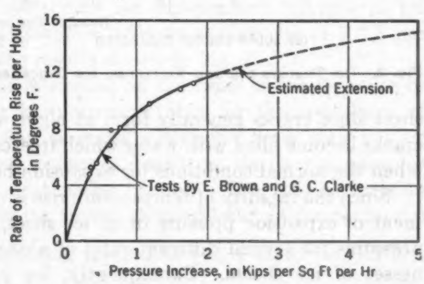

Fig. 1.—Pressure Change Resulting from Increases in the Temperature of Ice (Tests Conducted with No Lateral Restraint)

yielding of ice under sustained load given in the Report of the Joint Board of Engineers on St. Lawrence Waterway (6).

The importance of the time factor is indicated by these results—the greatest pressure change develops when the temperature rate of change is greatest. If temperature change in the ice is relatively rapid, the flow strain lags in relation to total strain, causing greater pressure to develop than occurs for the condition of slower temperature change. These experiments serve to verify previous tests and provide definite data on the magnitude of the forces occurring as a result of particular temperature changes.

4. Application of Experimental Data

As mentioned by Messrs. Brown and Clarke, the test conditions of their experiments are not entirely representative of field conditions of an expanding ice sheet: First because of the rate and extent to which a rise in air temperature will be felt through the ice sheet and, second, because of the effect of lateral restraint of the ice in a direction parallel to the dam. By estimating the maximum rate of air-temperature rise and the effect of lateral restraint, an analysis can be made that will give the maximum ice pressure for these conditions. Crack formation is assumed not to affect the continuity of the ice

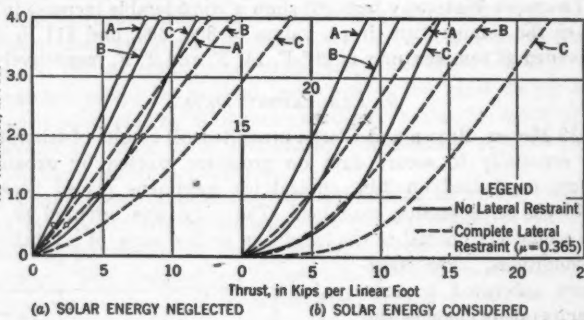

Fig. 2.—Ice Thrusts for the Variables, Ice Thickness, Air-Temperature Rise, and Restraint

sheet since cracks generally form at night when the ice has contracted. The cracks become filled with water which freezes to form a solid sheet at daybreak when the normal conditions for expansion begin.

Since the rapidity of temperature rise is of great importance in the development of expansion pressure in an ice sheet, it appeared desirable to compute pressures for several different rates of air-temperature rise and various thicknesses of ice sheets. Consequently, ice pressures were calculated for air-temperature rises of 5° F, 10° F, and 15° F per hr, for ice thicknesses as great as 4 ft. The results are shown in Fig. 2(*a*).

The assumptions used in this analysis were as follows:

1. The initial air temperature is − 40° F;

2. The initial ice temperature varies linearly from − 40° F at the air surface to + 32° F at the lower surface;

3. The air temperature changes at rates of $+5°$ F (curve A), $+10°$ F (curve B), and $+15°$ F (curve C) per hr, from $-40°$ F to $+32°$ F; then it remains constant at $+32°$ F until the temperature throughout the ice sheet has risen to about $+32°$ F;

4. Emissivity effects are neglected—that is, the temperature of the ice at the air surface is assumed the same as the air temperature itself;

5. The thickness of the ice sheet remains constant;

6. The diffusivity constant of ice, h^2, in feet² per hour, equals 0.0434 (4);

7. Poisson's ratio, μ (4), equals 0.365; and

8. Absorption of solar energy is neglected, consideration of this factor being treated subsequently.

The temperature gradients within the ice sheet are computed by the approximate method developed by E. Schmidt (9)(10)(11)(12). The ice sheet is considered divided into a finite number N of slabs having equal thickness increments, ΔL equals L/N, normal to the surface. The time interval Δt in hours and the space intervals ΔL in feet are selected so that:

$$\frac{(\Delta L)^2}{2\,h^2\,\Delta t} = 1 \qquad (1)$$

If θ_p, θ_q, and θ_r are temperatures at the beginning of the time interval Δt of three successive points, p, q, and r, distances ΔL apart, then

$$\theta'_q = \tfrac{1}{2}\,(\theta_p + \theta_r) \qquad (2)$$

in which θ'_q is the temperature of point q at the end of the time interval Δt.

From the temperature gradients in the ice sheet thus computed, the pressures at various depths developed are determined from Fig. 1. The total load per linear foot of structure can then be computed by summation across the depth of the ice sheet. Loads are plotted for various depths of ice sheets in Fig. 2(a). A maximum pressure of about 11.8 kips per lin ft is indicated for the 4-ft ice sheet for no lateral restraint. An independent analysis of ice pressure, by B. R. McGrath for an assumed air-temperature rise of 10° F per hr, gave a good comparison with the results shown in Fig. 2(a).

The effect of lateral restraint is estimated on the basis of the behavior of an elastic slab. Elastic behavior is approached only for the conditions of very rapid strain changes when flow is small. Poisson's ratio may not be applicable for flow conditions, but pressures based on elastic behavior for restraint conditions will give the most severe loading. The ratio of increase in stress for complete lateral restraint to the stress developed for no lateral restraint is given by $\frac{\mu}{1-\mu}$. Assuming $\mu = 0.365$ (4), a factor of 0.575 is obtained for the increase in ice thrust resulting from complete restraint. The values computed for no lateral restraint are increased by this factor and are plotted as dashed curves in Fig. 2(a). These curves represent the upper limit or extreme pressures for the assumed conditions. The maximum pressure for complete lateral restraint for the 4-ft ice sheet is shown as approximately 18.5 kips per lin ft.

Although the curve in Fig. 1 cannot be applied for more rapid temperature rises, rough estimates of pressures were made for extreme cases with rises of 20° F and 72° F per hr. Thrusts per linear foot of ice sheet 1 ft thick amounted to about 8 kips and 15 kips, respectively, for no lateral restraint and to about 12.5 kips and 24 kips, respectively, for full lateral restraint for the 20° F and the 72° F rise. A 4-ft ice sheet is estimated to exert a thrust of from about 15 kips for no lateral restraint to 24 kips for full lateral restraint for the assumed 20° F per hr of air-temperature rise.

5. Solar Radiation Considerations

When the ice sheet is free of snow and exposed to sunlight, its temperature may have an added increment of increase by solar radiation, quite apart from the change caused by an increase in air temperature. Some increase in ice pressure may be anticipated because of absorption of solar energy.

The magnitudes of ice thrusts are computed to include the solar energy effects for the same conditions assumed in the preparation of the data presented in Section 4. The following additional assumptions were made for inclusion of solar radiation:

9. The latitude is 40°;

10. The vernal equinox is considered as the time limit for the formation of clear solid ice of considerable thickness;

11. An atmospheric transmission constant (13)(14) of 0.9 is based on a clear atmosphere of low humidity at a fairly high elevation for continental United States; and

12. A coefficient of heat transfer (9) of 2 Btu per sq ft per hr per degree Fahrenheit is assumed to allow for surface losses of the absorbed solar energy.

For these assumed conditions, the solar energy that reaches the surface of the ice sheet during midday is then about 250 Btu per sq ft per hr. N. E. Dorsey (4) states that, in the visible spectrum, the absorptivity of ice is small but that, beyond a wave length of one micron, it is great and analogous to water. Consequently, about 40% of the solar energy reaching the surface, essentially all that of wave length greater than one micron, is absorbed within 4 in. of the surface. For a clear ice sheet, 1 ft thick, an additional 15% of the energy is absorbed whereas, for a 4-ft thickness, this additional absorption amounts to about 25%. Most of the remainder of the energy is transmitted although a small percentage is reflected.

The results of this analysis, shown in Fig. 2(*b*), indicate that the absorption of solar energy may produce a considerable increase in thrust above that caused by the rise of the air temperature only. This analysis is believed based on severe assumptions, and therefore the results represent a reasonable estimate of the maximum value of ice thrust. A maximum pressure of about 14.2 kips per lin ft is shown in Fig. 2(*b*) for the 4-ft ice sheet with no lateral restraint and with an air-temperature rise of 15° F per hr. This value represents about a 20% increase in the corresponding pressure developed, neglecting solar energy. For the thinner ice sheets, the percentage of pressure increase

to be expected with the inclusion of solar effects is higher, as shown by comparison of Figs. 2(*a*) and 2(*b*). Factors that influence the degree to which solar energy will affect the temperature and pressure changes in the ice sheet include: The sun's altitude, cloudiness, elevation above sea level, sky radiation, atmospheric transmission losses, clearness of ice, wind velocity, and losses due to convection, conduction, back radiation, and evaporation.

Records obtained at reservoirs controlled by the Bureau of Reclamation, United States Department of the Interior (USBR), show cases in which the ice sheet does not freeze solidly to the structure but is separated from the dam by a film of water or by unsound or rotten ice. Similar conditions often exist around the edges of a reservoir, in which case restraint is very limited. Factors which may contribute to this condition are exposure of the upstream face of a dam to direct sunlight and heat stored in a massive concrete structure. Under such conditions, when the ice adjacent to the dam is melted, rotten, or slushy, the thrust transmitted to the dam is insignificant.

If the upstream face of the dam is in the shade so that the ice sheet is likely to be well frozen to the dam and if a similar condition exists around the shore in the near vicinity of the dam, but a considerable area of the central part of the ice is exposed to the sun's radiation, then a condition probably exists favorable to the development of an increase in pressure against the dam as a result of solar energy absorption.

6. Field Data on Ice Pressures

The late William Cain, M. ASCE, cited a case (1) of the field measurement of ice pressure in which expanding ice between two bridge abutments 90 ft apart caused the surface to arch the ice 3 ft above its original level, developing a thrust of 21 kips for a 12-in. ice sheet. This value presumably represents thrust per linear foot although the reference (1) does not state specifically. Computation by the thin cylinder formula gives 20 kips per sq ft for this pressure. Another case of record (1) is that by Duncan MacPherson concerning a bridge pier subjected to ice pressure on one side only. The thrust of ice in this case was given as 18 kips per lin ft for a 12-in. ice sheet. At Keokuk, Iowa, a gate structure was broken by the thrust of an expanding ice sheet. This thrust, even though partly relieved by round-nose piers above the broken gate, exceeded 7.4 kips per lin ft (15).

Ice pressures and ice temperatures were measured at the Hastings Lock and Dam on the Mississippi River in Minnesota during the winter of 1932–1933. An account of these measurements (5) was given by H. M. Hill, M. ASCE. Simultaneous records of pressures and temperatures were obtained for a period of several days.

Measurements were taken at two different locations and by two different methods. In the first method, a simple beam of two 10-in. channel sections was placed in the plane of the ice sheet supported against the guide wall of the lock at the west side of the river. The beam was calibrated in a testing machine prior to its use, and the deflections were read by a micrometer with an electrical contact. This beam was set in place so as to measure the pressure exerted laterally—that is, normal to the direction of flow of the river.

Ice pressures were also determined in the upstream-downstream direction by strain measurements in the principal upper members of the Tainter gate near the central part of the dam. The pressure was determined directly from the stress-strain relation and the horizontal component of the strain measurement in the members. The gate framing is complicated, and a more exact determination of pressure would have necessitated strain measurements in all members of the gate. However, the strains in the top member provided guides to the intensity of ice pressure.

Ice temperatures at depths of 6 in., 12 in., and 15 in. in the 18-in. ice sheet were recorded at a point in the shade near the test beam. No ice temperatures were measured at the Tainter gate. There was a 2-in. cover of snow on the ice sheet during the period of measurement.

The maximum pressure measured at the beam was about 1.4 kips per lin ft and that at the Tainter gate was about 4 kips per lin ft. Factors that might have caused a larger pressure to exist at the gate are: (*a*) Increased thickness of ice sheet at the gate, (*b*) the downstream drag of the current on underside of the ice, and (*c*) the effect of arch action across those gates, which were open and through which water was discharging, causing a concentration of thrust at the gates that were frozen. The method of pressure measurement probably was not as accurate at the Tainter gate as at the beam.

Measured data at Hastings Dam indicate that pressure developed as the result of a rise in temperature in the subzero region will not be as great as that resulting from a similar temperature change above zero.

7. Comparison of Measured and Computed Values

The period of the most rapid temperature rise reported by Mr. Hill at the Hastings Dam (5) is selected for study. For the 23-hr period from midnight, January 17, to 11 p.m., January 18, the temperature rose from 10° F to 32.5° F. By applying the experimental temperature-pressure data of Messrs. Brown and Clarke to the temperature change actually recorded in the ice sheet during this period, pressure changes are computed to provide a check on the pressure changes determined from deflection and strain measurements over this same period.

A comparison of the measured ice-thrust changes (in pounds per linear foot) with those computed from the measured ice-temperature data is as follows:

Description	Thrust
Computed Thrust Change:	
No lateral restraint	695
Complete lateral restraint (Poisson's ratio assumed as 0.365)	904
Measured Thrust Change:	
At the test beam	890
At the Tainter gate	3,500

The record of temperature change indicated 1.538° F per hr for 13 hours, followed by 0.250° F per hr for 10 hours. Inspection of these values discloses that the computed change in ice thrust, with complete lateral restraint (904 lb

per ft) provides a close check on the measured value at the beam (890 lb per ft). However, it is not likely that lateral restraint was complete at this location. Therefore, an intermediate value between no lateral restraint and complete lateral restraint may be a more logical one for comparison and would give a slight increase in measured value over the computed value.

The measured thrust at the Tainter gate (3,500 lb per ft) is very high compared with that computed for complete restraint, but this unusually large value may be charged, at least partly, to the factors in Section 6. The uncertainty of the effect of these various factors scarcely justifies a quantitative comparison of measured values at the Tainter gates. However, the actual pressures developed at this location may be higher than those computed from the temperature-pressure data in Fig. 1.

8. Extremes in Air-Temperature Rise

Since the development of high ice pressures is a function of the rapidity of air-temperature rise, some study was made of the literature to determine the extent of extreme variations occurring in nature. Rapid air-temperature rises are not uncommon in regions where chinook winds occur.

Some extremely rapid values of temperature rise from low temperatures have been recorded at Havre, Mont., including one case of a rise of 27° F in 5 min. One of the most remarkable temperature fluctuations on record (16) occurred in the Black Hills region of South Dakota in January, 1943, after a severe cold wave in which low temperatures of − 40° F were recorded. The temperature at Rapid City, N. Dak., was characterized by alternating rapid rises and drops, such as a rise of 32° F in 4 min, followed by a drop of 22° F in 3 min, and then by another rise of 36° F in 5 min. The interval between these periods of extreme changes was usually less than an hour. After several cycles of this type of variation, the temperature remained stationary above freezing. An extreme rise of 49° F from − 4° F to + 45° F was recorded in 2 min at Spearfish, S. Dak., during this same period. Earlier Black Hills records include a number of similar fluctuations but none of such phenomenal rapidity.

These records indicate that very rapid temperature rises do occur in nature. Although the cases cited are extremes, it is not unreasonable, in certain localities where chinooks are common, to expect rapid temperature rises from subzero temperature to above the freezing point at rates of the order of 5° F to 15° F per hr. A sustained temperature rise for several hours at a rate approaching 5° F per hr might reasonably occur in almost any region of subzero winter temperatures.

9. Consideration of Buckling of an Ice Sheet

In an elastic-slab analysis (17), G. Albenga indicates that an ice sheet would buckle long before the high pressures sometimes considered could develop. He assumes that the ice sheet is in a rectangular basin and considers it as an elastic slab, simply supported at the boundary, and computes the critical pressure applied at the edges at which buckling will occur. A critical

value of about 16 kips per lin ft is obtained for an ice sheet about 20 in. thick in a square basin about 165 ft on a side.

In an unpublished memorandum on this subject, R. E. Glover states that Mr. Albenga has neglected the stabilizing effects of flotation forces on the slab. An analysis including these effects is then made and the results, when adjusted to the same modulus of elasticity used in Mr. Albenga's analysis, give a critical pressure of about 35.4 kips per lin ft.

At this point, the reefs or pressure ridges formed on northern lakes by the expansion and buckling of an ice sheet might be mentioned. Records indicate that reefs form in a warm period preceded by a very cold one and that generally the ice is free or nearly free of snow (7). The fact that pressure ridges usually form when there is little or no snow cover on the ice indicates that the lack of snow permits more rapid diffusion of surface heat throughout the ice with a consequent development of higher ice pressure. The thermal conductivity of snow, especially if it is fresh loose snow, is considerably lower than that of ice; therefore, it acts as an insulator. Pressure ridges seldom occur when the ice is thicker than 1 ft although they are known to have formed with the ice 20 in. thick. This phenomenon might be interpreted as indicating that, for ice sheets less than 1 ft thick, the critical buckling load is the limiting factor governing the ice pressure on a dam, whereas, for very thick ice sheets (about 2 ft or more), the crushing strength or pressure developed before appreciable flow would be the limiting factor.

10. Thickness of Ice Sheets

Although the air temperature is a factor that controls the rate of freezing of an ice sheet, actual thicknesses developed are dependent on local conditions of cloudiness, exposure to direct sunlight, snow cover, radiation, wind, water currents, latitude, and elevation.

Unpublished studies, by R. E. Kennedy, M. ASCE, of ice thicknesses on reservoirs of USBR projects indicate the occurrence of a maximum thickness of about 2.5 ft during the 4-yr period of record. Although these data are obtained for the latitude range of continental United States, greater thicknesses do occur in this country, and ice sheets more than 5 ft thick have been measured in Russia (18) and northern Canada (6).

The data recorded for the USBR projects also reveal that considerably greater ice thickness develops at places that are free of snow as compared to the snow-covered parts of the ice sheet a short distance away. This is in accord with expectations, but the extent of the variation in thickness is sometimes considerable. For example, on one reservoir, two measurements were taken approximately 60 ft apart, and the only factor that could be noted as contributing to the difference in ice thickness was a snow cover of 6 in. at the one point with no snow at the other. The ice thickness, relatively early in the winter period, was 9 in. at the former location, compared with 23 in. at the point of zero snow cover. Later, during the winter, the thicknesses at these two places approached uniformity as the result of continued cold weather and the drifting of snow. High winds sometimes keep the ice surface relatively free of snow, even after a considerable snowfall.

11. Reduction in Water Level to Compensate for Ice Thrust

At an existing dam, designed with no allowance for ice pressure, the following procedure may be used to provide safety against expanding ice. Generally all dams are designed for the full reservoir condition with the water surface at or very near the top of dam. It would be possible to compensate for the effect of an ice thrust by lowering the reservoir level during the season when ice pressures may exist, so that the total load at the critical section would not be larger than for the full reservoir condition.

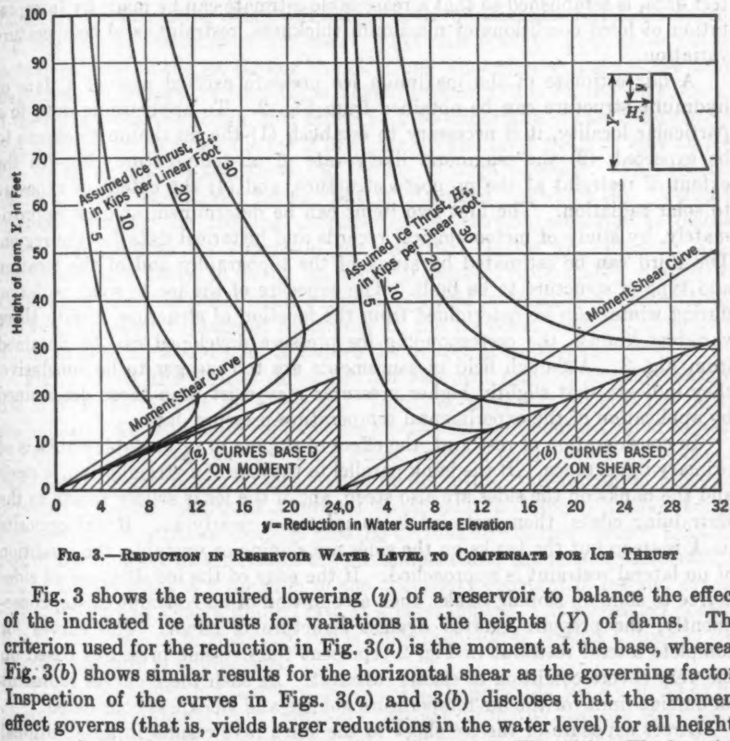

Fig. 3.—Reduction in Reservoir Water Level to Compensate for Ice Thrust

Fig. 3 shows the required lowering (y) of a reservoir to balance the effect of the indicated ice thrusts for variations in the heights (Y) of dams. The criterion used for the reduction in Fig. 3(a) is the moment at the base, whereas Fig. 3(b) shows similar results for the horizontal shear as the governing factor. Inspection of the curves in Figs. 3(a) and 3(b) discloses that the moment effect governs (that is, yields larger reductions in the water level) for all heights greater than those at the maximum points of curves in Fig. 3(a). The location above which moment governs and below which shear governs is shown by the indicated lines marked "moment-shear line" in Figs. 3(a) and 3(b). The base of a dam is ordinarily the critical section, but the curves can be applied to any other elevation by considering the height above the elevation in question. The curves are applicable to the gravity-type dam in which the load is transferred vertically downward to the foundation.

The curves indicate that, in the case of high dams, the ice thrust (H_i) is of relatively minor importance in its effect on forces at the base of the section, whereas for low dams it is of considerable importance. For high dams, it

should be borne in mind that an elevation at, say, midheight, might give a condition more severe than the base elevation, even though the latter is the location of maximum stress for full reservoir. Complete consideration of this factor requires actual stress and stability analyses.

12. Conclusions

In regard to the magnitude of ice pressures against dams, design loads of from 40 to 50 kips per lin ft appear to be too severe. A general guide for the determination of design loads, based on analysis applying available laboratory test data, is established so that a reasonable estimate can be made by interpretation of local conditions of maximum thickness, restraint, and temperature variation.

A fair estimate of the maximum ice pressure exerted against a dam or hydraulic structure can be obtained from Fig. 2. To apply these data to a particular locality, it is necessary to establish (1) the maximum thickness to be expected, (2) the maximum likely rate of air-temperature rise, (3) the extent of restraint at the proposed structure, and (4) the extent of exposure to solar radiation. The first two items can be determined, at least approximately, by study of meteorological records and historical data for the region. The third can be estimated by study of the topography and of the location and type of structure to be built. The exposure of the ice to solar radiation during winter can be determined from the location of structure. With these variables known, the corresponding ice pressure developed can be obtained from Fig. 2. Although field measurements are too meager to be conclusive, they indicate that slightly higher pressures may exist than those determined by application of the experimental temperature-pressure data.

In consideration of restraint, the effect of sloping or of unstable banks is of primary importance. If the bank parallel to the axis of a straight dam is steep and the banks on the sides are also steep, and if the ice is solidly frozen to the restraining edges, then restraint is complete, or nearly so. If the opposite bank is steep but the banks on the sides are sloping or unstable, the condition of no lateral restraint is approached. If the edge of the ice sheet on all sides is free to slide up sloping banks, then a condition of no restraint exists; consequently, the pressure exerted against structure is minor. The curves for complete lateral restraint in Fig. 2 represent the extreme pressures based on the very severe condition of elastic restraint. As such these curves represent an outside limit for the air-temperature change and thickness considered.

Direct exposure of the ice sheet to the sun's rays results in an additional ice-temperature rise and the transmission of increased thrust to the dam. If sound ice is frozen solidly to the dam and a large part of the ice sheet is exposed to the sun's rays, an allowance for ice pressure can be determined from Fig. 2(*b*). Comparison of results shown in Figs. 2(*a*) and 2(*b*), considering no lateral restraint, reveals that inclusion of solar energy causes increases in ice pressures of from about 10% to 65%. This inclusion of solar energy is based on the severe assumptions of 40° latitude and the time of the vernal equinox.

Before making a definite selection of the value obtained by use of Fig. 2 as the design load, consideration should also be given the following factors which may dictate some modification or special study:

1. The drag of current under an ice sheet, especially in regard to river ice;
2. Snow cover on the ice sheet;
3. The action of wind;
4. Confinement of ice in a location where volume expansion during the freezing process may cause damage; and
5. Fluctuation in reservoir water-surface elevation.

The drag of the current beneath an ice sheet (factor 1) is particularly important in regard to river ice. If continuous snow cover can be assumed (factor 2), the insulating effect will reduce both the thickness of ice developed and the rate of ice-temperature rise. Wind will tend to keep snow cover from remaining on the ice (factor 3). A strong wind blowing toward the dam may cause an increase in thrust due to skin-friction action on the ice surface. If the ice is broken or rough, this action may be important. This is especially true during periods when the ice is breaking up and large fields of moving ice may be piling against structures and forcing through passages. This special problem is not considered herein, but is discussed elsewhere (8). Volume expansion during the freezing process creates extreme pressures at places where opportunities for expansion are restricted (factor 4); but such conditions are not likely to occur in rivers or lakes. Appreciable change in elevation of reservoir water surface (factor 5) would be likely to cause bending, cracking, or other rupture of continuity of the ice sheet near the structure, which, in general, would tend to reduce the danger of ice thrust.

Fig. 2 shows the thrusts developed for assumed rates of air-temperature rise of 5° F, 10° F, and 15° F per hr. Values of from 5 to 20 kips per lin ft are indicated for maximum probable ice thrusts for continental United States. For those limited geographical areas where extreme temperature fluctuations have occurred and might be anticipated in the future, the maximum pressure expected (even for conditions of severe restraint and thick ice with solar energy included) is estimated at about 30 kips per lin ft as an extreme value. Regardless of the rapidity of the rise in the air temperature, the rate of temperature rise in the ice sheet is a function of the diffusivity constant of ice and consequently occurs at a more limited rate at greater depths. At increasing depths this reduced rate of temperature rise is more pronounced so that a limit to the possible pressure is approached.

The critical buckling pressures obtained by considering the ice sheet as an elastic slab are probably not ordinarily reached, primarily because the plastic yielding effect cannot be accounted for. Records of reef formation indicate that arching and buckling of an ice sheet does occur but that there is a limiting thickness of about 1 ft beyond which buckling will rarely occur. This fact might indicate that in a heavy ice sheet the stability is greater and that the flow of ice under pressure relieves the critical pressures required for buckling. In cases where the ice sheet is closely restrained and the horizontal dimensions are relatively small, more pressure may develop than in the case of an ice sheet of larger horizontal dimensions in which buckling may occur to relieve extreme pressures, provided that the thickness is small enough.

For existing structures not designed for ice pressure, although such pressures may occasionally occur, it may be desirable to limit the elevation of the

reservoir surface during the winter season so that ice pressure would not be acting coincident with the full water-load condition. Generally, all dams are designed for the full reservoir condition with the water level at or near the top of the dam. Fig. 3 presents the curves showing the required water-surface reduction from full reservoir condition during the season when ice thrust may occur so that the added effect of ice thrust is offset by the reduction in the water load. Curves are shown for several assumed values of ice thrusts for various heights of structure, based on moment and shear as governing criterions. The effect of ice thrust is of relatively minor importance at the base of high dams; but for low sections it represents a factor of considerable importance even for small ice loads. The data in Fig. 3 are based on the assumption that all the load is transferred vertically down to the foundation. For example, the effect of ice load on stresses in an arch dam could not be studied in this manner, but would require a complete stress analysis.

In general, the discussion has been applied to pressure against a vertica or nearly vertical face of a concrete structure. Since the adhering power of sound ice is great, considerable pressure could be exerted even though the surface of the structure is somewhat sloping. The slope of an earth dam would be very flat, however, and the extent of any damage would likely be limited to disturbance of riprap and surfacing material.

Because of the complex nature of the problem and the need for additional data, the ice-pressure problem was not analyzed more thoroughly and comprehensively at this time. It is desirable to secure test data to determine the effect of lateral restraint and especially to obtain more field measurements of both ice temperatures and pressures. When this information is available, it should be possible to prepare more definite design data. The results do present a reasonable basis for evaluating the magnitude of the ice pressures to be expected for the important factors of ice thickness, rapidity of air-temperature rise, lateral restraint, and solar radiation absorption.

13. Acknowledgments

The material presented herein is a result of work conducted in the Denver (Colo.) office, USBR. E. H. Larson assisted the writer in computing the data. Comments and suggestions by R. E. Glover were appreciated. The work was conducted in the Technical Engineering Division under the direction of Ivan E. Houk, M. ASCE. All designs and investigations were supervised by J. L. Savage, Hon. M. ASCE. All design and construction activities were under the general direction of Walker R. Young, M. ASCE. All activities of the USBR were under the direction of Harry W. Bashore, M. ASCE, commissioner, with headquarters in Washington, D. C.

DISCUSSION

ERNEST BROWN,[3] ESQ.—A welcome addition to the knowledge of factors that determine the pressure exerted by an expanding sheet of ice is presented in this paper. The writer first became interested in the fundamental question of the strength of ice in 1927 when he conducted tests for the Joint Board of Engineers on the St. Lawrence Waterway, and prepared the Appendix to the report, dealing with the strength of ice under different conditions. Some few years later, when plans were being made for the building of a hydroelectric plant on the Churchill River, the question of selecting a well-founded value for the ice thrust against the dam became urgent. Values as high as 45,000 lb per lin ft were recorded as having been used. Such a large value would indicate extremely large ice-pressure moments as compared with water-pressure moments, since the head was about 50 ft. The plant, if constructed, would be at the most northerly site yet developed in Canada. Absence of roads made it necessary to bring all materials to the site over frozen lakes and rivers during the winter months, and the economic aspect of the project depended largely on the question of the value of the ice thrust under probable conditions at the site. There seemed to be good reason to doubt the existence of such extremely high pressures as had been used.

However, the data from the waterways tests could not be used to furnish a dependable value for thrust likely to develop from a prolonged and gradual rise of temperature, although they supported the opinion that such high pressures as that mentioned above would probably not arise. Therefore, the writer, in association with G. C. Clarke, M. ASCE, conducted laboratory tests under controlled conditions in an effort to simulate the conditions in nature. The results were reported in a joint paper to the Engineering Institute of Canada in 1932, and along with the waterways tests, are listed in the Bibliography of the paper (3)(6). Mr. Rose has used these results in preparing the curves shown in Fig. 2, which give estimates of the thrust for ice sheets of different thicknesses, considering different rates of air temperature rise and restraint. He has applied the principles of heat transmission to estimate the temperature gradients within the ice sheet under prescribed conditions, and has used the data found by the writer and Mr. Clarke in the Churchill River tests in conjunction with the computed gradients to give the total thrust, using a process of summation.

Each individual project presents its own special conditions. The designer must estimate the probable thickness of ice sheet, nature of snow cover, rate of air temperature rise, restraint at the site, etc., and then must decide on a value for the thrust to be used. He must consider the question of the depth to which temperature changes of the atmosphere may penetrate the ice sheet, since the temperature gradient is an important factor. He may not be able to satisfy his desire for precise data, and will have to use his best judgment

[3] Emeritus Prof., and Prof. of Civ. Eng. (post-retirement), McGill Univ., Montreal, Que., Canada.

after a careful study of all available information. This procedure was followed for the Churchill River project, and no attempts were made to compute temperature gradients in the ice sheet.

It would be helpful if the author would give, in some detail, the calculations for a typical temperature gradient, and submit some selected curves showing the estimated gradients on which the thrusts in Fig. 2 are based. The applicability of the curves might be judged better if the engineer were enabled to consider the degree of agreement between the computed gradients for a few typical conditions, and the gradients that appear to be reasonably likely to occur when the available data for a particular project have been thoroughly studied. It is interesting to note that the curves in Fig. 2, although covering a very wide set of assumed conditions, do not indicate the likelihood of the existence of such high pressures as have been used in some designs. The writer believes that pressures as great as 50,000 lb per lin-ft are imaginary and fantastic. Mr. Rose's data seem to be better founded.

The writer's experience in the testing of ice in a laboratory suggests that experiments on temperature gradients would be very difficult, whether under controlled conditions or in a natural sheet of ice. However, at some future date experiments will be made and will form another link in the chain of knowledge. In the meantime, some typical examples of the gradients used in preparing Fig. 2 would add greatly to the valuable study of the problem which Mr. Rose has presented so ably.

The writer regrets that it has not fallen to his lot to pursue the work on the Churchill River project further. It is gratifying to find that the results then obtained have been used so effectively in the broad general study made by Mr. Rose.

B. R. McGrath,[4] Esq.—The determination of the thrust exerted by an expanding ice sheet is a complex problem because of the plastic behavior of the ice when subjected to temperature increases, and because of various conditions of restraint. There are also a number of influencing factors in nature which affect the rate of temperature change and the degree of restraint encountered at a specific location. The paper by Mr. Rose offers an excellent approach to the solution of this problem. Estimated ice pressures obtained by this analysis are believed to be sufficiently conservative for good practice in the design of hydraulic structures.

As suggested by the author's statement (see paragraph following Eq. 2), on June 22, 1942, the writer, with the aid of valuable suggestions from Douglas McHenry (20), submitted a memorandum to the chief designing engineer of the Bureau of Reclamation setting forth a method for computing ice pressures based on:

(a) The experimental data of Messrs. Brown and Clarke on ice pressures due to temperature increases (3);

[4] Engr., Bureau of Reclamation, Denver, Colo.

(*b*) An adaptation to ice sheets of the graphical method developed by E. Schmidt for obtaining temperature gradients within a mass for one-dimensional heat flow (11); and

(*c*) An evaluation of the effects of lateral restraint according to the theory of elasticity.

The preliminary nature of the work was emphasized in the memorandum, and it was recommended that additional studies be made to consider several factors entering into the problem. Shortly thereafter, the writer was called to

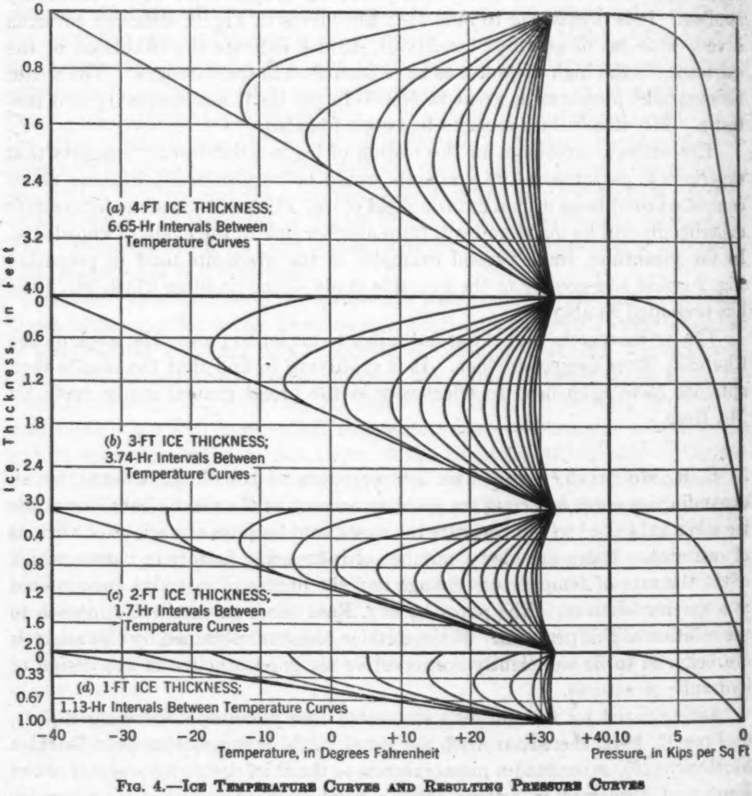

FIG. 4.—ICE TEMPERATURE CURVES AND RESULTING PRESSURE CURVES

active duty in the Civil Engineering Corps of the U. S. Navy and was unable to continue work on the problem.

The purpose of the study was to devise some simple usable curves for evaluating ice pressures against hydraulic structures. It was prepared from a

further interpretation of results obtained by Messrs. Brown and Clarke as cited by Mr. Rose (3). These writers (3b) called attention to two important factors in the problem of determining ice pressure on a dam—the rate and extent to which a rise in air temperature will be transmitted through the ice cover, and the effect of restraining the ice in a direction parallel to the dam.

An approach to the solution of the first of these problems began with the first three of the assumptions mentioned by Mr. Rose in Section 4. Using a graphical method developed by E. Schmidt (11) and described by Douglas McHenry (20), and data presented by Messrs. Brown and Clarke (3), the writer prepared the pressure diagrams shown in Fig. 4. They were taken from several temperature gradients, at known time intervals, and within a normal range

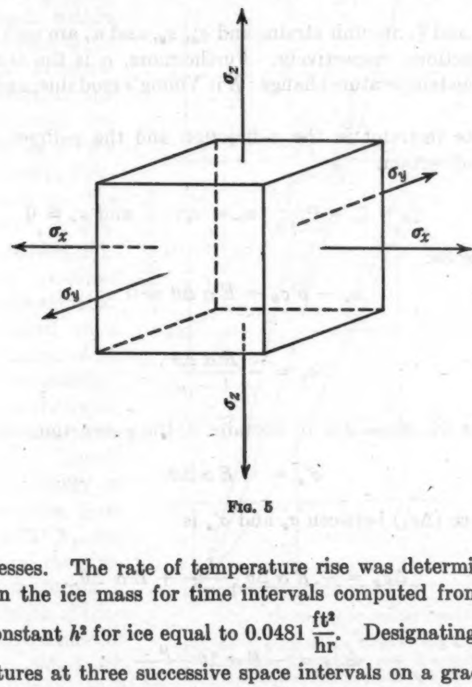

FIG. 5

of ice thicknesses. The rate of temperature rise was determined at different depths within the ice mass for time intervals computed from Eq. 1, with a diffusivity constant h^2 for ice equal to 0.0481 $\frac{\text{ft}^2}{\text{hr}}$. Designating θ_p, θ_q, and θ_r as the temperatures at three successive space intervals on a gradient curve at a given time, the writer developed substantially the formula cited by Mr. Rose as Eq. 2.

With the help of Fig. 4 equivalent ice pressures σ were found at each space interval for each temperature time interval. The total pressure acting within the ice was summed at each space interval for the total time intervals involved, and pressure curves were plotted showing the distribution of total pressure within the ice sheet.

The effect of the lateral restraint of the ice in a direction parallel to the dam may be estimated by first assuming a differential element of ice such as that shown in Fig. 5.

For static equilibrium:

$$\xi_x = \frac{1}{E}\,[\sigma_x - \mu(\sigma_y - \sigma_z)] + \alpha\,\Delta\theta \ldots\ldots\ldots\ldots\ldots (3a)$$

$$\xi_y = \frac{1}{E}\,[\sigma_y - \mu(\sigma_x - \sigma_z)] + \alpha\,\Delta\theta \ldots\ldots\ldots\ldots\ldots (3b)$$

and

$$\xi_z = \frac{1}{E}\,[\sigma_z - \mu(\sigma_x - \sigma_y)] + \alpha\,\Delta\theta \ldots\ldots\ldots\ldots\ldots (3c)$$

in which ξ_x, ξ_y, and ξ_z are unit strains and σ_x, σ_y, and σ_z are unit stresses in the x, y, and z directions, respectively. Furthermore, α is the coefficient of expansion; $\Delta\theta$ is the temperature change ; E is Young's modulus; and μ is Poisson's ratio.

For complete restraint in the x-direction and the y-direction and no restraint in the z-direction:

$$\xi_x = \xi_y = 0; \qquad \sigma_x = \sigma_y; \qquad \text{and } \sigma_z = 0 \ldots\ldots\ldots\ldots (4)$$

From Eqs. 3a or 3b:

$$\sigma_y - \mu\,\sigma_y + E\,\alpha\,\Delta\theta = 0 \ldots\ldots\ldots\ldots\ldots\ldots (5a)$$

or,

$$\sigma_y = -\,\frac{E\,\alpha\,\Delta\theta}{1 - \mu} \ldots\ldots\ldots\ldots\ldots\ldots (5b)$$

Let σ'_y represent the stress due to restraint in the y-direction only; then

$$\sigma'_y = -\,E\,\alpha\,\Delta\theta \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

and the difference ($\Delta\sigma_y$) between σ_y and σ'_y is

$$\Delta\sigma_y = -\,E\,\alpha\,\Delta\theta\,\frac{1}{1 - \mu} + E\,\alpha\,\Delta\theta \ldots\ldots\ldots\ldots\ldots (7a)$$

or,

$$\Delta\sigma_y = -\,E\,\alpha\,\Delta\theta\,\frac{\mu}{1 - \mu} \ldots\ldots\ldots\ldots\ldots (7b)$$

The ratio of increase of stress for complete lateral restraint then becomes

$$\frac{\Delta\sigma_y}{\sigma'_y} = \frac{-\,E\,\alpha\,\Delta\theta\,\dfrac{\mu}{1 - \mu}}{-\,E\,\alpha\,\Delta\theta} = \frac{\mu}{1 - \mu} \ldots\ldots\ldots\ldots (8)$$

If $\mu = 0.25$, then $\dfrac{\Delta\sigma_y}{\sigma'_y} = \frac{1}{3}$; and if $\mu = 0.5$, $\dfrac{\Delta\sigma_y}{\sigma'_y} = 1$. It is thought that the

two assumed values of $\mu = 0.25$ and $\mu = 0.5$ may be taken as limits, and that the stress for a condition of complete lateral restraint should be increased over that of no lateral restraint by a ratio somewhere between the values of $\frac{1}{3}$ and 1.

Fig. 6 shows ice pressures for thicknesses that would be likely to occur in the reservoir. Areas of pressure curves in Fig. 4 were plotted as points when constructing the curve for the condition of no lateral restraint. These points were then increased by $\frac{1}{3}$ and by 1, and curves were drawn corresponding to the limits mentioned. Table 1 is a comparison of ice-pressure values obtained from Fig. 6 and those obtained from curve B, Fig. 2(*a*). The values check within $3\frac{1}{2}$% for a condition of no lateral restraint. For complete lateral restraint, the maximum difference between the average of the two limiting values of Poisson's ratio used by the writer and curve B, Fig. 2(*a*), is approximately 2%.

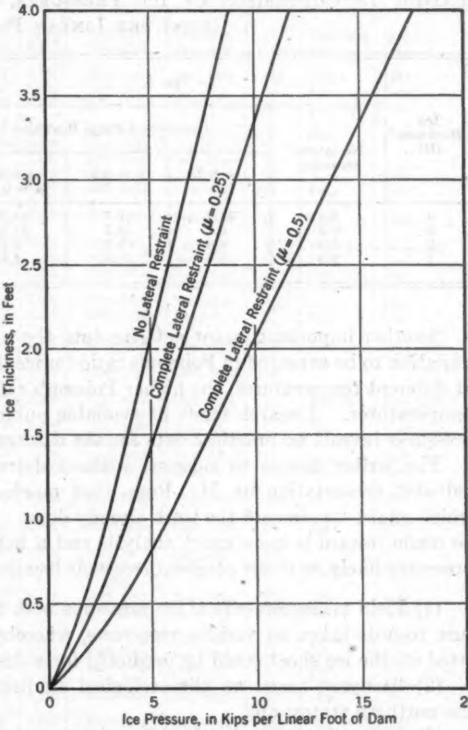

FIG. 6.—ICE PRESSURE CURVES FOR CONDITIONS OF NO LATERAL RESTRAINT AND COMPLETE LATERAL RESTRAINT, PLOTTED AGAINST ICE THICKNESS

Except in unusual cases, it is believed that ice pressures based on a temperature change of 5° F per hr would be satisfactory for design purposes especially for ice thicknesses greater than 2 ft. This is illustrated by a study of Fig. 4. After rising from −40° F to +32° F, the air temperature then remains constant during a considerable length of time while the temperature of the ice rises to this level. For an ice thickness of 2 ft this period is approximately 17 hours. Likewise, an ice thickness of 4 ft requires approximately 80 hours of constant air temperature at +32° F to permit the total pressure to develop.

It would seem very unlikely that such an assumption of constant temperature at this particular level would actually take place in nature immediately following a relatively short period of constant rise from −40° F. Some fluctuation of air temperature, either upward above freezing or downward, during

this period would seem most likely with a consequent reduction in ice pressures over those obtained in the analysis.

Further study of the problem would probably reveal that fluctuations of temperature tend to affect the pressures developed within an ice sheet in a manner somewhat similar to a relatively slower rate of constant temperature changes.

TABLE 1.—Comparison of Ice Pressures, in Thousands of Pounds (kips) per Linear Foot

Ice thickness (ft)	Fig. 6				Curve B, Fig. 2(a)	
	No lateral restraint	Complete Lateral Restraint			No lateral restraint	Complete restraint
		$\mu = 0.25$	$\mu = 0.5$	Average $\mu = 0.375$		$\mu = 0.365$
4....	8.8	11.7	17.7	14.7	9.1	14.4
3....	6.9	9.1	13.7	11.4	7.1	11.2
2....	4.9	6.5	9.7	8.1	5.0	7.9
1....	2.9	3.9	5.8	4.85	2.9	4.4

Another important factor entering into the solution of the problem is the variation to be expected in Poisson's ratio for ice due to changes in its plasticity at different temperatures, the higher Poisson's ratio values occurring at higher temperatures. A search made of available publications on the subject of ice pressures reveals no practical data for the determination of this effect.

The writer desires to suggest, without detracting in any way from the valuable presentation by Mr. Rose, that much remains to be accomplished which might supplement the work already done. Valuable contributions could be made toward a more exact analysis and a better understanding of the ice pressures likely to occur at given reservoir locations through:

(1) Field measurements of ice pressures with their accompanying temperature records taken at various reservoirs, whereby the degree of restraint exerted on the ice sheet could be predicted for a design problem;

(2) Analyses based on climatological studies of various locations within the northern states; and

(3) Laboratory tests for the determination of Poisson's ratio variations with ice-temperature changes.

Robert E. Kennedy,[8] M. ASCE.—In Section 10 of his paper the author mentions unpublished studies on ice thickness on reservoirs of Bureau of Reclamation projects. These studies were initiated in 1939 through the Office of the Chief Engineer. The readings were taken once a week in most cases and continued for three or four years. Since this is a limited period in which to determine any kind of maximum, another request was sent to the field offices in

[a] Average water-surface elevation, in feet. [b] Maximum range. [c] No dam. [d] Minidoka Dam. [e] No ice in the winter of 1940–1941. [f] Link River Dam. [g] Approximately 0.5 in. of ice in February, 1942. [h] Diversion Dam on Wind River.

December, 1944, asking for any other reliable records taken from memory or otherwise covering longer periods. All results are incorporated in Table 2.

A multiple correlation was made of observed maximum ice thickness with latitude and elevation. The correlation R of 0.479 with a standard error of 0.120 indicates a highly significant relationship. Significance is accorded a correlation of thirty or more items when R is at least twice its standard error, often called σ. High significance exists when the correlation is at least three times the value of σ.

The formula resulting from the correlation is

$$L_{max} = 1.15\,\phi + 2.58\,Z - 43.4 \qquad (9)$$

in which L_{max} is estimated maximum thickness in inches, ϕ is latitude in degrees, and Z is elevation in thousands of feet. The error of the estimate is 6.7 in., meaning that if Eq. 9 were used to compute the thickness for comparison with the observed value, about one third of the time the computed thickness would be larger or smaller than the observed thickness, by about 7 in. or more. Actually, it proved to be outside the ±7-in. range in thirteen of the forty-five readings.

The author uses ice thickness in units of a foot, and areas of pressure in terms of square feet. Eq. 9 could be expected to predict thicknesses that would fall within about a half foot of the observed value about two thirds of the time. That prediction is limited to places within latitudes 39° N. to 49° N., and elevations from 2,000 ft to 9,000 ft in western United States west of the 105th meridian, and for such meteorological conditions as existed mainly between 1939 and 1943. Extrapolation beyond the limits of the original data is always uncertain. The author cites a thickness of 5 ft observed in northern Canada. To compute such a thickness one must go as far north as seems probable, say, latitude 65° N., and to an unlikely elevation of 10,000 ft.

Eq. 9 has additional limitations. Although the correlation coefficient of 0.48 is highly significant with respect to its standard error, it, itself, is not high. In fact, it is so low that the corresponding coefficient of alienation is uncomfortably high. It raises doubts as to the efficacy of the formula. The alienation coefficient is $(1 - R^2)^{0.5}$ and amounts to 0.88. It measures the effect of omitting pertinent factors that contribute to the formation of ice. It would appear that more effective factors are omitted than are included.

To illustrate some of the omissions, reference is made to the larger items of heat in the energy equation. Heat contributed to a water surface comes mainly from two sources, the infrared wave lengths of solar energy and the latent heat released when ice is formed. Heat lost is mainly the outgoing black body radiation which figures so evidently in the freezing of ice on clear cold nights.

Latitude and elevation enter directly into the energy equation only in connection with solar radiation. Even there cloudiness is an important factor and it is omitted from Eq. 9.

Latitude and elevation have only an indirect effect on outgoing black body radiation which is primarily a function of surface air temperature expressed in degrees absolute. Eq. 9 does not include air temperature.

Omitted from Eq. 9 is the effect of atmospheric moisture in gaseous state but not in clouds. This moisture radiates back to earth in amounts 30% to 60% of that of a black body. Again the presence of low or middle clouds reduces outgoing radiation also.

Other factors not related at all closely to latitude and elevation are loss of heat by sublimation, conduction, convection and wind movement, and the saving of heat by snow cover.

Even with these limitations, Eq. 9 may be adequate for the problem in hand. The formation and dissipation of ice by the energy equation is another subject.

Edwin Rose,[6] Esq.—Temperature conditions in an ice sheet are governed by the fundamental equation for the case of one-dimensional flow of heat:

$$\frac{\partial \theta}{\partial t} = h^2 \frac{\partial^2 \theta}{\partial x^2} \qquad (10)$$

E. Schmidt (11) gives an approximate method for determination of temperatures to satisfy Eq. 10 under various boundary conditions. Use of this method is illustrated by the following example. Temperatures are computed in an ice sheet 2 ft thick based on the assumptions given in Section 4 for curve B, Fig. 2(*a*). The 2-ft ice sheet is assumed divided into eight slabs of equal thickness, ΔL, equal to 0.25 ft. From Eq. 1, the time interval, Δt, equals 0.72 hour. By Eq. 2, the temperature gradients at time intervals Δt are computed as shown in Table 3.

TABLE 3.—Typical Computation of Ice Temperatures, in Degrees Fahrenheit

Elapsed Time		Distance from Top Surface								
Intervals (1)	Hours (2)	0 (3)	$1\,\Delta L =$ 0.25 ft (4)	$2\,\Delta L =$ 0.50 ft (5)	$3\,\Delta L =$ 0.75 ft (6)	$4\,\Delta L =$ 1.00 ft (7)	$5\,\Delta L =$ 1.25 ft (8)	$6\,\Delta L =$ 1.50 ft (9)	$7\,\Delta L =$ 1.75 ft (10)	$8\,\Delta L =$ 2.00 ft (11)
0....	0	−40	−31	−22	−13	−4	5	14	23	32
$1\,\Delta t$....	0.72	−32.8	−31	−22	−13	−4	5	14	23	32
$2\,\Delta t$....	1.44	−25.6	−27.4	−22	−13	−4	5	14	23	32
$3\,\Delta t$....	2.16	−18.4	−23.8	−20.2	−13	−4	5	14	23	32
$4\,\Delta t$....	2.88	−11.2	−19.3	−18.4	−12.1	−4	5	14	23	32
$5\,\Delta t$....	3.60	− 4.0	−14.8	−15.7	−11.2	−3.5	5	14	23	32
$6\,\Delta t$....	4.32	3.2	− 9.9	−13.0	− 9.6	−3.1	5.2	14.0	23	32
$7\,\Delta t$....	5.04	10.4	− 4.9	− 9.7	− 8.0	−2.2	5.4	14.1	23.0	32.0

Use of Eq. 2 in a typical computation is shown by selecting three consecutive points $p = 0$, $q = 1\,\Delta L$, and $r = 2\,\Delta L$, at time $4\,\Delta t$. Then the temperature θ'_q at time $5\,\Delta t$ equals $\frac{\theta_p + \theta_r}{2}$ or $\frac{(-11.2) + (-18.4)}{2} = -14.8$, as given in Table 3. The temperatures may be computed in this manner or by the graphical method indicated by Mr. McGrath. Determination of temperature

[6] Engr., Bureau of Reclamation, U. S. Dept of the Interior, Denver, Colo.

changes in an ice sheet by solution of Eq. 10 for various exposure conditions has been obtained by F. W. Taylor.

Figs. 7 and 8 show estimated temperature gradients and the corresponding pressure curves and total thrusts for several selected examples covering a fairly

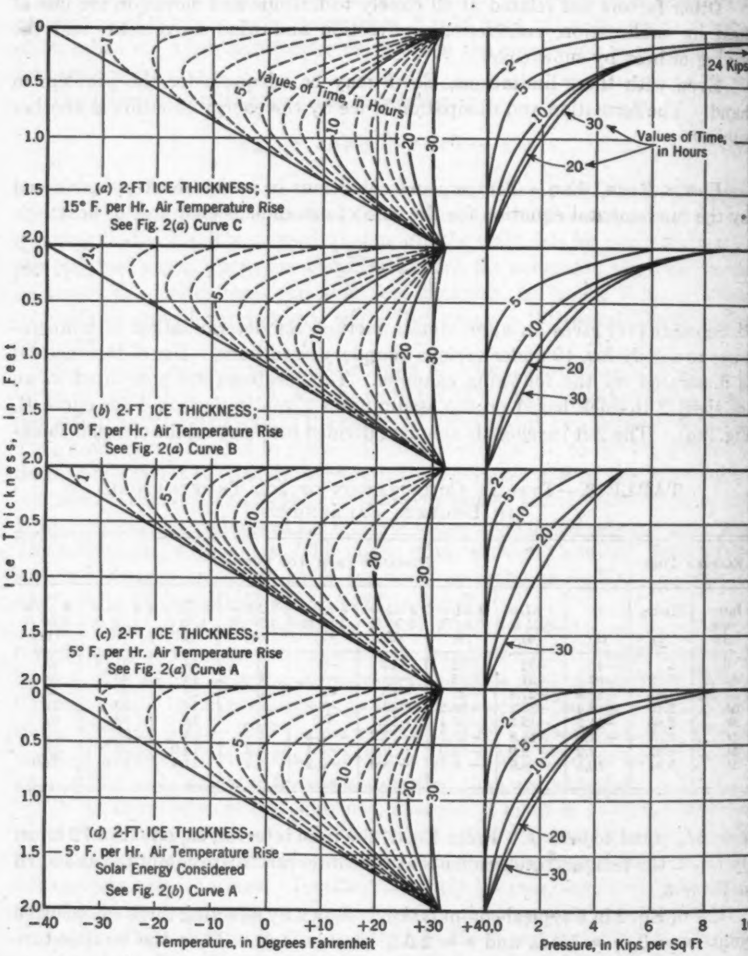

FIG. 7.—ICE TEMPERATURE CURVES AND RESULTING PRESSURE CURVES FOR 2-FT ICE SHEET

broad range of conditions. Fig. 7 gives curves and data for a 2-ft ice sheet with air temperature rises of 5° F, 10° F, and 15° F per hr (see curves A, B, and C, Fig. 2(a)), and also for the case of 5° F per hr with solar energy effects

included as discussed in Section 5 (see curve A, Fig. 2(*b*)). Fig. 8 illustrates the temperature gradients and pressures developed for 1-ft and 4-ft ice sheets with an assumed air temperature rise of 10° F per hr (see curve B, Fig. 2(*a*)).

The temperature gradients shown in Figs. 7 and 8 are estimated for 1-hour time increments. From these several temperature gradients, the pressures at the selected depths in the ice sheet are determined by the data given in Fig. 1,

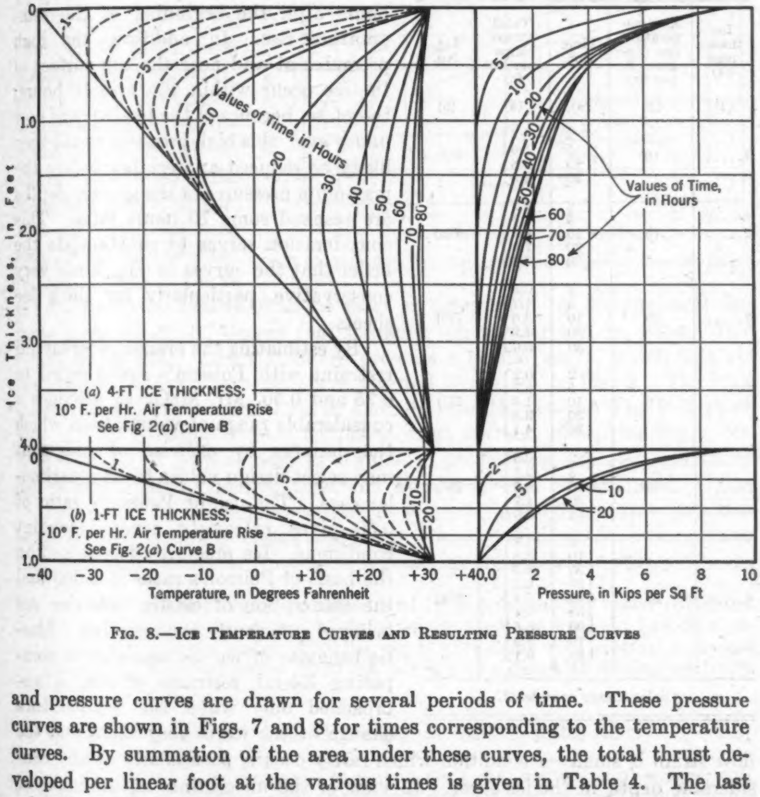

FIG. 8.—ICE TEMPERATURE CURVES AND RESULTING PRESSURE CURVES

and pressure curves are drawn for several periods of time. These pressure curves are shown in Figs. 7 and 8 for times corresponding to the temperature curves. By summation of the area under these curves, the total thrust developed per linear foot at the various times is given in Table 4. The last value for each condition in Table 4 corresponds to the value of thrust per linear foot plotted on the appropriate curve in Fig. 2.

Results of Mr. McGrath's analysis of ice pressures for an assumed air temperature rise of 10° F per hr, as given in Figs. 4 and 6 and Table 1, show a good comparison with data presented in Figs. 2(*a*), 7, and 8. Mr. McGrath presents the pertinent thought that pressures likely to develop in thick ice will probably be less than those obtained in the analysis. The writer agrees that

some reduction in the pressures as shown in Figs. 2, 6, and 8 for ice sheets thicker than 2 ft would seem justified due to the unlikely occurrence of the assumed constant air temperature of 32° F for a period of from 30 hours to 70 hours following a rapid rise in temperature from − 40° F. Inspection of the pressure curves given in Fig. 8 for the 4-ft ice sheet reveals that the maximum pressure ordinate at considerable depth in the ice is not reached until about 80 hours after the beginning of the temperature rise. In addition, the high pressures at and near the top surface of the ice occur within the first 10 hours; therefore, because of the tendency of flow under load, this high pressure would very likely be reduced appreciably before the maximum pressures at the greater depths are reached some 70 hours later. This consideration serves to substantiate the belief that the curves in Fig. 2 are very conservative, particularly for thick ice sheets.

[a] Solar energy considered.

By estimating the pressures for lateral restraint with Poisson's ratios equal to 0.25 and 0.50, Mr. McGrath provides a considerable range of values, from which the designer by exercise of judgment may select design values to fit a particular case. The use of Poisson's ratio of 0.50 gives extremely severe restraint conditions. Ice pressures determined on the basis of Poisson's ratio of 0.365 and the assumption of elastic behavior are believed sufficiently conservative. Elastic behavior of ice, as assumed in computing lateral restraint effects, is approached only when the temperature change of the ice is very rapid and the flow strain is small—a condition which rarely occurs, particularly at any considerable depth in the ice sheet. In view of the uncertainty of the value of Poisson's ratio for ice, the use of a range of values may be desirable, but a lower top value is suggested.

The tabulation of ice thicknesses recorded on reservoirs and lakes on various projects as listed by Mr. Kennedy in Table 2 is a worthy contribution of data. Credit is also due those men in the field who performed the difficult task of gathering the data. By a statistical analysis of the data in Table 2, Mr. Kennedy derives Eq. 9, which expresses the maximum ice thickness as a

function of latitude and elevation. This equation, although limited in accuracy due to both the short period of record of data and the omission of pertinent factors cited, can be used to approximate ice thicknesses. It is believed that a more adequate expression might be derived if consideration were given to air temperatures along with the data in Table 2 as fundamental factors influencing ice thickness.

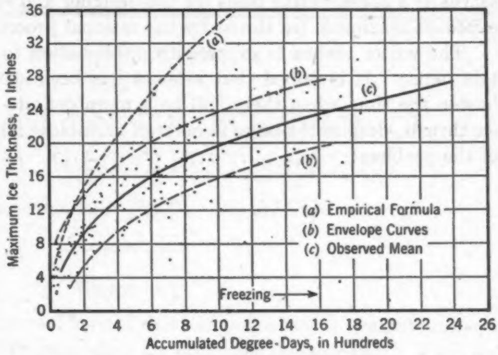

FIG. 9.—MAXIMUM ICE THICKNESS FOR FREEZING DEGREE-DAYS

Mr. Kennedy, in his study of the listed data, plotted the maximum recorded ice thicknesses against accumulated degree-days as shown in Fig. 9. Curve (c) is the mean line drawn by eye, with curves (b) enclosing roughly two thirds of the plotted points. Curve (a) represents the growth of an ice sheet as determined by the empirical formula given by N. E. Dorsey (4*a*) assuming quiet water and no snow. In a recent paper (21), Robert P. Sharp presents a similar curve, which falls approximately midway between curve (a) and curve (c) in Fig. 9. The wide range between the empirical curve and the recorded data in Fig. 9 is probably due to variation of such factors as wind, current, snow, cloudiness, etc. However, Fig. 9 may be used as a guide to predict the expected maximum ice thickness, if air temperatures are known or can be estimated.

In personal correspondence with S. P. Wing, M. ASCE, regarding allowance made for ice pressure in design of dams in Norway, Thor G. Brandzaeg states that, although no official Norwegian regulations are printed as yet:

> "* * * up to 1938 an ice pressure of 10 metric tons per meter (6720 lbs. per ft.) was used for design of dams; since then the ice load has been reduced to 8 tons per meter (5380 lbs. per ft.) for dams with vertical upstream faces and 5 tons per meter (3350 lbs. per ft.) for dams with sloping upstream faces."

In another paper (22), Paul E. Gisiger, M. ASCE, states that:

> "* * * static ice pressure, except in very confined areas or spaces, will, under the most severe climatic conditions, seldom exceed 10,000 lb per lin ft."

The writer agrees with Mr. McGrath that much remains to be accomplished to secure a better understanding of ice pressures. The Bureau of Reclamation under the immediate supervision of Douglas McHenry has undertaken a program to secure both field and laboratory data on ice pressures and related problems. No definite results are as yet available, but some field work has

been in progress. As Professor Brown states, the engineer may not be able to satisfy his desire for precise data and will have to use his best judgment after careful consideration and study of available information. It is believed that, until more precise information is available, the material presented in the paper serves as a conservative basis for the designer and enables him to estimate the expected maximum ice thrust by the rational procedure indicated.

The writer wishes to express his appreciation to those who commented on this paper. It is hoped that interest has been stimulated in this subject to hasten the time when there will be a more definite basis for determination of ice thrusts, despite the large number of variables and the recognized complexity of the problem.

OBSERVATIONS ON THE BEHAVIOR OF ALUMINUM ALLOY TEST GIRDERS

BY R. L. MOORE,[1] ASSOC. M. ASCE

SYNOPSIS

The results of an experimental investigation of the behavior of eight built-up test girders of a standard aluminum alloy are presented in this paper. Data on web-buckling characteristics, stress distribution, and ultimate girder strengths are included. The object of these tests was to show to what extent elastic buckling theory could be used to predict buckling phenomena and to provide some data on the relation between first buckling and ultimate load-carrying capacities in aluminum alloy structures of this type.

I. INTRODUCTION

The tests described in this paper were made in 1937 and 1938 as part of a general program of research on the behavior of aluminum alloy structures. Although the tests were made originally to aid in the design of built-up girders simulating types common in bridge and building construction, the information obtained relative to strength, stiffness, and capability of withstanding large deformations without failure is of fundamental importance in all fields of aluminum alloy structural design.

One of the primary objects of these tests was to determine to what extent the theory of elastic stability could be used as a basis for the prediction of buckling phenomena.[2] Experimental data are presented to show the buckling characteristics of a number of web panels of different sizes under various combinations of shear and bending stress. A few data on the local buckling resistance of outstanding flanges are also included. Of equal or perhaps even greater significance from the standpoint of design are the results obtained pertaining to the ultimate strengths of the girders. Tests to failure constitute an important part of aircraft structural analysis, whereas the designer in the field of general structures seldom has an opportunity to appraise conventional design

NOTE.—Published in June, 1946, *Proceedings*. The position and the title given are those in effect when the paper was received for publication.

[2] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York, N. Y., 1936, p. 408.

procedures in the light of ultimate load-carrying capacities. The third phase of the investigation concerns measurements of strain and deflection made as a check on the ordinary flexure theory applied to built-up girders.

II. Specimens

Fig. 1 shows the structural details of the eight girders built for test. All material, including the rivets, was aluminum alloy 17S–T having a nominal composition of 4.0% copper, 0.5% manganese, 0.5% magnesium, and the remaining 95% aluminum.[3] The tensile properties of the web and flange material are given in Table 1. Standard specimens for sheet metals were used.[4]

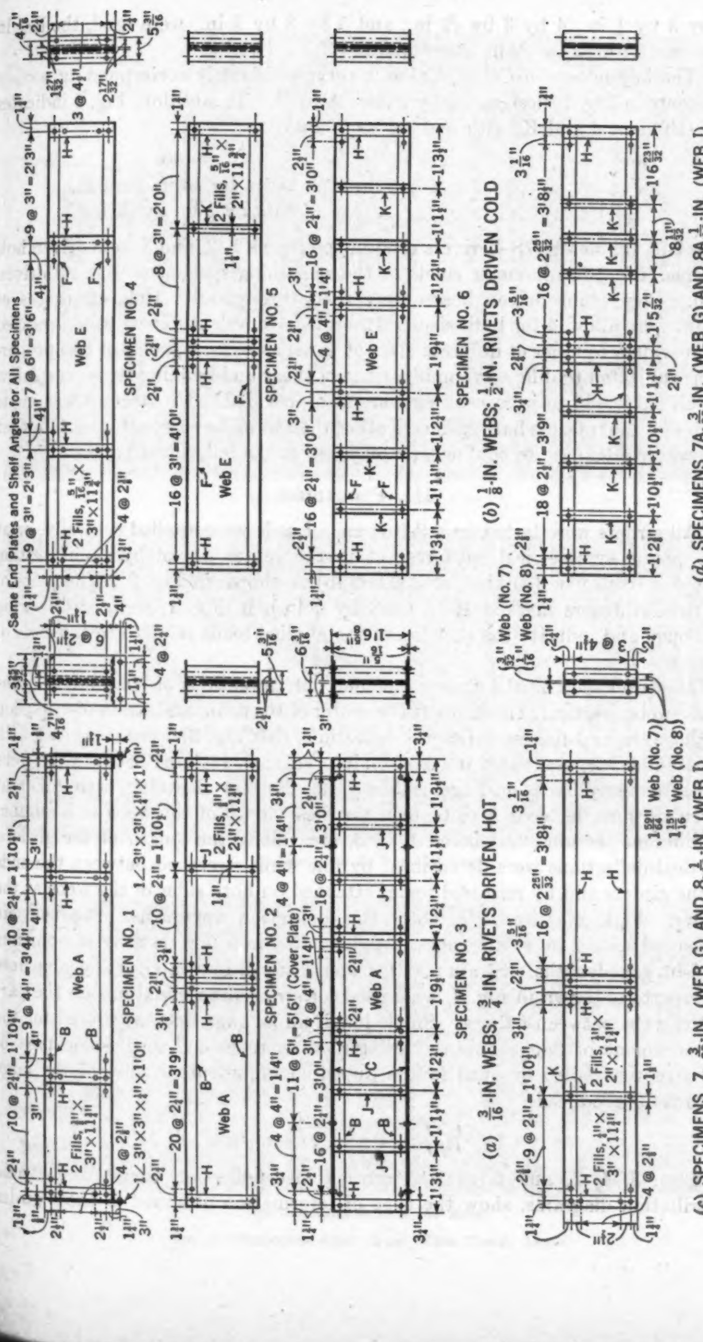

FIG. 1.—TEST GIRDERS, ALUMINUM ALLOY 17 S-T (FOR DIMENSIONS AND SECTION ELEMENTS, SEE TABLE 2)

3 by 3 by $\frac{1}{4}$ in., 4 by 3 by $\frac{5}{16}$ in., and 5 by 3 by $\frac{3}{8}$ in., were used, the last in one case with 12 by $\frac{5}{16}$-in. cover plates.

The key letters in Col. 4, Table 2, serve to identify corresponding section elements in Fig. 1, designated by letters A to H. In addition, Fig. 1 indicates the stiffeners J and K, with sections as follows:

Key	Section
J	$2\frac{1}{2}$ in. by $2\frac{1}{2}$ in. by $\frac{1}{4}$ in.
K	2 in. by 2 in. by $\frac{3}{16}$ in.

The $\frac{3}{4}$-in. diameter 17S–T rivets used in specimens 1, 2, and 3 were driven hot, whereas the $\frac{1}{2}$-in. diameter rivets in the remaining specimens were all driven cold. Cone-point driven heads were used throughout. Hole clearances of $\frac{1}{32}$ in. were allowed for both sizes. Intermediate web stiffeners were arranged to provide a number of different sizes of panel as well as panels of like proportions subjected to different combinations of shear and bending stresses. A few panels subjected to pure bending were also provided. No attempt was made to design the intermediate stiffeners other than to make reasonably certain that they were adequate to confine web buckling to the individual panels.

III. Procedure

All girders were tested on a 9-ft span. Loads were applied centrally, or at two points symmetrical with respect to the center, in an hydraulic testing machine (capacity 300 kips, or 300,000 lb) as shown in Fig. 2. The pairs of vertical stiffeners marked H (3 by 3 by $\frac{1}{4}$ in.), in Fig. 1, were load-bearing stiffeners and indicate the position of the applied loads relative to the ends of the span.

Measurements on the girders included determinations of lateral deflections of the webs, vertical deflections at the center of the span, and strain distribution in the webs and flanges. Lateral deflections (see Fig. 3) were measured with a dial indicator, graduated in 0.001-in. intervals and inserted between the webs and a reference bar placed against the girder flanges. Readings were taken at seven stations, lettered A to G, over the clear depth of the webs at a number of different sections, numbered 1, 2, 3, etc., along the length of the girders. Vertical deflections were determined by fine wires stretched between the ends of the girders and by mirrored scales attached on both sides of the webs at the center. Figs. 2(*a*) and 2(*c*) show this deflection apparatus. Strains were measured with 2-in. strain gages, supplemented in a few tests by tensometers on $\frac{1}{2}$-in. gage lengths. Strain rosettes, consisting of four intersecting gage lines 45° apart, as shown in Fig. 4, were used for strain determinations on the part of the webs between flanges. Single longitudinal gage lines were used for the measurement of flange strains. All girders were loaded until some part of the structure failed or until failure appeared imminent because of the large distortions produced.

IV. Results and Discussion

Figs. 3, 4, 5, and 6, in the form of load-deflection curves and stress-distribution diagrams, show the type of information obtained in these girder

tests. Detailed results for all specimens, including data on ultimate strengths, are presented in Tables 3, 4, and 5.

(*A*) *Lateral Deflections of Webs.*—Generally, it is not possible to obtain well-defined experimental buckling loads for flat web panels subjected to various

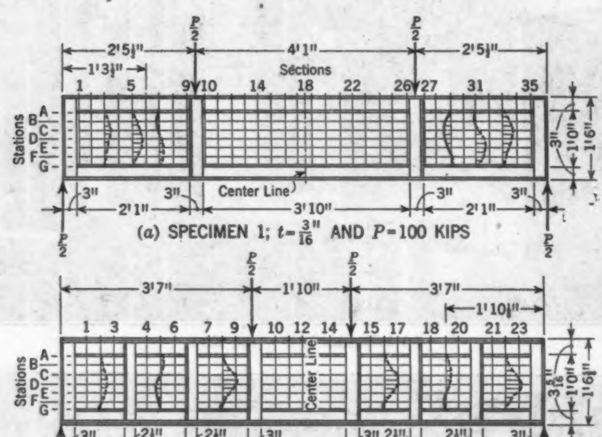

FIG. 3.—LATERAL DEFLECTIONS OF THE WEBS

combinations of shear and bending stress. In only about one fourth of the cases considered in this investigation was an abrupt change in the load-versus-lateral deflection characteristics of the webs observed which might be interpreted as indicating definite buckling phenomena. Figs. 5(*c*) and 5(*d*) show

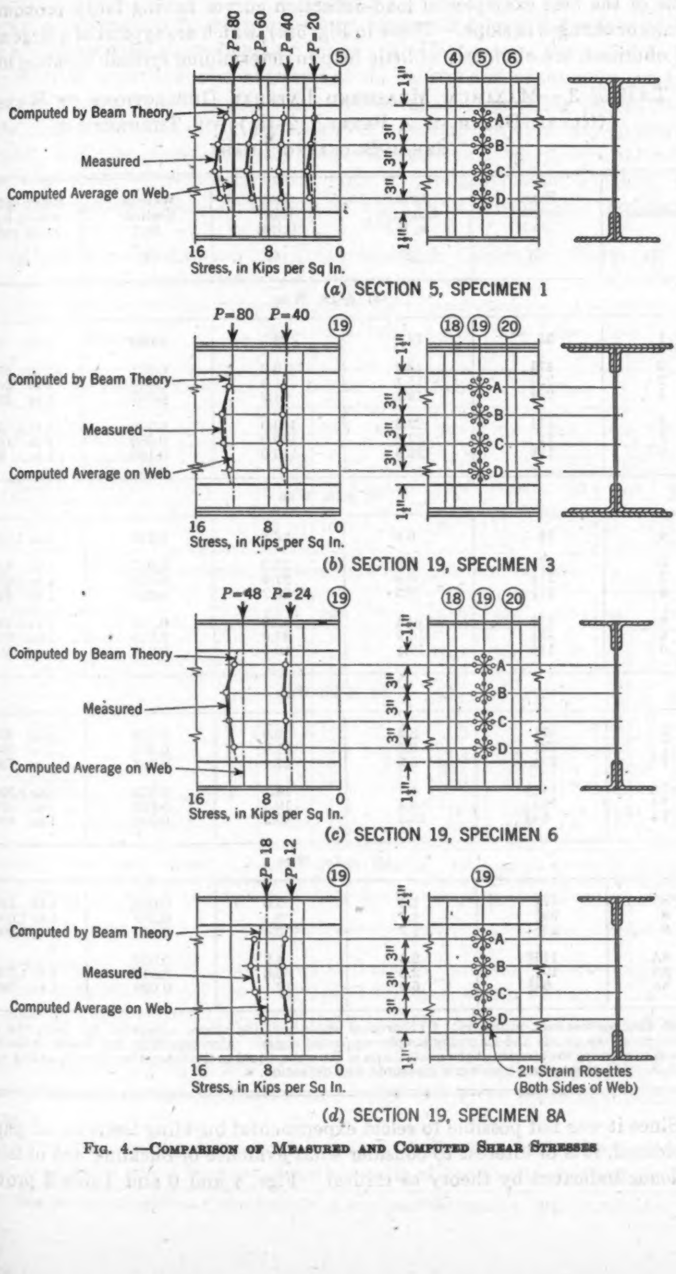

FIG. 4.—COMPARISON OF MEASURED AND COMPUTED SHEAR STRESSES

some of the best examples of load-deflection curves having fairly pronounced breaks or changes in slope. Those in Fig. 5(*a*), which are typical of a large number obtained, are obviously of little help in determining critical buckling loads.

[a] Clear distance between stiffeners. [b] Theoretical shear-buckling stress, computed by using the clear dimensions of the panels and assuming simply-supported edges. [c] Corresponding test loads, or the loads required to produce the stresses at the neutral axis of the webs, equal to the theoretical shear-buckling values in Col. 3. [d] Corresponding maximum measured web deflection.

Since it was not possible to select experimental buckling loads for all panels considered, it is of interest to consider what evidence of buckling was obtained for loads indicated by theory as critical. Figs. 4 and 6 and Table 3 provide

data for a comparison between maximum measured lateral deflections of the webs and theoretical shear-buckling loads. The latter were computed as the loads required to produce shear stresses at the neutral axis of the webs (according to the flexure theory) equal to the theoretical shear-buckling values, based on the clear dimensions of the panels and the assumption of simply-supported edges.[2,5] With the exception of the panels of specimen 3, which were subjected to average shear stresses sufficiently high to produce plastic buckling, the maximum measured lateral deflections were generally quite small. For fifteen

of the twenty-six sizes of panel listed in Table 3, for example, the maximum measured deflections were less than 1/500 the least width of panel. In only one case involving elastic action did the maximum deflection corresponding to the buckling load exceed one third of the web thickness. A number of the lateral deflection curves shown in Figs. 5(*c*) and 5(*d*) indicate that the webs remained essentially flat for loads considerably above the theoretical buckling values.

Theoretical shear-buckling loads were selected as the basis of comparison in Fig. 5 and in Table 3 because of the low ratio of bending to shearing stresses

[5] "Alcoa Structural Handbook," Aluminum Co. of America, Pittsburgh, Pa., 1945, pp. 42 and 61.

computed for the panels considered. The load-versus-lateral deflection curves in Figs. 5(*c*) and 5(*d*) indicate that there was no consistent or significant difference between the behavior of the panels near the center of span, where the bending moments were a maximum, and the behavior of panels at the ends of the span subjected to the same shear but where the moments were relatively small.

It was concluded from these observations that, in general, shear-buckling

[a] At the center of the span. [b] For specimen 3, the flange stresses (Cols. 5 and 6) are the averages for the cover plates, since the web at the point indicated was not accessible. The web stresses (Cols. 7 and 8) are the averages for the underside of the flange angles (see Fig. 6(*c*)). All other values are extreme fiber bending stresses.

loads computed in the manner described underestimate the point at which significant web buckling may occur and that such loads therefore provide a conservative basis for design. (Theoretical shear-buckling loads for fixed edges are about 65% greater than those for simply-supported edges.[6]) The web panels considered (clear distances) were not simply supported at the edges, as assumed, because of the restraining effects of the flange and stiffener angles. As far as the web deflections observed in these tests were concerned, however, accidental eccentricities of loading, resulting either from initial out-of-flatness of the webs or from the manner in which the loads were applied, tended to offset the edge-restraining effects. These compensating factors will be present in all girder webs.

[6] "Formulas for Stress and Strain," by R. J. Roark, McGraw-Hill Book Co., Inc., New York, N. Y., 1938, p. 269.

The photographs in Figs. 2(*a*) and 2(*c*) and the load-versus-lateral deflection curves in Figs. 5(*a*), 5(*b*), and 5(*c*) show no evidence of web buckling in the panels at the center of the girders subjected to pure bending. Application of the buckling theory[2,5] to panels of this type indicates that the stresses required

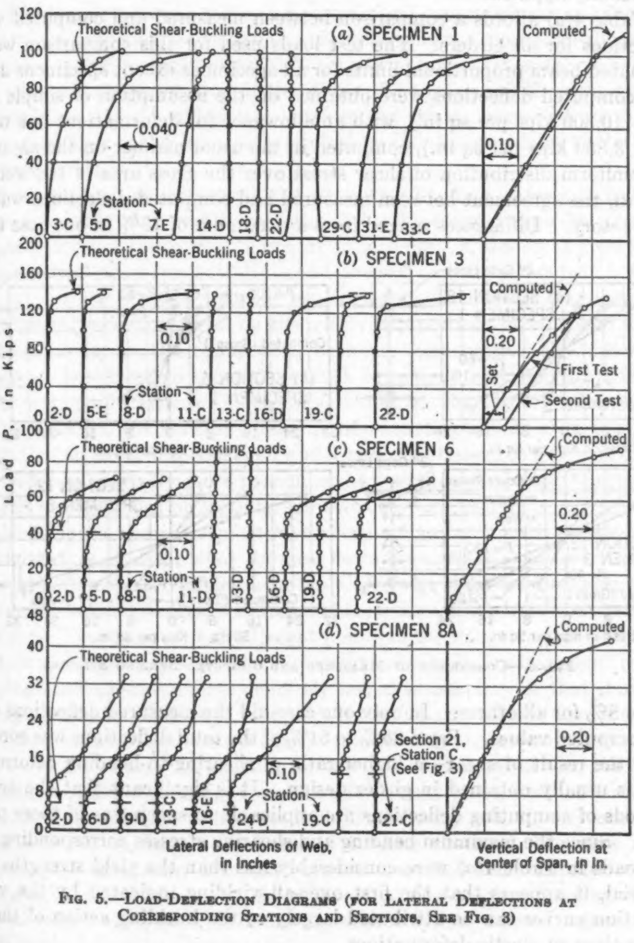

FIG. 5.—LOAD-DEFLECTION DIAGRAMS (FOR LATERAL DEFLECTIONS AT CORRESPONDING STATIONS AND SECTIONS, SEE FIG. 3)

to produce buckling were appreciably higher than the maximum developed in these tests.

(*B*) *Vertical Deflections.*—Fig. 5 also shows typical relations between loads and measured vertical deflections at the center of the span. A comparison of

these with the lateral deflection data in Fig. 5 indicates that the vertical deflections of the girders were not sensitive to the first buckling action of the webs. Approximately linear relations between load and vertical deflection were obtained for loads considerably beyond the point at which buckling of the webs was readily apparent.

Table 4(*a*) affords a comparison between measured and computed vertical deflections for all girders. The test loads used for this comparison were the estimated beam proportional limits for all specimens except specimens 2 and 3. The computed deflections were obtained on the assumption of simple flexure (E = 10,300 kips per sq in.), with an allowance for deformations due to shear (G = 3,850 kips per sq in.), computed in the usual manner on the assumption of a uniform distribution of shear stress over the gross area of the webs. In general, the agreement between measured and computed deflections was quite satisfactory. Differences ranged from a maximum of 13% in one case to from

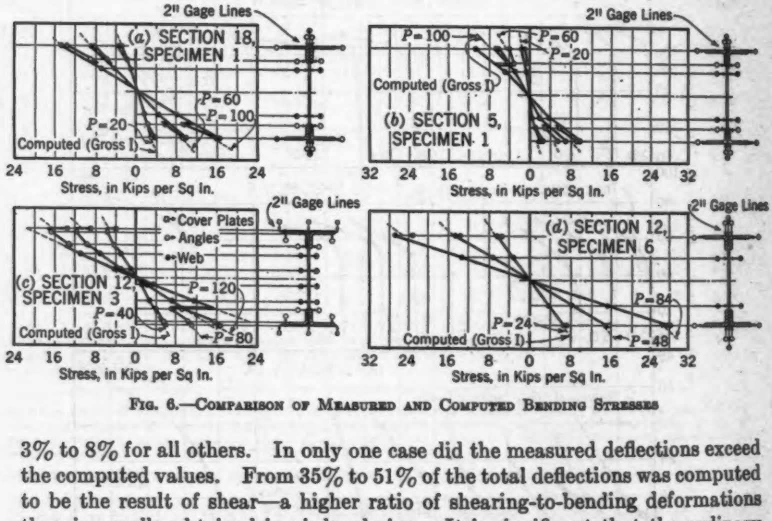

FIG. 6.—COMPARISON OF MEASURED AND COMPUTED BENDING STRESSES

3% to 8% for all others. In only one case did the measured deflections exceed the computed values. From 35% to 51% of the total deflections was computed to be the result of shear—a higher ratio of shearing-to-bending deformations than is usually obtained in girder design. It is significant that the ordinary methods of computing deflections are applicable to specimens of these proportions. Since the maximum bending and shearing stresses corresponding to the test loads in Table 4(*a*) were considerably less than the yield strengths of the material, it appears that the first over-all yielding indicated by the vertical deflection curves can be attributed largely to the buckling action of the webs rather than to plastic deformations.

(*C*) *Stress Distribution.*—The shear-buckling loads selected for the girders were those loads which, according to the flexure theory, were required to produce shearing stresses at the neutral axis of the webs equal to the theoretical shear-buckling stresses for the panels. If the buckling loads had been based on the assumption that the critical stresses in shear were uniformly distributed

over the entire gross area of the webs (as is generally assumed in design), somewhat higher buckling loads would have been obtained. However, the shearing-stress distribution diagrams shown in Fig. 4, and the comparison between measured and computed values shown in Table 4(*b*) indicate that the theoretical distribution of shear stress between flanges was approached very closely in these tests. Differences between average measured and computed vertical shearing stresses for the four rosette locations on the webs were not more than about 3%, as compared to differences of about 10% between measured stresses and average values based on the gross area of the webs. The measured shearing stresses were determined as the differences between the strains measured on the 45° diagonal gage lines of the rosettes multiplied by the shear modulus of elasticity (3,850 kips per sq in.).[7]

Differences between measured and computed bending stresses in built-up girders apparently may result from the lack of integral action between the component parts of the girder, the reductions in area of section at rivet holes, and the effect of stress concentrations and unequal distribution of load between rivets. Complete integral action is usually assumed although the degree attainable would seem to depend on the relative proportions of webs and flanges and the efficiency of the connections between these parts. The differences between measured and computed vertical deflections in Table 4(*a*) did not indicate any significant lack of integral action in the test girders, although it is quite evident from the bending-stress-distribution diagrams in Figs. 6(*a*), 6(*b*), and 6(*c*) that all parts of specimens 1 and 3 were not stressed to the same degree. This effect was generally more pronounced on sections subjected to combined shear and bending than on sections subjected to pure bending.

Table 5 gives a comparison between measured and computed stresses in the webs and flanges of all girders. In most cases the stresses measured in the top flanges, in both webs and angles, were less than those observed at corresponding points on the bottom flanges. Extreme fiber stresses in the webs were generally higher than those measured at adjacent points in the flange angles—indicating some lack of integral action. The agreement between individual measured and computed bending stresses was definitely not as satisfactory as that shown for shearing stresses in Table 4(*b*), although it will be appreciated that the stress distribution in the flanges was probably considerably more complex than that produced in the webs. In addition to the lack of integral action, the length and position of the strain-gage lines relative to rivet holes, and the possibility of considerable variation in load on individual rivets, undoubtedly accounted for some of the variations in measured stresses observed. In view of the generally good agreement obtained between measured and computed vertical deflections, it seems reasonable to believe that the average bending stresses along the length were likewise in fair agreement with computed values.

General structural design practice is not consistent regarding the procedure to be followed in making allowances for rivet holes in computing section elements. The use of net rather than gross section elements for the tension

[7] "The Determination of Stresses from Strains on Three Intersecting Gage Lines and Its Application to Actual Tests," by William R. Osgood and R. G. Sturm, *Research Paper No. 559*, National Bureau of Standards, 1933.

flanges would have resulted in a generally better agreement between average measured and computed tensile stresses. The use of net section for the compression flanges, however, would have resulted in poorer agreement.

(*D*) *Ultimate Strengths of the Girders.*—Table 6 gives a summary of the maximum test loads, together with the corresponding computed maximum bending stresses or moduli of failure and the average shearing stresses on the gross areas of the webs. Average shear and bearing stresses in the flange and load-bearing stiffener rivets are also included. These stresses were all computed on the assumption that the structural action of the girders was the same as that obtained in the early stages of the tests before web buckling. The bending stresses in all cases were considerably less than the tensile yield strengths of the material given in Table 1. The average shear stresses exceeded

the shear yield strength of 22 kips per sq in. estimated for the web material[5] in four of the eight cases considered and ranged from one to approximately twelve times the theoretical shear-buckling stresses for the largest panels of each girder. The latter comparisons emphasize how little effect the buckling action of the web may have on the ultimate strength of a girder.

Three types of failure were obtained. In specimens 1, 3, and 4, the shearing distortions produced in the webs became so great that it seemed advisable to stop the tests. It was quite evident, both from the condition of the girders and the marked increases in deflection obtained without appreciable increases in load, that a practical limit of load-carrying capacity had been reached. Figs. 2(*a*) and 2(*c*) show the nature of the web buckling produced. The average shearing stresses, corresponding to the maximum loads on these specimens, ranged from 20.9 to 25.1 kips per sq in., whereas the maximum computed bending stress was only 23.2 kips per sq in.

In specimens 2 and 5, failure occurred by a combination of web buckling and twisting of the compression flanges although, from the relatively low value of flange stress computed for the buckled region, it would appear that web buckling was the primary cause of failure. There was no evidence of flange twisting on the opposite sides of these same girders where intermediate web stiffeners were used and web buckling was not so pronounced. Figs. 2(*b*) and 7 illustrate the type of buckling failures obtained. The maximum test loads

represent ultimate load-carrying capacities even though the average shearing stresses were slightly less than 16 kips per sq in.

In specimens 6, 7A, and 8A, the web distortions were accompanied by local buckling of the compression flanges. Secondary diagonal-tension fractures of the web were also obtained in specimen 8A as shown in Fig. 8. Fig. 7 illustrates the nature of the buckling failures. The bending stresses of from 32.0 to 37.7 kips per sq in., computed for these specimens, were the highest obtained. The

FIG. 7.—ALUMINUM ALLOY GIRDERS AFTER TEST TO FAILURE

(a) SPECIMENS 4, 5, AND 6 (1/8-IN. WEBS)
(b) SPECIMENS 7A AND 8A (3/32-IN. WEBS)

average shear stresses ranged from 19.9 to 24.4 kips per sq in. From the standpoint of utilizing the strength of the web and flange material, the specimens of this group represent the most balanced designs.

The data pertaining to local buckling of outstanding compression flanges on specimens 6, 7A, and 8A are probably not sufficient to establish a general criterion for predicting buckling of this type. The average flange stresses computed for the sections at which buckling actually occurred correspond to the buckling stresses computed for flat plates, subjected to edge compression, with one edge free and the other from 50% to 100% fixed.[5]

The average shearing stresses given in Table 6 for the flange and stiffener rivets indicate that there was a considerable margin of safety against failure in these connections, since the ultimate shear strength of aluminum alloy 17S-T is about 36,000 lb per sq in. The average computed bearing stresses, however, were higher in some cases than the ultimate bearing strengths generally accepted for this alloy. The variation in rivet-hole distortions shown in Fig. 8 indicates that the bearing stresses on some rivets, near the ends of the diagonal-tension buckles, must have been considerably higher than the averages computed. The maximum increases in hole diameter ranged from about 15% to 20%.

(*E*) *Tension-Field Action.*—As stated in Section IV(D), the initial buckling load for a shear-resistant girder web does not necessarily limit its ultimate load-carrying capacity. For example, specimen 8A supported a load approximately twelve times that which produced first buckling of the largest panels. The civil engineer has become accustomed to look on buckling as an undesirable phenomenon and avoids such action by the use of low design stresses and intermediate web stiffeners. The aeronautical engineer, on the other hand, recognizes that buckling of a girder web means a transition from shear-resistant action, where diagonal tensile and compressive forces are equally effective in resisting shear, to so-called tension-field action, where the shear in excess of the buckling value is carried largely by diagonal tension. The strength of a web considered on the latter basis depends on the properties of the web material and on the capacity of the flanges and stiffeners to resist failure until the web has reached its ultimate load-carrying capacity.

The original theory of tension-field action, in which the web was assumed to have no flexural stiffness and all the shear was carried by diagonal tension, was presented by Herbert Wagner.[8] The practical results of this analysis have been summarized by Paul Kuhn,[9] A. S. Niles, Assoc. M. ASCE, and J. S. Newell.[10] Since all webs are shear resistant to some extent, however, considerable experimental as well as analytical work has been done in an effort to modify the theory to make it more suitable for design. E. E. Sechler and L. G. Dunn have presented a summary[11] of the results of some of this work; and they give data on the yield and ultimate strengths of a number of tension-field girders of aircraft proportions. This approach to the shear problem in girder webs is emphasized because it represents an attempt in some fields of design to take advantage of useful girder strengths beyond first buckling values.

Although the tests in this report have provided considerable evidence of the factors associated with tension-field action, the proportions of the girders were not believed to justify a detailed tension-field analysis in view of the present state of the theory. A tension-field failure was obtained in only one girder (8A), and this action was accompanied by local buckling of the compression

flange. Tension-field action presupposes that the web buckles into a large number of small folds and that the diagonal tensile forces are distributed fairly uniformly along the flanges and end stiffeners. The buckle patterns in Figs. 2(*a*) and 7 and the variation in hole elongations in Fig. 8 are scarcely consistent

with this assumed action. Stiffener spacings relative to the depth of web are generally much closer in aircraft tension-field girders than was the case in these tests. Ratios of web depth to thickness, moreover, may range from 500 to 1,000 or more, whereas the highest ratio in these tests was only 192.

The choice of buckling angle is an important factor in tension-field analysis, although the dependence of this factor on girder proportions is as yet unknown. Some evidence was obtained in these tests to show that the buckling angle does not remain constant with changing loads. In specimen 5, for example, the angle of buckle shifted from approximately 33° at a load of 40 kips to 15° for the maximum load of 70.8 kips (Fig. 7).

Fig. 9 shows a comparison of measured and computed principal stresses and maximum shears in the web of specimen 8A. The measured stresses were based on the average of strains on both sides of the webs.[7] The computed stresses were determined as the maximum values for combined bending and shear at the various rosette locations. The interesting observation to be made from this figure is that the diagonal compressions measured at the center of the largest panel (section 16) were approximately equal to the diagonal tensions for loads to 18.0 kips—or more than four times the theoretical buckling load for the panel. Strain measurements were not made for loads in the vicinity of the maximum test value, so it is not possible to state at which point tension-field action, which ultimately fractured the web, became significant. For girders of the proportions considered herein, the problem obviously requires further investigation.

V. Conclusions

The results of this investigation of the structural behavior of a number of built-up test girders of aluminum alloy 17S–T are believed to warrant the following conclusions:

a. Well-defined buckling loads generally cannot be obtained experimentally for flat webs subjected to combined bending and shear because of unavoidable eccentricities of loading. The computation of buckling values for shear alone, using clear dimensions of panels and assuming simply-supported edges,[2,5] probably underestimates the buckling resistance of most panels but provides a simple, conservative basis for design. Edge-restraining effects, which tend to retard visible buckling, are offset to some extent by eccentricities of loading and the effects of bending superimposed upon those of shear.

b. The measured vertical deflections at the center of span in Table 4(*a*) averaged within about 5% of the computed values based on a consideration of bending and shear. Approximately linear relations between load and deflection were obtained for loads considerably greater than those which produced first web buckling, indicating that over-all stiffness was not particularly sensitive to the first buckling action of the webs.

c. The measured vertical shearing stresses shown in Table 4(*b*) for the part of the webs between flanges were in very close agreement with values computed according to the flexure theory, the maximum difference being about 3%. These stresses, which were the significant values from the standpoint of web buckling, averaged about 10% higher than those based on the gross area of the webs.

d. The measured bending stresses for the flanges in Table 5 were not in as close agreement with computed values as shown in Table 4(*b*) for shearing

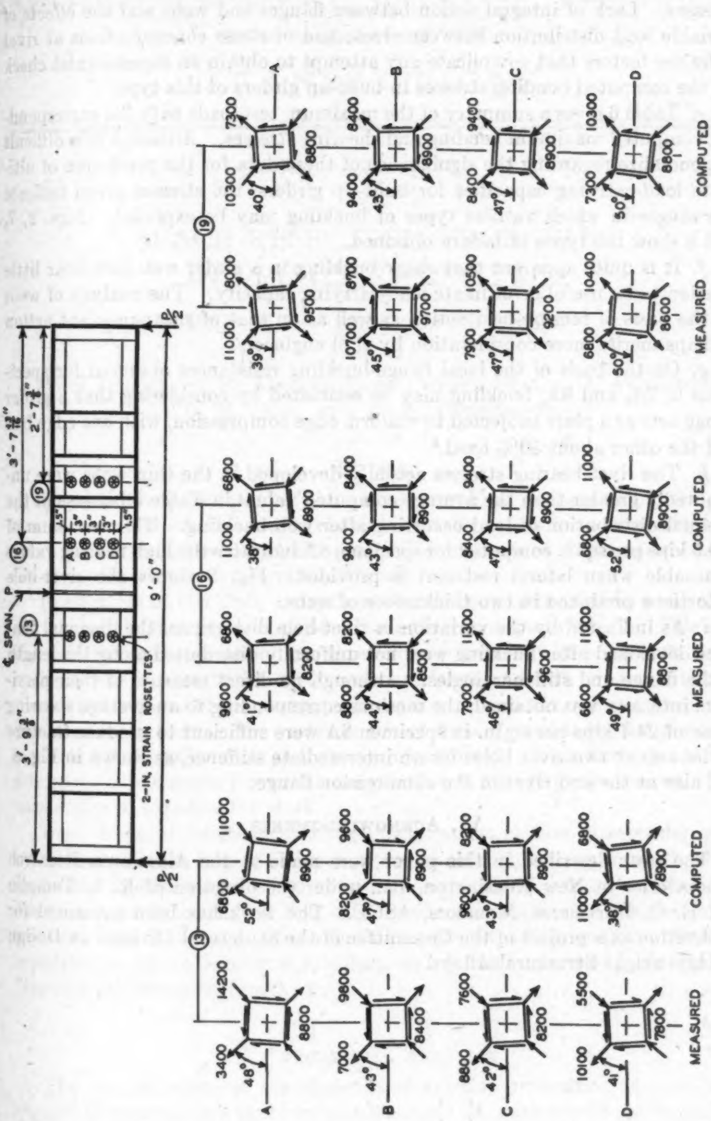

FIG. 9.—PRINCIPAL STRESSES AND MAXIMUM SHEARS FOR A LOAD P OF 18 KIPS; SPECIMEN 8A (STRESSES, IN KIPS PER SQ IN., ARE THE AVERAGES FOR TWO SIDES OF THE WEB)

stresses. Lack of integral action between flanges and webs and the effects of variable load distribution between rivets and of stress concentrations at rivet holes are factors that complicate any attempt to obtain an experimental check on the computed bending stresses in built-up girders of this type.

e. Table 6 gives a summary of the maximum test loads with the corresponding computed maximum bending and shearing stresses. Although it is difficult to generalize regarding the significance of these data for the prediction of ultimate load-carrying capacities for built-up girders, the stresses given indicate the ranges in which various types of buckling may be expected. Figs. 2, 7, and 8 show the types of failure obtained.

f. It is quite apparent that shear buckling in a girder web may bear little relation to its useful or ultimate load-carrying capacity. The analysis of webs on the basis of tension-field action as well as on that of shear-resistant action perhaps merits more consideration by civil engineers.

g. On the basis of the local flange-buckling resistances observed for specimens 6, 7A, and 8A, buckling may be estimated by considering that a girder flange acts as a plate subjected to uniform edge compression, with one edge free and the other about 50% fixed.[5]

h. The rivet-bearing stresses actually developed in the thin webs were undoubtedly greater than the average computed values in Table 6 because of the unequal distribution of load occurring after web buckling. The maximum of 130.5 kips per sq in. computed for specimen 8A indicates the high bearing values attainable when lateral restraint is provided. Fig. 8 shows the rivet-hole distortions produced in two thicknesses of webs.

i. As indicated by the variation in rivet-hole distortions, the diagonal tensions developed after buckling were not uniformly distributed along the length of the flange and stiffener angles. Although no direct measure of their maximum intensity was obtained, the tensions corresponding to an average shearing stress of 24.4 kips per sq in. in specimen 8A were sufficient to produce fracture of the web at two rivet holes for an intermediate stiffener, as shown in Fig. 8, and also at the end rivet in the compression flange.

VI. Acknowledgments

The tests described in this paper were made at the Aluminum Research Laboratories in New Kensington, Pa., under the direction of R. L. Templin and E. C. Hartmann, Members, ASCE. The work has been sponsored for publication as a project of the Committee of the Structural Division on Design in Lightweight Structural Alloys.

SPACE RESECTION PROBLEMS IN PHOTOGRAMMETRY

By P. H. Underwood,[1] M. ASCE

With Discussion by Messrs. Earl Church, Ralph O. Anderson, G. H. Dell, and P. H. Underwood.

Synopsis

The paper gives a solution of the resection problem in space to find the position of a camera station and to obtain orientation data for a vertical photograph with a small amount of tilt by applying methods of mathematical calculation combined with some graphical work.

In solutions of this kind, approximate methods must be used for some of the steps. In this paper such approximations play an important part. The solution is based upon the use of two three-sided pyramids with a common vertex at the camera station, with sides in common planes, and with triangular bases—the one in the plane of the photograph and the other in the plane of the control points on the ground. The vertex angles of these pyramids are calculated by methods not very dissimilar to those commonly used. Then the lengths of the side edges of the ground pyramid are calculated, by use of the cosines of the base angles to expedite the work.

In solving next for the coordinates of the camera station, squared terms are introduced to make it easy to reach a precise solution by approximations. A method of "position circles" to obtain the elements of exterior orientation is developed and it is believed that this considerably facilitates this part of the solution. A method is also given for finding the tilt, swing, and azimuth of the principal line by mathematical calculations. A numerical example is added to illustrate the theoretical methods.

Theoretical Analysis

The determination of the elements of exterior orientation of a so-called vertical photograph is a problem that has received much consideration and has been treated in various ways. A useful list of references has been published

Note.—Published in September, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Prof., Surveying, School of Civ. Eng., Cornell Univ., Ithaca, N. Y.

by R. Hugershoff and H. Cranz.[2] Earl Church,[3] Assoc. M. ASCE, has also done considerable work on this subject in the United States. The writer proposes to outline a method, certain steps of which he believes to have advantages over other methods in current use.

The letter symbols are defined where they first appear, in text or by illustration, and are assembled alphabetically, for convenience of reference, in the Appendix.

The problem may be outlined thus: A vertical photograph of the ordinary type with a certain small angle of tilt is being analyzed. On this photograph are three points of control which are suitably located for determining the elements of exterior orientation; that is, points not near the center of the photograph and not close to one another. The rectangular coordinates of these three points with respect to axes on the photograph are known. The y-axis is vertical and the x-axis horizontal, the origin being at the principal point of the picture. Let these three points be designated a, b, and c (Fig. 1) with coordinates x_a, y_a, x_b, y_b, x_c, and y_c, respectively. Let the corresponding points on the ground be A, B, and C, whose known coordinates with respect to a coordinate system on the ground are X_A, Y_A, Z_A, etc. The focal length of the camera f has supposedly been determined by calibration and is known. The problem is to find the tilt i, the swing s, or angle made by the principal line with the y-axis on the photograph, the coordinates of the camera station on the ground control system, and the azimuth of the principal line on the ground-control system.

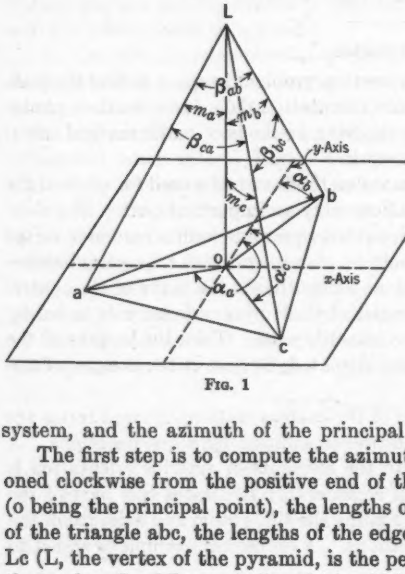

FIG. 1

The first step is to compute the azimuths on the plate α_a, α_b, and α_c, reckoned clockwise from the positive end of the y-axis, of the lines oa, ob, and oc (o being the principal point), the lengths of these lines, the lengths of the sides of the triangle abc, the lengths of the edges of the plate pyramid, La, Lb, and Lc (L, the vertex of the pyramid, is the perspective center, or lens center), and the angles aLo, bLo, and cLo which will be designated m_a, m_b, and m_c, respectively. Thus:

$$\tan \alpha_a = \frac{x_a}{y_a} \quad \text{(1a)}$$

$$\tan \alpha_b = \frac{x_b}{y_b} \quad \text{(1b)}$$

[2] "Grundlagen der Photogrammetrie aus Luftfahrzeugen," by R. Hugershoff and H. Cranz, Konrad Wittwer, Stuttgart, 1919.

[3] "Manual of Photogrammetry," Am. Soc. of Photogrammetry, 1944, Chapter XII.

and

$$\tan \alpha_c = \frac{x_c}{y_c} \qquad (1c)$$

Also,

$$\overline{\mathrm{oa}} = \sqrt{x^2_a + y^2_a} \qquad (2a)$$

$$\overline{\mathrm{ob}} = \sqrt{x^2_b + y^2_b} \qquad (2b)$$

and

$$\overline{\mathrm{oc}} = \sqrt{x^2_c + y^2_c} \qquad (2c)$$

As a check, $\overline{\mathrm{oa}} = \dfrac{x_a}{\sin \alpha_a} = \dfrac{y_a}{\cos \alpha_a}$, etc. Furthermore,

$$\overline{\mathrm{ab}} = \sqrt{(x_b - x_a)^2 + (y_b - y_a)^2} \qquad (3a)$$

$$\overline{\mathrm{bc}} = \sqrt{(x_c - x_b)^2 + (y_c - y_b)^2} \qquad (3b)$$

and

$$\overline{\mathrm{ac}} = \sqrt{(x_a - x_c)^2 + (y_a - y_c)^2} \qquad (3c)$$

Finally,

$$\overline{\mathrm{La}} = \sqrt{\overline{\mathrm{ao}}^2 + f^2} \qquad (4a)$$

$$\overline{\mathrm{Lb}} = \sqrt{\overline{\mathrm{bo}}^2 + f^2} \qquad (4b)$$

and

$$\overline{\mathrm{Lc}} = \sqrt{\overline{\mathrm{co}}^2 + f^2} \qquad (4c)$$

The next step is to solve for the angles aLb, bLc, and cLa at the vertex of the pyramid, calling these angles for brevity β_{ab}, β_{bc}, and β_{ca}, respectively. These calculations are somewhat similar to those described by Professor Church.[4] Solve for these angles by applying the cosine formula for a plane triangle in succession to the triangles aLb, bLc, and cLa. Thus,

$$\cos \beta_{ab} = \frac{-\overline{\mathrm{ab}}^2 + \overline{\mathrm{La}}^2 + \overline{\mathrm{Lb}}^2}{2\,\overline{\mathrm{La}} \times \overline{\mathrm{Lb}}} \qquad (5a)$$

$$\cos \beta_{bc} = \frac{-\overline{\mathrm{bc}}^2 + \overline{\mathrm{Lb}}^2 + \overline{\mathrm{Lc}}^2}{2\,\overline{\mathrm{Lb}} \times \overline{\mathrm{Lc}}} \qquad (5b)$$

and

$$\cos \beta_{ca} = \frac{-\overline{\mathrm{ac}}^2 + \overline{\mathrm{Lc}}^2 + \overline{\mathrm{La}}^2}{2\,\overline{\mathrm{Lc}} \times \overline{\mathrm{La}}} \qquad (5c)$$

Also solve for m_a, m_b, and m_c by the formulas:

$$\tan m_a = \frac{\overline{\mathrm{ao}}}{f} \qquad (6a)$$

$$\tan m_b = \frac{\overline{\mathrm{bo}}}{f} \qquad (6b)$$

and

$$\tan m_c = \frac{\overline{\mathrm{co}}}{f} \qquad (6c)$$

[4] "Manual of Photogrammetry," Am. Soc. of Photogrammetry, 1944, Chapter XII, p. 537.

These calculations may be checked by the formulas:

$$\sin m_a = \frac{\overline{\text{ao}}}{\text{La}}, \qquad \sin m_b = \frac{\overline{\text{bo}}}{\text{Lb}}, \qquad \text{and} \qquad \sin m_c = \frac{\overline{\text{co}}}{\text{Lc}};$$

or by

$$\cos m_a = \frac{f}{\text{La}}, \qquad \cos m_b = \frac{f}{\text{Lb}}, \qquad \text{and} \qquad \cos m_c = \frac{f}{\text{Lc}}.$$

The various steps in the solution that is to follow necessitate finding the coordinates with respect to the ground-survey system of the camera station L. After finding the coordinates of L the remainder of the solution includes finding the tilt, the swing, and the azimuth with respect to the ground-survey system of the principal plane of the photograph. It is now proposed to outline the various steps required to determine the coordinates of point L.

When the camera station L is connected to the three control points on the ground by the lines LA, LB, and LC a triangular pyramid may be considered to be formed with the vertex at point L and with the triangle ABC forming its base. The base of this pyramid will generally be inclined to the horizontal since the three control points are likely to be at different elevations.

The inclined lengths of the sides of the base may be calculated by the formulas:

$$\overline{\text{AB}} = \sqrt{(X_B - X_A)^2 + (Y_B - Y_A)^2 + (Z_B - Z_A)^2} \quad \text{.......(7a)}$$

$$\overline{\text{BC}} = \sqrt{(X_C - X_B)^2 + (Y_C - Y_B)^2 + (Z_C - Z_B)^2} \quad \text{.......(7b)}$$

and

$$\overline{\text{CA}} = \sqrt{(X_A - X_C)^2 + (Y_A - Y_C)^2 + (Z_A - Z_C)^2} \quad \text{.......(7c)}$$

For later use the horizontal lengths of these sides should also be computed by dropping the Z-terms from Eqs. 7. If the Z-differences are small, the calculations may be checked by the approximate formula,

$$(\text{Slope length}) - (\text{horizontal length}) = \frac{(Z\text{-difference})^2}{2\ (\text{horizontal, or slope, length})} \quad \text{..(8)}$$

A graphical solution to find approximate lengths of the lines LA, LB, and LC should now be made. To do this the angles β (Fig. 1) are laid off with a

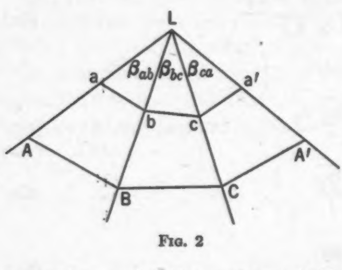

FIG. 2

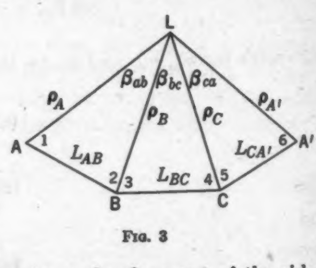

FIG. 3

protractor, or by the method of tangents, to give a development of the sides of the plate and ground pyramids, which have a common vertex and common side faces (see Fig. 2). The construction of the angles may be checked by

scaling off on these lines the distances La, Lb, and Lc, respectively, and then scaling from the drawing the lengths of ab, bc, and ca, and comparing with the previously calculated values.

To draw the base of the developed ground pyramid and thus determine the lengths of LA, LB, and LC the computer makes use of two conditions: First, that the lengths of the sides of this pyramid included between the lines La, Lb, Lc, and La′ must be equal in order to the corresponding inclined lengths AB, BC, and CA and, second, that the length of LA must be equal to that of LA′ since, of course, each represents the same edge of the ground pyramid. Graphically this problem cannot be solved directly but must be done by a trial-and-error method. After drawing AB to scale, parallel or approximately parallel to ab, strike an arc with radius equal to BC and center at point B to cut Lc at point C, and another arc with radius of length to scale equal to line CA, to cut La′ at point A′. If LA′ is not equal to LA (and it probably will not be) or nearly so, another trial may be made, starting at a point near A which is judged to meet the conditions more nearly. (A graphical method of finding the new position of point A, which, however, involves considerable labor, will be outlined subsequently.) In this way approximate lengths of LA, LB, and LC may be obtained, the precision of which will depend upon the scale of the drawing, the care with which the drafting is done, and the degree to which the approximation is carried. As a matter of fact the analytical solution which is to follow, although facilitated by having closely approximate values of LA, LB, and LC at the start, may be made from no more accurate initial values than can be found from the approximate relations $\frac{\overline{\text{LA}}}{\text{La}} = \frac{\overline{\text{AB}}}{\text{ab}} = \frac{\overline{\text{CA}}}{\text{ca}}$, to find the length LA, averaging to obtain a better result. The degree of approximation in the value of LA thus obtained is dependent, of course, upon the tilt of the picture and the differences in elevation between control points.

In Fig. 3 the radial lines are designated ρ and the angles at the base of the pyramid are numbered for simplicity. Beginning with the approximate value of LA found by one of the methods just outlined, ρ_A, ρ_B, ρ_C, and $\rho_{A'}$ are computed in turn from the known quantities, the slope lengths AB, BC, and CA or L_{AB}, L_{BC}, and $L_{CA'}$, and the known angles β at the vertex of the pyramid. Since it is desired also to determine values of the angles 1, 2, 3, 4, 5, and 6, Fig. 3, these calculations will be made by use of the sine law. Thus,

$$\sin \angle\,(2) = \frac{\rho_A \sin \beta_{ab}}{L_{AB}} \qquad \text{(9a)}$$

$$\angle\,(1) = 180° - [\beta_{ab} + \angle\,(2)] \qquad \text{(9b)}$$

and

$$\rho_B = \frac{\rho_A \sin \angle\,(1)}{\sin \angle\,(2)} = \frac{L_{AB} \sin \angle\,(1)}{\sin \beta_{ab}} \qquad \text{(9c)}$$

The sides ρ_C and $\rho_{A'}$ are then computed in turn, first solving for ρ_C from ρ_B and then for $\rho_A{}'$ from ρ_C by similar formulas.

Of course, the value of $\rho_{A'}$ should be equal to ρ_A but it almost certainly will not prove that way since the value of ρ_A is only approximate. This first solu-

tion may be considered a trial one from which the engineer may derive, by the method now to be developed, a more accurate one. If this second solution does not give a sufficiently close check between $\rho_{A'}$ and ρ_A, further trials, as needed, may be made to yield a final solution with any required degree of precision.

A relationship between small changes in ρ_A and corresponding changes in $\rho_{A'}$ may be established by the method of rates and differentials. In the triangle LAB, applying the cosine formula:

$$L^2_{AB} = \rho^2_A + \rho^2_B - 2\,\rho_A\,\rho_B \cos\beta_{ab} \dots\dots\dots\dots\dots (10)$$

In Fig. 3, L_{AB} and β_{ab} may be considered constant and ρ_A and ρ_B, variables. Then, $0 = 2\,\rho_A\,d\rho_A + 2\,\rho_B\,d\rho_B - 2\,\rho_A \cos\beta_{ab}\,d\rho_B - 2\,\rho_B \cos\beta_{ab}\,d\rho_A$; whence $\rho_B\,d\rho_B - \rho_A \cos\beta_{ab}\,d\rho_B = -\rho_A\,d\rho_A + \rho_B \cos\beta_{ab}\,d\rho_A$. Consequently,

$$\frac{d\rho_B}{d\rho_A} = -\frac{\rho_A - \rho_B \cos\beta_{ab}}{\rho_B - \rho_A \cos\beta_{ab}} \dots\dots\dots\dots\dots (11a)$$

Similarly, it can be shown that

$$\frac{d\rho_C}{d\rho_B} = -\frac{\rho_B - \rho_C \cos\beta_{bc}}{\rho_C - \rho_B \cos\beta_{bc}} \dots\dots\dots\dots\dots (11b)$$

and

$$\frac{d\rho_{A'}}{d\rho_C} = -\frac{\rho_C - \rho_{A'} \cos\beta_{ca}}{\rho_{A'} - \rho_C \cos\beta_{ca}} \dots\dots\dots\dots\dots (11c)$$

For simplicity, let the product of Eqs. 11 be

$$\frac{d\rho_B}{d\rho_A} \times \frac{d\rho_C}{d\rho_B} \times \frac{d\rho_{A'}}{d\rho_C} = \frac{d\rho_{A'}}{d\rho_A} = u \dots\dots\dots\dots\dots (12)$$

The constant u may be found from Eqs. 11 directly or it may be found more simply from a relationship between functions of the known angles 1, 2, 3, 4, 5, and 6, Fig. 3. From the triangles formed by dropping perpendiculars from points A, B, C, and A′ upon the adjacent lines from L—that is, upon LA, LB, LC, and LA′, Fig. 3—the numerators in Eqs. 11 are found to be: $L_{AB} \cos \angle$ (1), $L_{BC} \cos \angle$ (3), and $L_{CA'} \cos \angle$ (5), respectively, whereas the corresponding denominators are $L_{AB} \cos \angle$ (2), $L_{BC} \cos \angle$ (4), and $L_{CA'} \cos \angle$ (6). Substituting these values in Eq. 12, the lengths L cancel out and

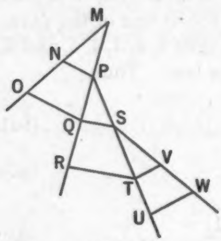

FIG. 4

$$u = \frac{d\rho_{A'}}{d\rho_A} = -\frac{\cos\angle(1)}{\cos\angle(2)} \times \frac{\cos\angle(3)}{\cos\angle(4)} \times \frac{\cos\angle(5)}{\cos\angle(6)} \dots\dots (13)$$

This value of u may be found graphically as follows: After making a trial graphical solution as already described (to make La′ = La in Fig. 2) draw a line MO, Fig. 4, and on this line lay off to any convenient scale MN equal in length to $L_{AB} \cos \angle$ (1) and NO equal to $L_{AB} \cos \angle$ (2) and on an intersecting

line MR lay off MP equal to $L_{BC} \cos \angle$ (4). Connect points N and P and draw line OQ parallel to line NP. Then by the well-known formula for proportionality of intercepts between parallel lines, $\overline{MN}/\overline{NO} = \overline{MP}/\overline{PQ}$. Now lay off QR equal to $L_{BC} \cos \angle$ (3), draw an intersecting line PU through point P, lay off PS equal to $L_{CA'} \cos \angle$ (5) and draw RT parallel to QS. Then $\overline{PS}/\overline{St} = \overline{PQ}/\overline{QR}$. By a similar construction lay off TU equal to $L_{CA'} \cos \angle$ (6), draw an intersecting line SW through point S and draw the parallel lines TV and UW. Then $\overline{ST}/\overline{TU} = \overline{SV}/\overline{VW}$.

By multiplying together the three sets of ratios just obtained, PQ and ST cancel out and $\dfrac{\overline{MN} \times \overline{PS}}{\overline{NO} \times \overline{TU}} = \dfrac{\overline{MP} \times \overline{SV}}{\overline{QR} \times \overline{VW}}$ or, rearranged,

$$\frac{\overline{SV}}{\overline{VW}} = \frac{\overline{MN} \times \overline{QR} \times \overline{PS}}{\overline{NO} \times \overline{MP} \times \overline{TU}} \qquad (14)$$

By construction, $\overline{MN} = L_{AB} \cos \angle$ (1), $\overline{QR} = L_{BC} \cos \angle$ (3), $\overline{PS} = L_{CA'} \cos \angle$ (5); $\overline{NO} = L_{AB} \cos \angle$ (2), $\overline{MP} = L_{BC} \cos \angle$ (4), and $\overline{TU} = L_{CA'} \cos \angle$ (6). Substituting these values in Eq. 14*a*, the ratio $\dfrac{\overline{SV}}{\overline{VW}}$ is found equal to u as expressed in Eq. 13. In other words, by dividing the scaled length of line SV by that of line VW in Fig. 4, the value of the ratio u is obtainable.

For infinitesimal changes in ρ_A and $\rho_{A'}$, $d\rho_{A'} = u\, d\rho_A$ and, for small changes of finite amount,

$$\Delta\rho_{A'} = u\, \Delta\rho_A \qquad (15a)$$

—approximately. To effect a solution of the given problem the two edges of the ground pyramid must be made equal—that is, in Fig. 3, LA′ must be made equal to LA. Thus,

$$\rho_A + \Delta\rho_A = \rho_{A'} + \Delta\rho_{A'} \qquad (15b)$$

In Eq. 15*b*, substituting for $\Delta\rho_{A'}$ its value from Eq. 15*a* and solving for $\Delta\rho_A$:

$$\Delta\rho_A = \frac{\rho_{A'} - \rho_A}{1 - u} \qquad (16)$$

It should be noted that usually when the control points have been properly chosen the angles, 1, 2, 3, 4, 5, and 6, will all be acute angles with positive cosines and thus u will be a negative quantity, and $\Delta\rho_A$ and $\Delta\rho_{A'}$ will be of opposite sign.

For use in graphical solutions (and, in fact, for analytical solutions except when a highly accurate solution is desired) $\Delta\rho_A$ and $\Delta\rho_{A'}$ may be found graphically in Fig. 4 by laying off SW equal in length to $\rho_{A'} - \rho_A$ before drawing the parallel lines UW and TV. Then line SV will be equal, to scale, to $\Delta\rho_{A'}$ and VW to $\Delta\rho_A$. The signs may be noted separately.

After finding the corrections to ρ_A and $\rho_{A'}$ as indicated, a corrected value of ρ_A may be found and a second solution for ρ_B, ρ_C, and $\rho_{A'}$ carried through in the same way as the first—that is, either graphically or analytically—to reach more accurate results than in the first. Unless a very precise solution is required, a third approximate solution will usually not be necessary. Any sub-

sequent solution after the first may be checked approximately as ρ_B and ρ_C are found, because the corrections to the old values of these quantities to obtain the new ones may be found, from the value of $\Delta\rho_A$ used, by the relationships:

$$\Delta\rho_B = -\frac{\cos \angle (1)}{\cos \angle (2)} \Delta\rho_A \ldots\ldots\ldots\ldots\ldots\ldots (17a)$$

and

$$\Delta\rho_C = -\frac{\cos \angle (3)}{\cos \angle (4)} \Delta\rho_B \ldots\ldots\ldots\ldots\ldots\ldots (17b)$$

After two approximate solutions have been made a third one may be made, to give highly precise results, by using the values of u obtained in the first two solutions to compute an average value of this as ρ_A changes from its value obtained in the second solution to a predicted value to be obtained by a third solution. Thus u will change a certain amount as ρ_A changes from its first value to its second. Using the value of u from the second solution the value of ρ_A is calculated for a third solution. Assuming that, as ρ_A changes, u changes in proportion, a value of u may be calculated for the proposed third solution. Then the change in ρ_A may be recalculated by using a value of u which is an average of the value after the second solution and the value obtained in the manner mentioned for a third solution. Unless u is changing rapidly this value should lead to a value of ρ_A which is close to the true value.

Favorable and Unfavorable Positions of the Three Control Points.—As previously stated, control points should be well separated on the photograph, preferably located so as to form a nearly equilateral triangle when adjoining pairs are connected, with the principal point near the center of the triangle. Under these circumstances the angles 1 to 6, Fig. 3, will be acute angles whose cosines are of considerable size and not changing very rapidly. Furthermore, the value of u will be nearly unity and will not change rapidly as ρ_A is modified from one approximate solution to the next. If one of the angles 1 to 6 should be a right angle or nearly so, the solution would be much more unstable, because the cosine would be zero, or very small, and would be changing at a rapid rate with any modification of sides in effecting a solution. One side might be changed by a considerable amount without changing an adjoining one very appreciably. Thus small errors in the coordinates of the control points, or small errors in the solution, might result in large errors in the calculated lengths of the edges of the ground pyramid.

Coordinates of Station L.—Having determined the values of LA, LB, and LC, the next step in the solution is to obtain the coordinates, in space, of the camera station L. If X_L, Y_L, and Z_L represent these coordinates and if the formula for finding the distance between them is applied (see Eqs. 7):

$$(X_L - X_A)^2 + (Y_L - Y_A)^2 + (Z_L - Z_A)^2 - \overline{LA}^2 = 0 \ldots\ldots (18a)$$

$$(X_L - X_B)^2 + (Y_L - Y_B)^2 + (Z_L - Z_B)^2 - \overline{LB}^2 = 0 \ldots\ldots (18b)$$

and

$$(X_L - X_C)^2 + (Y_L - Y_C)^2 + (Z_L - Z_C)^2 - \overline{LC}^2 = 0 \ldots\ldots (18c)$$

Since it is impractical to solve Eqs. 18 directly for the unknown X_L, Y_L, and Z_L, approximate methods must be used again. A graphical or analytical solution of the three-point problem may be used to obtain approximate values of X_L and Y_L. This solution utilizes the angles about the principal point on the picture as approximations of the corresponding angles in the map plane about the vertical point, or horizontal projection of the camera station. In the graphical method the three control points are plotted on a map by the use of their coordinates; after taking off the three lines oa, ob, and oc, from the photograph, on a piece of transparent paper, cloth, or celluloid, the transfer is slipped around on the map until the three lines pass through the corresponding mapped points. The principal point is then pricked through to give the approximate location, in plan, of the camera station from which to scale off the approximate values of X_L and Y_L. Those who have a calculating machine available and are familiar with the method of solving for the coordinates of a point by the three-point problem, working directly from the coordinates of the control points, very likely can make an analytical solution more quickly than they can the graphical one, unless the points have already been mapped. No very exact solution need be made (nor can it be made) in either case, since the horizontal angles are only approximately known.

A sufficiently accurate value of Z_L may be known from the height of flight or from that of an adjoining photograph in the same flight. If not thus known it may be calculated to a sufficient degree of accuracy in the following way by comparing distances on the map with corresponding ones on the photograph. The distances OA, OB, and OC from the camera station O, to each of the control points, in turn, are scaled on the map. Then, approximately,

$$Z_L - Z_A = \frac{\overline{\mathrm{OA}} \times f}{\overline{\mathrm{oa}}} \qquad \text{(19a)}$$

$$Z_L - Z_B = \frac{\overline{\mathrm{OB}} \times f}{\overline{\mathrm{ob}}} \qquad \text{(19b)}$$

and

$$Z_L - Z_C = \frac{\overline{\mathrm{OC}} \times f}{\overline{\mathrm{oc}}} \qquad \text{(19c)}$$

Since the method is approximate there will be discrepancies in the values of Z_L obtained from Eqs. 19. An average may be taken.

Next, let $X_L = X_{LO} + \Delta X$, $Y_L = Y_{LO} + \Delta Y$, and $Z_L = Z_{LO} + \Delta Z$, in which X_{LO}, Y_{LO}, and Z_{LO} are the approximate values of the coordinates of the camera station just found and ΔX, ΔY, and ΔZ are corrections to these to obtain the true values X_L, Y_L, and Z_L. By substituting these values of X_L, Y_L, and Z_L in the three simultaneous equations already written and combining and simplifying numerical values three simultaneous equations in ΔX, ΔY, ΔZ are obtained, as follows:

$$a_1 \Delta X + b_1 \Delta Y + c_1 \Delta Z + \tfrac{1}{2}(\Delta X^2 + \Delta Y^2 + \Delta Z^2) + q_1 = 0 \qquad \text{(20a)}$$

$$a_2 \Delta X + b_2 \Delta Y + c_2 \Delta Z + \tfrac{1}{2}(\Delta X^2 + \Delta Y^2 + \Delta Z^2) + q_2 = 0 \qquad \text{(20b)}$$

and

$$a_3\,\Delta X + b_3\,\Delta Y + c_3\,\Delta Z + \tfrac{1}{2}\,(\Delta X^2 + \Delta Y^2 + \Delta Z^2) + q_3 = 0 \ldots\ldots (20c)$$

In Eqs. 20,

$$a_1 = X_{LO} - X_A \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21a)$$

$$b_1 = Y_{LO} - Y_A \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21b)$$

$$c_1 = Z_{LO} - Z_A \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21c)$$

and

$$q_1 = \tfrac{1}{2}\,(a^2{}_1 + b^2{}_1 + z^2{}_1 - \overline{\mathrm{LA}}^2) \ldots\ldots\ldots\ldots\ldots\ldots (21d)$$

Corresponding terms in Eqs. 20 are written similarly. If good approximations have been made to the true values of the coordinates of the camera station, ΔX, ΔY, and ΔZ will be relatively small quantities and the further solution will be simplified. However, by the approximate method about to be explained a solution for ΔX, ΔY, and ΔZ, accurate to a high degree of precision, may be made without excessive labor even though the approximation in coordinates is not close. To simplify Eqs. 20 assume that $\tfrac{1}{2}(\Delta X^2 + \Delta Y^2 + \Delta Z^2) = k$ and write

$$a_1\,\Delta X + b_1\,\Delta Y + c_1\,\Delta Z + k + q_1 = 0 \ldots\ldots\ldots\ldots (22a)$$

$$a_2\,\Delta X + b_2\,\Delta Y + c_2\,\Delta Z + k + q_2 = 0 \ldots\ldots\ldots\ldots (22b)$$

and

$$a_3\,\Delta X + b_3\,\Delta Y + c_3\,\Delta Z + k + q_3 = 0 \ldots\ldots\ldots\ldots (22c)$$

Eqs. 22 are now to be solved for ΔX, ΔY, and ΔZ. The first step is to eliminate ΔZ between Eq. 22*a* and Eq. 22*b* and then between Eq. 22*a* and Eq. 22*c*, each time finding coefficients for the *k*-terms. This will result in two simultaneous equations in ΔX and ΔY in which there will be *k*-terms. Usually the coefficients of *k* will be small because the *c*-coefficients are likely to be nearly of the same magnitude, since Z_L is large compared with the differences in elevation between the control points. Next eliminate ΔY between the equations just found, again carrying through the coefficients of *k*. Neglecting *k*, solve for ΔX and then for ΔY and ΔZ by substituting back in the preceding equations. With these values of ΔX, ΔY, and ΔZ compute a value of *k* and then solve again, correcting this time for the value of *k*. This will result in a closer approximation to the values of ΔX, ΔY, and ΔZ. If considered necessary a new value of *k* can be found and the substitution made for a third solution, and similarly for other solutions, to approach values as precise as necessary. It will be found, however, that a rapid approach to true values is made by this method. The addition of these values to X_{LO}, Y_{LO}, and Z_{LO}, respectively, gives X_L, Y_L, and Z_L, which may be checked if desired by substituting back into Eqs. 18.

Let the angles between the vertical LV and each of the lines, LA, LB, and LC, in turn be designated M_A, M_B, and M_C, respectively. (Point V is the vertical intersection in the XY-plane). Then

$$\cos M_A = \frac{Z_L - Z_A}{\mathrm{LA}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (23a)$$

$$\cos M_B = \frac{Z_L - Z_B}{\mathrm{LB}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (23b)$$

and

$$\cos M_C = \frac{Z_L - Z_C}{\overline{LC}} \qquad (23c)$$

It will be necessary later to know the azimuths in the ground-survey system of the lines VA, VB, and VC, which may as well be found at this time. The azimuth of line VA, say α_A, may be found from the formula

$$\tan \alpha_A = \frac{X_A - X_V}{Y_A - Y_V} \qquad (24)$$

and α_B and α_C, the azimuths of lines VB and VC, are found by similar formulas. As a check on the computed values of M_A, M_B, and M_C, find the length of VA, by the formula,

$$\overline{VA} = \frac{X_A - XL_L}{\sin \alpha_A} = \frac{Y_A - Y_L}{\cos \alpha_A} \qquad (25)$$

The lengths VB and VC are determined by similar formulas. Next compute M_A, M_B, and M_C by the formulas:

$$\tan M_A = \frac{\overline{VA}}{Z_L - Z_A} \qquad (26a)$$

$$\tan M_B = \frac{\overline{VB}}{Z_L - Z_B} \qquad (26b)$$

and

$$\tan M_C = \frac{\overline{VC}}{Z_L - Z_C} \qquad (26c)$$

Elements of Exterior Orientation.—It is now proposed to develop a method of finding the elements of exterior orientation by an application of position circles, thus finding the tilt and the swing of the photograph and the azimuth on the ground-survey system of the principal plane. Thus in Fig. 5, length Lo is the principal distance or (as it is usually called) the focal length f, whereas o is the principal point and v is the vertical point on the photograph. The principal line is ov. In the ground datum plane point V is the nadir point, or vertical point, and O is the intersection of the camera axis with the ground plane. The swing s is the plate azimuth of the principal line ov reckoned clockwise from the positive end of the y-axis on the photograph. Line VO is the intersection of the principal plane with the datum plane or ground plane and its azimuth (α_{VO}) reckoned, say, from the north, is an element of exterior orientation. One of the points of control, A, is photographed at point a and point A′ is the intersection of line LA with the datum plane. Similar points for the control points B and C are shown at b, c, B′, and C′. From calculations already made m_a, m_b, m_c, M_A, M_B, and M_C are known as well as the azimuth angles on the plate α_a, α_b, α_c and these on the ground α_A, α_B, and α_C. The solution of this problem requires the determination of the tilt of the photograph, i, which is equal to the angle oLv or OLV, the swing, s, and the azimuth of the principal plane, α_{VO}.

To facilitate this solution a sphere is taken with its center at the camera station L. Although the radius might be made any arbitrary length, in this case it is taken equal to the focal length. Hence, the plane of the picture will be tangent to the sphere at point o. The various lines and planes through

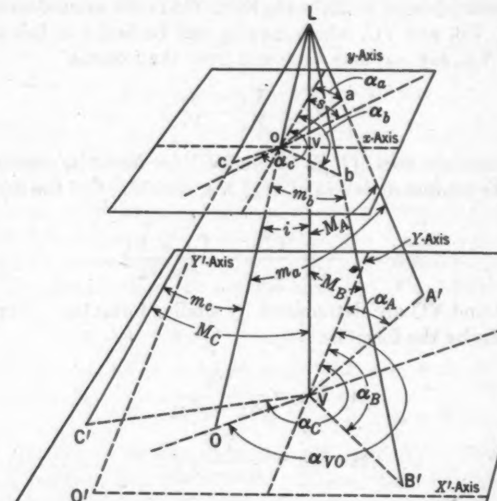

FIG. 5

point L may be considered to intersect the surface of the sphere and thus give points and arcs upon it. As yet the position of v is unknown because it has not been established with respect to point o; nor has the position of point O been established on the ground-control system. It is known, however, that on the surface of the sphere the distances in arc from point o to points a, b, and c as projected onto the sphere by the radial lines are equal, respectively, to m_a, m_b, and m_c and that point V on the sphere must lie at arc distances of M_A, M_B, and M_C from points a, b, and c, respectively. Therefore, if position circles are drawn on the sphere with points a, b, and c, respectively, as centers using in turn the arcs M_A, M_B, and M_C as radii, point V must lie at their intersection. To show these circles requires a projection similar to an azimuthal equidistant map projection with point o as the center, and with points a, b, and c placed in correct azimuthal relationships. The latter are in the plane of the picture and at distances from point o equal to their actual distances in arc from that point on the sphere. Fig. 6 is such a projection to be considered as showing relationships seen from the inside of the sphere. The lines oa, ob, and oc are drawn so as to reproduce their directions on the photograph and their lengths in arc (equal, respectively, to m_a, m_b, and m_c) are laid off to a certain linear scale, as for instance one millimeter equals one degree. Using the same scale, if arcs are struck with a, b, and c as centers and with M_A, M_B, and M_C,

respectively, as radii, these circles will be represented on the projection fairly accurately in the region of particular interest (the region in the vicinity of point o) and will thus fix, by their intersection, approximately the position of the vertical point v (see Fig. 6). However, for small values of the tilt such as are encountered in well-taken vertical photographs, the distance vo is short

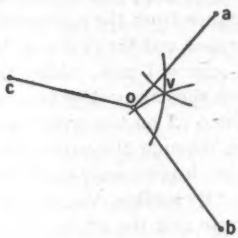

FIG. 6

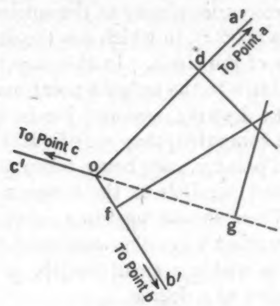

FIG. 7

compared to lengths oa, ob, and oc, and neither its length nor its direction will be well established by this method of construction. For a better determination, the scale of the projection will be much enlarged to show only the area in the vicinity of points o and v and, therefore, with points a, b, and c, no longer available as centers of arcs. Thus in Fig. 7 by use of the coordinates of the points a, b, and c in the photograph, or in some other way, lay off the lines oa′, ob′, and oc′ to represent the lines radiating from point o to points a, b, and c. It is known that the position circle with its center at point a and with its radius of M_A cuts line oa′ at a distance equal to $m_a - M_A$ from point o. This intersection will be on the same side of point o as point a′ if $m_a - M_A$ is plus, but on the opposite side of point o from a′, and, therefore, on a′o extended, if $m_a - M_A$ is minus. Therefore (see Fig. 7) line od is laid off equal to $m_a - M_A$ to a large scale such as 1 mm = 1 min. In this illustrative example, od is laid off on line oa, since it is assumed that M_A is smaller than m_a; and at point d a perpendicular to line oa′ is erected. The perpendicular to od at d is the tangent to the position circle at that point and may be considered to represent approximately the position circle for a short distance on either side of this point. Similarly, line of is laid off along line ob′, and line og along line oc′ extended, equal in length, respectively, to $m_b - M_B$ and $m_c - M_C$. (If the difference such as $m_a - M_A$ is plus, it is laid off from point o in the direction of the point; whereas if it is minus, as in the case of line og, it is laid off in the opposite direction or on the line extended.) Perpendiculars to lines ob′ and oc′ are drawn at points f and g to represent the tangents to the position circles through those points. While the position circles, if they could be accurately drawn, would meet in a point, the perpendiculars will meet in pairs to give three points of intersection and what may be considered a triangle of error. By considering that the arcs would lie on the same side of the tangents that the control points

do, one may spot the approximate location of point v. Then, by scaling off the length of line ov and its direction with respect to the y-axis, values of i and s may be obtained.

By a small amount of computation and further construction work, an accurate location of point v may be obtained. Thus it is known that for some little distance from the point of tangency of a circle the offset from the tangent to the circle varies closely as the square of the distance along the tangent; and is equal to $h^2/(2\,r)$, in which h is the distance from the point of tangency and r the radius of the circle. In this case the distance from the approximate location of point v to the tangent point may be scaled and the radius is M_A to the scale of the drawing, assumed herein to be 1 mm = 1 min. After the offsets have been computed, they may be laid off from their respective tangents in the vicinity of point v, care being taken to lay them off on the proper side of the tangent, and parallels to the tangents drawn through the extremities of the offsets. These should meet in a point or, if not, leave a very small triangle of error to fix point v in either case very closely. By scaling, the tilt should then be found to within a small fraction of a minute and the swing s to within a small fraction of a degree.

By considering the construction to be in the ground plane with the sphere tangent at the vertical point, a similar construction centering on point V gives a check solution for i and makes it possible to scale off the value of α_{VO}, which should be as accurate as the value previously found for s.

Mathematical Solution.—Of course graphical methods may be avoided in finding i, s, α_{ov}, and α_{VO} by using a mathematical method based on the application of spherical trigonometry. Consider the lines Lo, Lv, La, Lb, and Lc to be prolonged from the center of the sphere at point L, Fig. 5, until they intersect the surface of the sphere; and suppose these points to be connected with arcs of great circles to form the construction sketched in Fig. 8. The arcs ab,

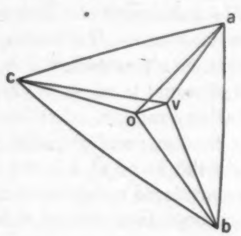

Fig. 8

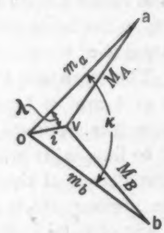

Fig. 9

bc, and ac are equal, respectively, to β_{ab}, β_{bc}, and β_{ca}, the angles at the common vertex of the plate and the ground pyramid. Solving this triangle, formed by points a, b, and c, one can find its interior angles. Also arcs oa, ob, and oc are equal, respectively, to the known angles m_a, m_b, and m_c. Angles aob, boc, and aoc can be found from the plate azimuths. By the sine law one may then solve by spherical trigonometry to find the angles at points a, b, and c in the triangles aob, boc, and aoc. Similarly, knowing that arcs av, bv, and cv are equal,

respectively, to M_A, M_B, and M_C, and finding the angles avb, bvc, and avc from the azimuths on the ground system of lines VA, VB, and VC, one may solve for the angles at points a, b, and c, in the triangles avb, bvc, and avc. Then in the triangle avo, for instance, the sides av and ao are known; the angle vao is the difference between angles bav and bao. A solution may then be made for the length vo or i and for the angles at points v and o. From these angles the azimuth of line ov, or s, can be found by adding the angle aov to the plate azimuth of line oa; and the azimuth of line vo on the ground-survey system may be obtained by subtracting the angle avo from the azimuth of line VA on the ground system. The solution may be checked by similar use of the triangles bvo and ovc, one or both. These calculations are rather long and tedious and are not likely to check very well unless extended to a number of decimal places either by natural functions or by logarithms, since the angles at points a, b, and c in the triangles oav, obv, and ovc are small.

The following method may be adopted to check the values of i, s, and avo and to obtain them to a higher degree of precision. Consider two of the three triangles involving the line vo (say, aov and bov with the side vo or i, Fig. 9, in common). The sides ao, bo, av, and bv are known accurately to be equal to m_a, m_b, M_A, and M_B, respectively. The value of $\overline{\text{vo}}$ is known approximately from the graphical solution. For simplicity let the angle boa, which is known, be designated by κ and the angle aov, which is known only approximately, be designated by λ; then:

$$\cos M_A = \cos m_a \cos i + \sin m_a \sin i \cos \lambda \qquad (27a)$$

and

$$\cos M_B = \cos m_b \cos i + \sin m_b \sin i \cos (\kappa - \lambda) \qquad (27b)$$

By solving each equation for sin i and equating values,

$$\sin i = \frac{\cos M_A - \cos m_a \cos i}{\sin m_a \cos \lambda} = \frac{\cos M_B - \cos m_b \cos i}{\sin m_b \cos (\kappa - \lambda)} \qquad (28a)$$

which may be written

$$\frac{\cos (\lambda - \kappa)}{\cos \lambda} = \frac{\sin m_a (\cos M_B - \cos m_b \cos i)}{\sin m_b (\cos M_A - \cos m_a \cos i)} \qquad (28b)$$

Since $\cos (\lambda - \kappa) = \cos \lambda \cos \kappa + \sin \lambda \sin \kappa$:

$$\cos \kappa + \tan \lambda \sin \kappa = \frac{\sin m_a (\cos M_B - \cos m_b \cos i)}{\sin m_b (\cos M_A - \cos m_a \cos i)} \qquad (28c)$$

Solving for $\tan \lambda$:

$$\tan \lambda = \left[\frac{\sin m_a (\cos M_B - \cos m_b \cos i)}{\sin m_b (\cos M_A - \cos m_a \cos i)} - \cos \kappa \right] \frac{1}{\sin \kappa} \qquad (29)$$

From the graphical solution, i is known approximately. Therefore, since i is small and the cosine changes but slowly for changes in the angle, cos i may be considered to be known closely. All other quantities involved in the right-hand

member of Eq. 29 are known; and by substitution in this equation an approximate value of λ can be determined, a value accurate enough for all practical purposes. Eqs. 28 can then be solved for i from its sine, giving a close approximation to the true value of i. The swing s may be obtained by adding λ to the direction of line ao. By the sine law the angle avo may be found, and this value, subtracted from the azimuth of line VA, will give α_{VO}. Thus, i, s, and α_{VO} may be determined to a high degree of precision by computations supplementing the graphical solution.

Azimuths from Measurements of Photographs.—Another application of "position circles" is in finding azimuths from the vertical point on the ground as functions of directions from the principal point to points on the photograph. If this is done for a point showing in the overlapping part of two photographs whose elements of orientation have been found, the data may be used to compute the coordinates and elevation of the point. Thus, let position q be any point on a vertical photograph. Suppose that the coordinates of this point on the photograph are x_q and y_q. The direction of line q measured on the photograph may then be scaled, or computed from the relation that

$$\tan \alpha_q = \frac{x_q}{y_q} \qquad (30)$$

Solve also for the angle m_q at the vertex of the pyramid.

On the diagram from which line ov, or i, was originally determined, or on a new diagram such as Fig. 10, lay off the line oq′ in the direction of point q,

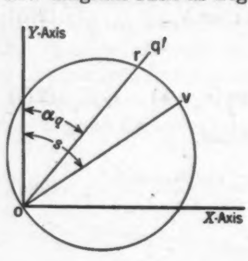

FIG. 10

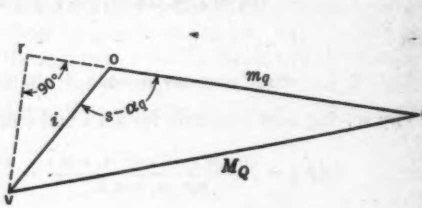

FIG. 11

making the angle between line oq′ and the y-axis equal to α_q. Also draw the line ov (if it has not already been drawn), laying off its length to the same scale that was formerly used in determining line ov or using a similar large scale such as 1 mm = 1 min or arc. If many points are to be dealt with, a circle should now be constructed on line ov as a diameter. The chord formed by the intersection of the line (prolonged if necessary) and the circle (line or in Fig. 10) is scaled, as is also the chord rv—say, in minutes of arc to the same scale as line ov. The distance ro gives the approximate difference between M_Q and m_q. A more accurate value of this difference may be found by correcting by an amount equal to $\frac{\overline{vr}^2}{2\,M_Q}$ in which $\overline{vr}$ and M_Q are both expressed in minutes of arc. The correction in this case should be added to $\overline{ro}$ to derive a more accurate value

of the difference $M_Q - m_q$. By adding this difference to m_q the distance M_Q may be found. In the triangle voq, Fig. 11,

$$\frac{\sin \mathrm{v}}{\sin (s - \alpha_q)} = \frac{\sin m_q}{\sin M_Q} \quad \text{(31}a\text{)}$$

and

$$\frac{\sin \mathrm{q}}{\sin (s - \alpha_q)} = \frac{\sin i}{\sin M_Q} \quad \text{(31}b\text{)}$$

The angles v and q can be determined by Eqs. 31.

An alternative solution, which may be made with the slide rule or computing machine, is to consider the right triangle rvq, Fig. 11, and to use the formula—

$$\sin \mathrm{q} = \frac{\sin \overline{\mathrm{rv}}}{\sin M_Q} \quad \text{(32)}$$

—to find the value of q. The spherical excess, in minutes, (e) of triangle voq may be found approximately by using the formula,

$$e = \frac{\pi}{21{,}600} \times \overline{\mathrm{rv}} \times \overline{\mathrm{mq}} \quad \text{(33)}$$

in which $\overline{\mathrm{rv}}$ and m_q are to be expressed in minutes of arc. Then $<$ ovq is the difference between $(180 + e)$ and $(s - \alpha_q + <\text{ovq})$. The azimuth of the arc Vq is obtained by adding the angle ovq to the azimuth α_{vo} of arc VO. If a map is under construction, after the vertical points have been plotted, radial lines to points such as q can be laid off with the protractor, or the coordinates of points suitably placed for intersections can be computed. By scaling or computing, the horizontal distance from the located points to the camera stations can be found and, by using angles such as M_Q, the elevation may be determined either graphically or by calculation. For the point q the difference in elevation between it and the camera station is equal to the horizontal distance times the cotangent of M_Q. This completes the determination of the coordinates of point q.

Numerical Example

To demonstrate the application of theory by a numerical example, a 7-in. by 9-in. photograph is selected for the purpose of determining the elements of orientation. This print designated ART-3-14 was one of a series taken for the Agricultural Adjustment Administration, U. S. Department of Agriculture, which covers an area well controlled by ground surveys. On this photograph three control points A, B, and C, well located for the purpose, were chosen; their coordinates, referred to axes through the principal point (center) of the photograph, were measured by a method that was fairly precise. These coordinates, x and y, were determined to hundredths of a millimeter. The ground coordinates came from triangulation and traverse surveys for the X and Y, and from spirit leveling for the Z. They are expressed in feet, with the Z-coordinates giving the elevations above sea level, as shown in Table 1. The

lengths of AB, BC, and CA, and the horizontal and slope distances in Table 1, were computed by aid of a computing machine from the survey coordinates by use of the formulas in the first part of this paper (see Eqs. 7 and 8).

TABLE 1.—COORDINATES OF CONTROL POINTS; HORIZONTAL AND SLOPE DISTANCES

Description	Point A	Point B	Point C
Ground Coordinates, in Feet:			
X	35,900.2	27,420.5	36,541.0
Y	5,890.9	15,924.9	16,481.3
Z (elevations above sea level)	1,238.4	1,384.6	1,348.9
Map Coordinates, in Millimeters:			
x	−26.88	+102.69	−33.11
y	+74.57	− 70.70	−83.16
Horizontal distances, in feet	13,137.23	9,137.46	10,609.77
Slope distances, in feet	13,138.03	9,137.53	10,610.34

Calculations are now made from the coordinates of the points on the photograph and the focal length f, which is known to be 209.55 mm, to determine the azimuths (α in line 2, Table 2) from the principal point to the control points.

TABLE 2.—AZIMUTHS FROM PRINCIPAL POINT TO CONTROL POINTS; ANGLES AT VERTEX

Line	Quantity	Point a	Point b	Point c
1	Tan $\alpha = x/y$	0.36046668	1.45247525	0.39814815
2	Azimuth, α	340° 10′ 39″	124° 32′ 48″	201° 42′ 36″
3	$x^2 + y^2$	6,283.2193	15,543.7261	8,011.8577
4	Distance, $\sqrt{x^2 + y^2}$	79.267	124.675	89.509
5	$x_2 - x_1$	+129.57	−135.80	+6.23
6	$y_2 - y_1$	−145.27	− 12.46	+157.73
7	$l^2 = (x_2 - x_1)^2 + (y_2 - y_1)^2$	37,891.7578	18,596.8916	24,917.5658
8	Length, l	194.655	136.370	157.853
9	$x^2 + y^2 + f^2$	50,194.42	59,454.93	51,923.06
10	Slope distance ($\sqrt{\text{line } 9}$)	224.041	243.834	227.866
11	Sin m	0.353806	0.511311	0.392814
12	Tan m	0.378272	0.59465	0.427149
13	Angle m	20° 43′ 13″	30° 45′ 04″	23° 07′ 47″

The distances ab, bc, and ca on the picture, and the slope distances La, Lb, and Lc, are given in lines 8 and 10, Table 2. The angles between Lo and each of the lines La, Lb, and Lc, in turn, are given in line 13, Table 2. As a check, these angles are found from their tangents and checked by their sines.

The vertex angles aLb, bLc, and cLa, Fig. 2, are now computed by applying Eqs. 5, in turn, to each of the three triangles aLb, bLc, and cLa, the sides of which are known. The foregoing calculations do not differ greatly from those used by Professor Church[4]. Thus, by Eq. 5a:

$$\cos \beta_{ab} = \frac{-37{,}891.7578 + 50{,}194.4218 + 59{,}454.9286}{2 \times 224.041 \times 243.834}$$

$$= \frac{71{,}757.5926}{109{,}257.6264} = 0.65677422;$$

$\beta_{ab} = 48° 56' 44''.46$; and $\sin \beta_{ab} = 0.75408730$. Similarly, by Eq. 5b, $\cos \beta_{bc} = 0.83494086$; $\beta_{bc} = 33° 23' 25''.15$; and $\sin \beta_{bc} = 0.55033968$. Finally, by Eq. 5c, $\cos \beta_{ca} = 0.75610098$; $\beta_{ca} = 40° 52' 42''.00$; and $\sin \beta_{ca} = 0.65445494$.

The next step in the solution is to find values of LA, LB, and LC, and for this purpose it is necessary to have an approximate value of one of these, say, of LA $= \rho_A$, to use in the solution. This approximate value may be found in any one of several ways. A simple one is to consider the lines ab, bc, and ca to be parallel, respectively, to AB, BC, and CA, and to solve by proportion considering the face triangles to be similar. In this example a somewhat more precise method, partly graphical and partly by calculation, which will not be described, was used. The approximate value of LA found by this method was 15,234 ft. Using this value the calculations shown below were made. Referring to Fig. 3: AB $= L_{AB} = 13{,}138.03$; BC $= L_{BC} = 9{,}137.53$; CA $= L_{CA'} = 10{,}610.34$. Substituting these values of L and β in Eqs. 9: $\sin \angle (2) = 0.87439016$ and $\angle (2) = 60° \; 58' \; 22''.38$; $\angle (1) = 180° - \beta_{ab} - \angle (2) = 70° \; 04' \; 53''.16$; and $\sin \angle (1) = 0.94017777$. By Eq. 9c, $\rho_B = 16{,}380.18$. By similar adaptations of Eqs. 9 values of ρ_C and $\rho_{A'}$ are found to be 15,169.91 and 15,213.49, respectively. As this is done, angles 3, 4, 5, and 6 are found to be, respectively, 66° 00′ 58″.40, 80° 35′ 36″.45, 69° 46′ 52″.82, and 69° 20′ 25″.18. By substitution of values of the cosines of angles 1 to 6 in Eq. 13 it is possible to compute u as $-0.7021 \times 2.4873 \times 0.9795 = -1.7105$, which, by Eq. 15a, is equal to $\dfrac{\Delta\rho_A'}{\Delta\rho_A}$.

As stated in connection with Eq. 15b, $\Delta\rho_{A'}$ and $\Delta\rho_A$ are the corrections to be applied to $\rho_{A'}$ and ρ_A, respectively, to make them equal; thus, $15{,}234 + \Delta\rho_A = 15{,}213.49 + \Delta\rho_{A'}$ and $\Delta\rho_A = \Delta\rho_{A'} - 21.51$. As computed by Eq. 15a, $\Delta\rho_{A'} = -1.7105\,\Delta\rho_A$; and, thus, $2.7105\,\Delta\rho_A = -21.51$ and $\Delta\rho_A = -7.567$. Also $\Delta\rho_B = -0.7021\,\Delta\rho_A = +5.313$, $\Delta\rho_C = +1.7463\,\Delta\rho_A = -13.214$, and $\Delta\rho_{A'} = -1.7105\,\Delta\rho_A = +12.943$. Applying these corrections to the previously computed values of ρ, the following corrected values of these quantities are: $\rho_A = 15{,}226.43$, $\rho_B = 16{,}385.49$, $\rho_C = 15{,}156.70$, and $\rho_{A'} = 15{,}226.43$.

A recalculation of these quantities (which is not shown herein for lack of space) showed that these results were practically correct, the value of ρ_B checking exactly, that of ρ_C within a tenth, and that of $\rho_{A'}$ within two one hundredths. These values have been computed to more significant figures than would be warranted in practice in order to show that the solution may be extended to a high degree of precision by the method outlined.

To set up the equations for solving for the coordinates in space, X_L, Y_L, and Z_L of the camera station, it is necessary to have approximate values of these coordinates. A graphical solution of the three-point problem, under the assumption that the photograph is vertical, gives approximate values of X_L and Y_L. The third coordinate, Z_L, may be found by use of the m-angles, and values of ρ to obtain three values of Z_L, which are then averaged to derive the value to be used. In this case a somewhat more accurate method was used but will not be explained.

The approximate values used and the resulting equations and solution for finding the corrections to these are presented in Table 3(a).

7	+1	+0.05958	0	0	− 6.9562
8	0	+1.23843	0	0	+ 5.2920

The equations A, B, and C, Table 4, are the original Eqs. 22 from which Eqs. 1, 2, and 3 are derived by dividing each in turn by its ΔZ-coefficient. Eq. 4, Table 4, is obtained by subtracting Eq. 1 from Eq. 2; and Eq. 5 is similarly obtained by subtracting 3 from 2. This eliminates ΔZ. A similar elimination of ΔX gives Eq. 8, which may be solved for ΔY. Substitutions in Eqs. 6 and 1 of Table 4 give ΔX and ΔZ; thus: $\Delta Y = \dfrac{-5.2920}{1.23843} = -4.273$; $\Delta X = +12.248 - 5.037 = +7.211$; and $\Delta Z = -2.406 + 1.615 + 0.734 = -0.057$.

Since k is equal to $\frac{1}{2}(\Delta X^2 + \Delta Y^2 + \Delta Z^2)$ these terms are negligible in this case, and have been neglected. By making a solution without them and then computing a value of k to be substituted, a fairly exact solution is possible even when ΔX, ΔY, and ΔZ are large.

By applying the corrections just found to the approximate values of the coordinates, the following final values are found for the camera station L: $X_L = 34{,}463.2$; $Y_L = 11{,}245.2$; and $Z_L = 15{,}419.7$.

The angles, M_A, M_B, and M_C, which the lines LA, LB, and LC make with the vertical, are computed by Eq. 23, as shown in Table 3(b). The values of X_L, Y_L, and Z_L may be checked as was done in this case by applying the formulas for computing distances from coordinate difference (Eqs. 7 and 18) to obtain values of LA, LB, and LC from the quantities in Table 3(b). These calculations are not shown.

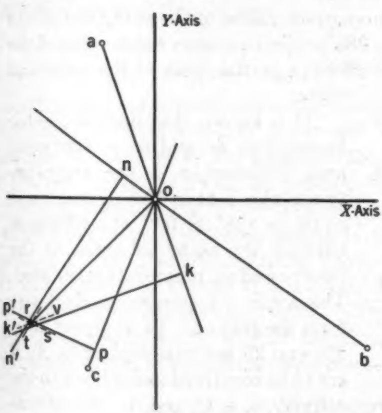

FIG. 12

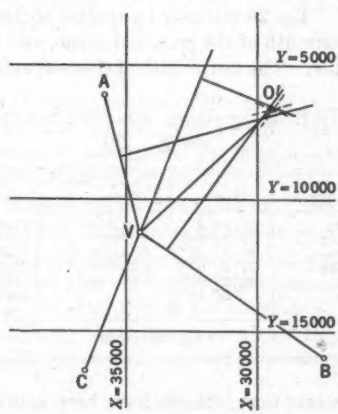

FIG. 13

The vertical point of the photograph is now found in Fig. 12, which is drawn similarly to Fig. 7. The distances ok, on, and op are laid off equal to $m_a - M_A$, $m_b - M_B$, and $m_c - M_C$, respectively, using a scale of 1 mm = 1 min of arc. In Fig. 12, the three perpendiculars kk′, nn′, and pp′ instead of meeting in a point form, by their intersections, a triangle rst that may be called a triangle of error or, more accurately, the "triangle of the tangents." It is known that v, the point sought, lies in or near this triangle in such a position that its distances

from the perpendiculars kk′, nn′, and pp′ are proportional to the squares of the distances from the lines oa, ob, and oc, respectively. With this in mind a point was spotted as a trial position of v. (This is not shown in Fig. 12 but was near the position shown for v.) By the method previously explained these offsets are calculated and laid off from their respective lines to locate some parallel lines, shown dotted, which should meet at the required point, v. In this case a small triangle of error was found, within which the point v was located by estimation. The distance ov was scaled and found to be 86.8 min or 1° 26′.8, which is the tilt i. The direction of ov, clockwise from the y-axis, was found by scaling to be 225° 55′. This is the swing.

The azimuth of the principal plane is found by aid of Fig. 13, which represents a map upon which the positions of A, B, C, and V are plotted by their coordinates to a scale of 1 in. = 1,000 ft. By a construction similar to that in Fig. 12, the point O′ where the camera axis prolonged would meet the map plane is found. The scaled length O′V gives the tilt, and the azimuth of VO′, (from the south in this case) gives the azimuth of the principal plane. The value of the tilt was found to be 1° 26′.8 (checking that previously determined) and the azimuth of the principal plane was found to be 227° 40′.

As an indication of the precision of the method of Table 3(c) it may be stated that an analytical method gave the following values: i = 1° 26′ 47″; swing, s = 225° 59′ 35″; and the azimuth of the principal plane, α_{VO} = 227° 24′ 23″. Thus the tilt checked exactly, the swing within 5 min, and the azimuth of the principal plane within 15 min.

Eq. 29 will now be applied to find more exact values of the swing and of the azimuth of the principal plane, and Eq. 28a to obtain a more exact value of the tilt. The use of both of these equations affords a partial check on the numerical work.

TABLE 5.—DATA FOR THE SOLUTION OF EQ. 29

Symbol	Angle	Sine	Cosine
m_a	23° 07′ 47″	0.392814	0.919618
M_A	21° 49′ 09″	0.371678	0.928362
m_b	20° 43′ 13″	0.353806	0.935319
M_B	21° 21′ 07″	0.364096	0.931361
κ	138° 28′ 03″	0.663045	−0.748580
i	1° 26′ 48″[a]	....	0.999681

[a] Approximately

It is known that line ov lies between lines oc and oa in this case; and, therefore, κ is the angle between the latter two lines, or is equal to 138° 28′ 03″, the difference between the plate azimuths of the lines oc and oa, previously calculated. The angle λ is measured clockwise from the line oc. In applying Eqs. 28a and 29 the subscripts a, b, A, B are to be construed as applying to the points that hitherto have been called, respectively, c, a, C, and A. Substituting, in Eq. 29, appropriate values from Table 5:

$$\tan \lambda = \left[\frac{0.392814\ (0.931362 - 0.935021)}{0.353806\ (0.928362 - 0.919325)} + 0.748580\right] \frac{1}{0.663045} = 0.451161.$$

Therefore: λ = 24° 16′ 59″; $\sin \lambda = 0.411245$; $\cos \lambda = 0.911525$; $\kappa - \lambda$ = 114° 11′ 04″; and $\cos(\kappa - \lambda) = -0.409675$. Similarly, for the solution of Eq. 28a: By the first equality—

$$\sin i = \frac{0.009037}{0.358060} = 0.025239 \text{ and } i = 1^\circ\ 26'\ 47''$$

and, by the second equality—

$$\sin i = \frac{-0.003659}{-0.144945} = 0.025244$$

The latter value checks the former value, although the first of the two expressions in Eq. 28*a* is probably the more exact since it is derived from larger quantities. The swing is found by adding the angle λ to the plate azimuth of line oc and is thus found to be 225° 59′ 35″.

It remains to find the azimuth of the principal plane. This may be done by solving for the angle at point v in the triangle ocv by using the sine law and then subtracting this angle from the azimuth of line VC. The latter azimuth is found by the coordinate differences between the X-ordinate and Y-ordinate of the vertical point V and those of point C. These coordinates of point V are the same as those of the camera station L.

Thus, sine $\overline{ovc} = \dfrac{\sin \lambda \sin m_a}{\sin M_A} = 0.434631$ and $\angle\ \overline{ovc} = 154° 14' 17''$. Tan $\alpha_{VC} = \dfrac{X_C - X_V}{Y_C - Y_V} = \dfrac{+2{,}077.8}{+5{,}236.1} = 0.396822$ and α_{VC}, the azimuth of line VC, = 21° 38′ 40″. By subtracting the angle ovc from α_{VC} the azimuth of the principal plane is found to be 227° 24′ 23″. Thus, as previously stated, the tilt found by this more exact method checks the value found by the graphical method to 0.1 min, the swing checks within 5 min, and the azimuth of the principal plane within 15 min.

Summary

It is believed that the main contribution of this paper lies in the use of the cosines of the base angles of the ground pyramid to obtain a rapid solution in finding the lengths of the edges of this pyramid, and in the application of "position circles" in fixing the position of the vertical point, first on the photograph and then on the map. Although the method of solving equations of the second degree such as those arising in finding the coordinates of the camera station by approximations, using Taylor's theorem as a basis, is well known, it is thought that the use of a constant k to represent the sum of the squares of the corrections is an innovation. The special application of the methods of spherical trigonometry to find the tilt, the swing, and the azimuth of the principal plane, it is believed, also has some merit.

APPENDIX. NOTATION

The following letter symbols are introduced in this paper. Discussers are requested to adapt their comments to these letters to avoid confusion of concept. In general, ground-point locations and line designations are not italicized, single letters in italics being used to designate quantities that can take a numerical equivalent. In designating points or lines small letters refer to

locations on the map or photograph and capital letters are the corresponding points or lines on the ground

a = a mathematical coefficient (with b and c in Eqs. 20, 21, and 22);
b = a coefficient (see a);
c = a coefficient (see a);
e = spherical excess;
f = focal length of a camera;
h = a distance along a tangent to a circle, measured from the point of tangency;
i = tilt angle of a photograph;
k = a substitution constant (see Eq. 22);
L = length between traverse points measured on the ground;
l = length between traverse points measured on the map or photograph, corresponding to L;
M = angle to any ground object from a vertical through the lens center (see Fig. 5);
m = angle to any map or photograph object, measured from the plate perpendicular, corresponding to M (see Fig. 1);
q = a substitution constant (see Eq. 22);
r = radius of a circle;
s = swing, or angle made by the principal line, with the Y-axis;
u = a constant (see Eq. 12);
X = variable distances parallel to the X-axis, as observed on the ground; ΔX = correction to be applied to an X-value;
x = variable distances on a map or photograph corresponding to X;
Y = variable distances parallel to the Y-axis, as observed on the ground; ΔY = correction to be applied to a Y-value;
y = variable distances on a map or photograph corresponding to Y;
Z = variable value of height or ground elevation; ΔZ = correction to be applied to an elevation;
α = azimuth from the y-axis in the xy-plane, or from the Y-axis in the XY-plane, the direction line being denoted by appropriate subscript;
β = face angles of a triangular pyramid, the particular face being shown by appropriate subscript;
κ = an angle boa (Fig. 8) in a plane that is tangent to a sphere at point o;
λ = an angle aov (Fig. 8) in a plane that is tangent to a sphere at point o; and
ρ = radial distances from the lens center to ground points designated by appropriate subscripts.

DISCUSSION

Earl Church,[5] Assoc. M. ASCE.—Although this paper is entitled "Space Resection Problems in Photogrammetry," in reality it gives a solution of the space orientation problem (finding certain quantities or elements which serve to specify uniquely the orientation of the aerial photograph in space) as well as of the space resection problem (finding the survey space coordinates of the exposure station). These two problems are often treated together, as has been done by Professor Underwood.

In this paper the space resection problem has been approached by the often tried but seldom used pyramid method—determining the desired position of the exposure station by the lengths of the pyramid edges. The particular solution of this problem is very interesting, especially the use of Eq. 13 for finding the ratio u representing $d\rho_{A'}/d\rho_A$.

The method has two detractive features: (1) The solutions of the triangles forming the pyramid faces are tedious, inasmuch as they must always be made twice and often three times; and (2) the completion of this phase of the problem gives only the corrected lengths of the pyramid edges, still leaving the desired survey coordinates of the exposure station undetermined.

The part of the computation for finding these coordinates, simple as it is in principle, involving only the solution of the three simultaneous Eqs. 18, is, of course, troublesome in practice. Professor Underwood proposes a solution by approximations involving two preliminary computations, one consisting of the three-point problem in a plane and the other of the simple scale problem of photogrammetry. He then solves Eqs. 18, by the use of k as explained in the text following Eqs. 22 and cited in the "Summary." Possibly the straightforward algebraic solution of Eqs. 18 (of three spheres) with no preliminary computations, might even be more time saving than this method of approximations.

In either case, Professor Underwood's solution of the space resection problem is interesting; and, although perhaps somewhat longer than the usual space-analytics method, it is certainly not long enough to be impracticable.

Then space orientation is considered. The solution shows an interesting method of determining both the intersection of the photo plane with the vertical line through the exposure station and the survey position of the intersection of the camera axis with the ground plane. The former obviously determines at once the tilt and the swing, and the latter determines indirectly the azimuth of the principal plane of the photograph. The graphical determination of these two points, despite the large-scale drawings (Figs. 12 and 13), leaves something to be desired. What appear to be "triangles of error" in these graphs, as Professor Underwood states, must not be regarded as triangles of error, as far as errors in either control surveying or photographic measuring are concerned. They are triangles of error in either the analytical or the graphical phases of the computation itself.

[5] Prof. of Photogrammetry, College of Applied Science, Syracuse Univ., Syracuse, N. Y.

On the whole, Professor Underwood's solution of the space orientation problem is of considerable interest because of the manner in which it attacks essential features of the problem. However, instructive as it is, the method compares unfavorably with several equally precise space-analytics methods in both simplicity and time required for the computations.

Professor Underwood's illustrative computation, although entirely correct, scarcely does justice to his method. The initial values for the desired quantities in his solution, obtained by methods of approximation, are much nearer to the correct values than would ordinarily be available in actual practice. This result might cause suspicion regarding convergence of the solution, should less accurate initial values be used. However, in the writer's experimental work with Professor Underwood's method, the solutions have been found to converge very satisfactorily under far less favorable conditions than those shown in the paper.

It must always be remembered that only by consideration of all the various solutions advanced can the most practical methods be evolved for handling these complex problems in practice. Professor Underwood's paper, therefore, deserves thorough reading and careful consideration by all photogrammetrists.

RALPH O. ANDERSON,[6] Assoc. M. ASCE.—The noteworthy fact about the work reported by Professor Underwood is the solution of the space equations without resorting to partial differential calculus (Eqs. 22). The implications of the foregoing statement are of technical importance in more ways than one. The advantages thus gained are as follows: High tilt in high relief may be computed with the same amount of work as that required for low tilt in low relief; and the method is considerably more simple in both derivation and application than the calculus method.[7] The first innovation consists of developing the ground pyramid for the purpose of determining the lengths of the three pyramid edges (LA, LB, and LC, Fig. 1). The suggested method will yield the correct lengths when the calculus method of adjustment is applied.

However, the graphical method will yield fairly close results. It was found that with careful drafting these pyramid edge lengths could be determined graphically within 10 ft. The errors were found to be 5-ft, − 4 ft, and 10 ft for the three edges. For example, lay off the sloping ground lengths on three transparent strips to some convenient scale, such as 1 in. equals 1,000 ft. Starting at a random point on leg A determine length A′ by fitting the sloping ground lengths between their respective pyramid edges. Repeat the operation using the starting length (leg A) equal to $\frac{1}{2}$ (LA + LA′), and repeat until LA equals LA′. This repetition is quite simple and can be done rapidly. Errors as great as 10 ft should not cause more than a 3-min tilt error. This is quite permissible in photogrammetry.

It was also found unnecessary to assume that k vanishes to zero in Eq. 22. Starting with a graphically determined exposure station expressed as a function of the principal point (letting k equal zero): $\Delta X = 252.22$, $\Delta Y = 262.20$, and $\Delta Z = -6.52$. The resulting exposure station coordinates are: $X_L = 34{,}463.22$, $Y_L = 11{,}245.20$, and $Z_L = 15{,}424.48$. Repeating the solution and letting

[6] Mathematician II, TVA, Chattanooga, Tenn.

[7] "Manual of Photogrammetry," Am. Soc. of Photogrammetry, 1944, Chapter XII, p. 536.

$k = 66{,}964$: $X_L = 34{,}463.20$, $Y_L = 11{,}245.25$, and $Z_L = 15{,}419.74$. These values agree precisely with the values computed by means of Professor Church's method.[7]

Professor Underwood's method of determining the tilt, when the exposure station coordinates are known, is excellent; but his method of adjustment is not clear to the writer. By referring to Figs. 5 and 12, it should be obvious that angles m_a and M_A do not lie on the same plane. Therefore, the incremental difference cannot be plotted on line ao extended (Fig. 12) without introducing an error. However, there is nothing else to do but plot the angles on their respective principal point radials. Consequently the three raised perpendiculars will not intersect at a common point. Therefore, it is necessary to apply an adjustment. Using the approximate v-position (Fig. 12) as a point within the triangle of error, compute a tilt and swing. Locate the nadir point v ($f \tan t$ from o) on the photograph (contact size). Drop perpendiculars from v to the three radials (oa, ob, and oc). Measure the lengths of these dropped perpendiculars (w) and also the lengths from the foot of these dropped perpendiculars to their respective control points (a, b, and c) and denote them as l. The angle M_A, when projected to oa, then becomes:

$$M'_A = M_A \left(\frac{l}{\frac{w^2}{2\,l} + l} \right) \qquad \text{(34)}$$

For radial ao: $M_A = 1{,}281.1$; $l = 3.2$ in.; and $w = 0.18$ in. Therefore,

$$M'_A = 1{,}281.1 \left(\frac{3.2}{3.20506} \right) = 1{,}279.08 \text{ min of arc}$$

$$m_a = 1{,}243.22$$

$$m_a - M'_A = -\,35.86 \text{ min of arc.}$$

Using the revised value (M'_A, M'_B, and M'_C), the raised perpendiculars intersect to form a very small triangle of less than 0.01 in. in depth. All other data being correct, this would mean a tilt error of only 0° 00′ 15″, which is negligible. In large nadir throws or large tilts, possibly a second or third repetition would be needed to make the triangle of error vanish.

It is hoped Professor Underwood will treat this matter in his closing discussion.

Determination of Tilt.—For purposes of comparison a numerical example of computations to determine tilt by the "dropped perpendicular" method[8] is presented in Table 6.

Values under "First Determination" pertain to the initial computation using the principal point as the argument. Under "Second Determination," point v and the tilt i are used as arguments. Datum ratios (Table 6(a)) in the first determination are obtained by dividing the datum scales S_d by S_{do}. The value of S_{do}(1,723 ±) is determined by interpolating (visually) the datum scales (situated at their respective scale-point positions) into the principal point. The ratios of the second determination are determined as a function of the three computed tilt-axis scales (S_{di}), one for each check line. The computed tilt-axis

[8] "Applied Photogrammetry," by Ralph O. Anderson, Edward Bros., Inc., Ann Arbor, Mich.

scale for a given line is:

$$S_{di} = \frac{S_d}{1 \pm M_1 \tau} \qquad (35)$$

in which M_1 is the normal distance from the tilt axis to its corresponding scale

[a] In addition to the notation of the paper: P is the photographic length of the check line; D is the horizontal ground distance; $S_p = D/P$; t is the tilt angle; S_{di} is the tilt axis scale; R_H, R_{int}, and R_L represent the highest, intermediate, and lowest datum ratios, respectively; l' represents the length between the scale points conforming to R_L and R_H; and l represents l' projected normal to the line of constant ratios. The lengths l' and l are determined graphically when the datum scales are computed.

point and τ equals the sine of the tilt angle divided by f. The mean of the three S_{di}-values (1,723.789) is used as S_{di}. Accordingly, for a given check line,

$$R_d = \frac{S_d}{S_{di}} \text{ (average)} \qquad (36)$$

The flying height above sea level is equal to H = (average) $S_{di}(f)$ + datum elevation = 15,421.3 ft. This is in error 1.6 ft.

The results of the first determination would generally be accepted in most photogrammetric work. The tilt and swing error is only 0° 05′ and 1° 00′, respectively. However, the second determination, which can be computed in a few minutes, will yield more accurate results. The resulting errors of tilt and swing (of the second determination) are 0° 01′ and 0° 40′, respectively. In

addition, a more accurate determination is possible by applying the corrections, ΔM, ΔM_e, and h_e. These corrections are not needed in the current example because of the low tilt and relief.

When horizontal and vertical control is to be extended (without the aid of ground surveys except at flight ends) by means of computed tilts, elevations, and flying heights, all refinements must be used. A method of control extension (horizontal and vertical) is possible, using a triple parallax differential equation in conjunction with various expedients. This method is exact mathematically, but lends itself to a rapid graphical determination. The graphic errors introduced are well within the allowable tolerance. These tests were made on hypothetical examples. The photographic lengths were used to the nearest thousandth of an inch (computed) but all work from there on was performed graphically wherever possible. In a stereoscopic model of 6.5 sq miles, it was found that the maximum error in horizontal or vertical position was about 3 ft. When all values are computed to seven decimal places, the resultant position errors are less than a thousandth of a foot. The latter is really not an error but a difference due to fact that figures beyond the seventh decimal places were ignored. The method is then numerically proved.

The triple parallax differential equation consists of conjugate differences of three values which are readily determined graphically. Some simple arithmetical computations are also needed in the course of computing the elevation difference between two image points.

Professor Underwood's paper is most welcome, as diversified methods of spatial mathematics of the photogrammetric problem are practically nonexistent. The only precedent is the solution conceived by Professor Church, cited by the author.[7] Therefore, a comparison of Professor Underwood's method (A) against Professor Church's method (B) is unavoidable.

The early objective of method (A) is to determine the correct lengths of the three ground pyramid edges. These lengths can be determined graphically with a surprising degree of accuracy and also by means of a calculus adjustment. The graphically determined lengths will be close enough for all practical purposes. Knowing the correct (or nearly correct) pyramid edges, Eqs. 22 (method A) are solvable without excessive work. This solution is a near approach to a direct solution even though it consists of two parts—(1) letting k equal zero; and (2) inserting the value of k. When the value of k is inserted, the resolution is quite simple as only the constant terms are refactored.

The spatial equations in method (B) are mathematically correct but the complexity forbids a direct solution. Therefore, the partial differential calculus method of adjustment is employed. The approximate exposure station coordinates are obtained by means of the well-known, graphical three-point method. These coordinates conform approximately to the principal point ground values.

The exposure station coordinates, as initially used, are then in error. These errors, which are solved for as differentials, vary as the magnitude of the tilt. By definition, a differential is the smallest assignable value of the variable approaching zero as a limit. Therefore, differential equations express precise conditions only when the variable approaches zero as a limit. As these differentials grow in magnitude, the accuracy of the differential condition diminishes.

By this reasoning the number of repetitions required by method (B) varies as the magnitude of tilt. As before stated, the equations of method (A) are in error initially as k is dropped. However, when it is inserted the initial error vanishes at a rapid rate. Re-solution is quite simple as only the constant terms are affected and they alone are factored by the same initial factors. It may then be said that method (A) is more efficient than method (B) in solving for the exposure station. However, it must be remembered that method (A) utilizes the lengths of the three pyramid edges. Therefore, in order to compare the two methods it is necessary to contrast the efficiency (ease of computation) of determining the lengths of the pyramid edges (A) against the two different exposure station computations. Method (A) will probably be more efficient than method (B). The latter would be definitely so if the pyramid edges were determined graphically and if a tolerance of from 3 min to 5 min were allowed on the tilt. The graphical method of determining tilt, method (A), is decidedly more efficient than method (B). The tilt (using exact pyramid lengths) could be determined graphically within 0° 0′ 30″ by method (A).

The general trend in photogrammetric analysis leans toward the promotion of streamlined procedures in the general direction of extending horizontal and vertical control without the aid of ground surveys other than at the flight ends. Much has been done in this direction.

G. H. Dell,[9] Assoc. M. ASCE.—The graphical methods in this paper, supplemented in places by numerical calculations, provide a comparatively rapid determination of the required orientation data. The accuracy of the solution should prove adequate in most instances, particularly with the refinements afforded by Eqs. 29 and 28*a*. The author's adaptation of the theory of the line of position is noteworthy as a step in extending this concept to new fields.

The writer has found that the angles 1 to 6, Fig. 3, can be obtained fairly rapidly, to the nearest second, by the use of six-place log sines (see Eqs. 9). For the numerical example given by the author the equations are as follows:

$$\log \sin \angle(5) = \log \sin \angle(2) + 31{,}259 \ldots\ldots\ldots\ldots (37a)$$

$$\angle(6) = 139°07'18'' - \angle(5) \ldots\ldots\ldots\ldots (38a)$$

$$\log \sin \angle(3) = \log \sin \angle(6) - 10{,}350 \ldots\ldots\ldots\ldots (37b)$$

$$\angle(4) = 146°36'35'' - \angle(3) \ldots\ldots\ldots\ldots (38b)$$

$$\log \sin \angle(1) = \log \sin \angle(4) - 20{,}909 \ldots\ldots\ldots\ldots (37c)$$

$$\angle(2) = 131°03'15'' - \angle(1) \ldots\ldots\ldots\ldots (38c)$$

[9] Asst. Prof., Civ. Eng., Univ. of Illinois, Urbana, Ill.

To begin with, an approximate value of $\angle(2)$ is used. This quantity may be found by the graphical method described by Professor Underwood (see Fig. 2), or may be obtained from the following equation, in which it is assumed that the photograph is without tilt:

$$\angle \text{LBA} = \angle \text{Lba} - \sin^{-1} \frac{\sin i_{BA} \sin \text{Lba}}{\cos m_b} \ldots\ldots\ldots\ldots (39)$$

in which i_{BA} is the inclination of line BA with respect to the horizontal (positive for upward inclination). The values obtained by the writer for $\angle$LBA ($= \angle 2$) were: By the graphical method, 62°00′; and, by Eq. 39, 60°51′44″. The solution shown in Table 7, which verifies that presented by the author, begins with the former value. Quantities obtained from Eqs. 37 and Eqs. 38 are shown in parentheses in Table 7.

α_{VO}...	$\alpha_{VO} = \alpha_{VB} - (90° - \angle \text{fbv})$	227°23′49″

A method consisting primarily of plane trigonometry was used by the writer to check the calculation of the coordinates of L and V, and the results agreed within 0.1 ft, on the average, with those given by the author. Accordingly, in the calculation of i, α_{ov}, and α_{VO}, by a similar procedure, the author's data were used. Referring to Fig. 14, the vertical distances of points a, b, and c, with respect to point L—denoted by p_a, p_b, and p_c, respectively—were computed and the horizontal line be was located. Line fo is the trace of a vertical plane through point L perpendicular to line be. Point o is the principal point of the photograph, and point v is the vertical projection of point L on the horizontal plane through line be. Angle fbv is a horizontal

angle, whereas angle fbo lies in the plane abc, the inclination of which is i_{f_o} = the tilt, i. The equations and numerical results are given in Table 8, and again it will be seen that the author's solution is substantially verified.

In the course of these calculations it was noted that a relatively small error in the β-angles had a pronounced effect on the calculated coordinates of points L and V. The writer would like to inquire whether Professor Underwood has made an estimate of the probable error of these coordinates, in the example in question, assuming that the solution is without error other than in the determination of the coordinates of the control points on the photograph.

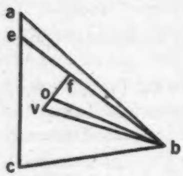

Fig. 14.

Attention is called to the fact that the computation of the angle λ, shown beneath Table 5, is accurate to only four significant places. Using the numerals given in brackets, the writer obtained 0.451024 as the value of the tangent, corresponding to an angle of 24°16′36″. The value obtained by the use of six-place logarithms was 24°14′53″, and, by seven-place natural functions, 24°16′19″. The solution in Table 8 involves a similar weakness, although to a lesser extent.

This paper deals with a very interesting problem, and the author has presented a commendably clear and well-written treatment.

P. H. Underwood,[10] M. ASCE.—Since the paper was written with the idea that it might be of interest theoretically and with the hope that it might be of some practical value, it was expected that the methods outlined would be compared with other methods, as has been done in the interesting discussions. Professor Church's method has been used to a considerable extent in practice. As a result, routine procedures have been established to facilitate calculations. It is possible that the writer's method could be simplified by a more careful arrangement of the work and by certain approximations in the calculations.

As stated in the paper, the calculations and the final results were carried out to more decimal places than would be warranted by any practical application. With an exposure interval of 1/100 sec in taking a photograph and with a plane speed of 200 miles per hr, the camera would move some 3 ft during the exposure. Considering this and also the errors from other sources, such as lens errors and the precision required in coordinates for mapping purposes, there would seem to be little value in determining results to fractions of a foot. As Mr. Anderson has stated, a graphical solution to obtain the lengths of the edges of the ground pyramid yields values within a few feet. Following this, a single solution by calculation of the plate pyramids should generally yield results of sufficient accuracy for practical purposes, especially if corrections are made by the cosine multipliers.

[10] Prof. of Surveying, School of Civ. Eng., Cornell Univ., Ithaca, N. Y.

Mr. Anderson's solution using scale check lines to determine tilt, swing, and height of camera station is interesting. The writer has been much interested in this method and its modification by Jack Rihn[11] and has published a paper[12] on this subject, which leads to a fairly exact solution even under such adverse conditions as high relief and considerable tilt. It is believed that this method may be still further extended to give quite accurate solutions for space coordinates of exposure stations.

In his discussion Mr. Anderson raises questions relative to determining tilt when the exposure station coordinates are known, stating that the writer's method of adjustment is not clear to him. To attempt to clarify this point requires considerable explanation.

It should be considered that the position circles involved in the solution are on the surface of a sphere. Since the graphical solution must be made on a plane surface, it is necessary to apply some form of projection. In this case a "zenithal" projection was used, with the center of the projection at the principal point o and with points on this projection located at distances in proportion to their arc distances on the sphere and in directions corresponding to those on the sphere from the point of tangency o. This procedure necessarily introduces some distortion, which has not been investigated, but which is believed to be small in its effect on the use to be made of the projection.

On the sphere it is known that the distances from v (the point where the vertical from the exposure station L cuts the sphere) to a, b, and c are equal to M_A, M_B, and M_C, respectively. On the projection this condition would be true to a high degree of approximation if the tilt is small, since these distances would be measured nearly radially from o.

When the plotting of the projection is done to a large scale (as in Fig. 12), the radii of the "position circles" become so large that it would be impractical to draw them with centers and a beam compass. Thus, M_B is equal to 31° 04′ or to 1,864 min of arc. At the scale of the original drawing for Fig. 12 (1 mm = 1 min), the radius of the circle would be about 75 in.—that is, line no, if drawn to scale, would be more than 6 ft long. It is known that the center of this circle at b is at a distance from o equal to m_b with m_b less than M_B by 19.0 min. Thus, n, at the relatively short distance of 19.0 min to scale from o on the line ob, is the point where the position circle with b as center would cut that line. Consequently the perpendicular nn′ is the tangent to this circle at n. Similarly, perpendiculars kk′ and pp′ are tangents. Compared with the radii of the position circles, these tangents are short and approximate to their respective circles. They should not meet in a point but the "triangle of tangents" formed with their points of intersection as vertices should be small and should aid in closely approximating, as explained in the paper, the point where the circles would intersect, or point v. Computed offsets from the tangents give an even closer approximation to the point sought. Thus, the tangents, giving

[11] "Manual of Photogrammetry," Am. Soc. of Photogrammetry, 1944, p. 274.

[12] "The Determination of Tilt from Scale Check Lines," by P. H. Underwood, *Photogrammetric Engineering*, March, 1947, pp. 143-155.

what was termed first a "triangle of error" and then "the triangle of the tangents," should not meet in a point theoretically, whereas the position circles should: (1) Meet if drawn on the sphere; and (2) fail to meet by only a small amount (which has not been evaluated but which for small tilts should certainly be small) if drawn on the projection. The position of each one of these three circles in the vicinity of the point sought can be found closely by use of the offsets from the tangents as shown in the paper, thus obtaining a close approximation to the vertical point.

DESIGN OF PLYWOOD I-BEAMS

By Howard J. Hansen,[1] Assoc. M. ASCE

With Discussion by Messrs. Dick W. Ebeling, I. Oesterblom, C. J. Hogue, Sidney Novick, and Howard J. Hansen.

Synopsis

The general formulas and methods presented herein are applicable to I-sections and box sections of various dimensions, but the M/f-values and W-values presented in Figs. 2(*a*) and 2(*b*) are based on a flange width of five times the web thickness and a flange depth of ten times the web thickness for I-beams. Eq. 12, which is also based on these ratios, is not applicable for other values; but, by substituting any other ratios in Eqs. 10*a*, 10*b*, and 11, a similar expression may be derived.

Since the greatest problem in designing any I-beam or box section is the determination of stiffener spacing, a method is suggested based on the application of a formula for isotropic materials.

No attempt has been made to determine the most efficient section with unequal flanges. From Eq. 2, as the depth of the compression flange increases the form factor increases. Accompanying this is an increase in I/C, up to a certain point, and these two factors will increase the strength in bending.

Introduction

The use of Douglas fir plywood webs and solid or laminated wood flanges for large I-beams is a comparatively recent development. The assembly consists of a plywood web of standard construction with the flanges and stiffeners fastened to the web by glue, bolts, or bolts and connectors. Plywood girders built up in this manner have several distinct advantages over the usual type of heavy timber construction; for example:

1. Larger cross sections and lengths can be manufactured than are available as single pieces;

2. The girder can be constructed so that highly stressed parts contain pieces with the least number of defects, and lower grades of lumber and plywood can be used elsewhere;

Note.—Published in June, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Associate Prof., Civ. Eng., Agri. and Mech. College, College Station, Tex.

3. The girder is composed of relatively small pieces, which are rapidly seasoned, and green lumber and shrinkage effects are at a minimum; and
4. The members are easily fabricated and erected.

The design of a plywood girder involves several factors that are not normally considered in the design of solid members. For instance, the shear between the flange and the web will often determine the depth of the flange. If the flange is glued to the web, the allowable unit shear at this point is one eighth of the allowable unit horizontal shear for the plywood web. The allowable horizontal shear stress is 240 lb per sq in. and the allowable web-flange shear is 30 lb per sq in. These values decrease as the grade of plywood is reduced below a 100% grade. Descriptions of the various grades of Douglas fir plywood, as well as other valuable data, are available elsewhere.[2] Since the unit horizontal shear is eight times the web-flange shear, the depth of a flange glued to the web should be eight times the thickness of the web when the full allowable shear is developed in the web. In preparing the design curves for this paper, the depth of the flange was taken as 10 b_w, b_w being the web thickness.

Because horizontal shear will govern the design of plywood girders except for very long spans, it seems unnecessary to make the flange width greater than 5 b_w. Based on this flange width, the fiber stress is approximately six times the horizontal shear stress and the allowable fiber stress in bending will not be reached until the length of the girder is about sixteen times the depth. Of course, by adding material to the flanges, the girder can be designed to carry a greater load. With these factors known, the design of a plywood girder becomes fairly easy. The difficult features are found in the design of splices and the placement of stiffeners.

Notation

The letter symbols in this paper are defined where they first appear, in the text or by illustration, and are assembled alphabetically in the Appendix for convenience of reference.

Flexure

Before the allowable fiber stress can be used in the customary flexure formula—

$$f = \frac{M\,c}{I} \qquad (1)$$

—it must be reduced by a factor whose value is dependent on the shape of the cross section. Because wood is much stronger in tension than in compression parallel to the grain, it might be expected that the allowable stress in compression parallel to the grain should be used in Eq. 1 when computing moments of resistance. Actually, however, the fibers in a wood beam do give way first on the compression side, but the adjacent fibers then receive a higher stress, which tends to move the neutral axis toward the tension side and increases the stress in tension. This procedure continues until tension failure occurs. In a wood beam the individual fibers help support each other; and, since the

[2] "Technical Data on Plywood," Douglas Fir Plywood Assn., Tacoma, Wash., 1943.

fibers at the neutral axis are less stressed, they act as supports for the extreme fibers, enabling them to take a higher load. This is not the case when a wood member is subjected to direct compression parallel to the grain. Under this condition all the fibers are stressed alike and will not give as much support to each other as in a beam.

The original tests[3] used as a basis for developing structural grades were made on specimens 2 in. by 2 in. in cross section. Additional tests on larger sizes showed that, as the height of a beam increased, the modulus of rupture decreased. Since the effect of this decrease has been included in the working stresses for structural grades of lumber, the allowable fiber stress does not need to be reduced in designing rectangular sections. However, in an I-beam the complete supporting action of the wood fibers is only over a width equal to the width of the web. The supporting action of the fibers outside the web depends on the depth of the compression flange. For this reason an I-beam is weaker than a solid beam of the same height and the same section modulus. Therefore, it is necessary to multiply the allowable fiber stress by a form factor depending on the dimensions of the I-beam. The form factor may be calculated from the following formula[4] or taken directly from Fig. 1:

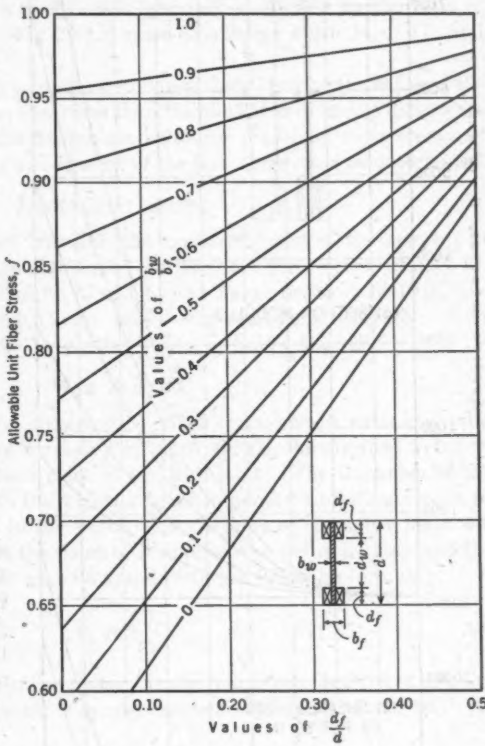

FIG. 1.—FORM FACTORS

$$B = 0.58 + 0.42\left[u_d\left(1 - \frac{b_w}{b_f}\right) + \frac{b_w}{b_f}\right] \qquad (2)$$

in which B is the form factor; u_d depends on the ratio of d_f/d, as given in Table 1; d_f is the depth of compression flange; d is the total depth; b_w is the thickness of web; and b_f is the width of flange.

calculating the moment from the S-value obtained from this chart, the fiber stress, f, must be multiplied by the appropriate form factor B.

SHEAR

In computing the unit horizontal shear in the plywood web the general formula—

$$v_h = \frac{V_e\,Q}{I\,b_w} \quad \ldots\ldots(3)$$

—may be used, in which v_h is the unit horizontal shear; V_e is the external shear; Q is the statical moment of area above or below neutral axis; and I is the moment of inertia.

The values in Fig. 2(*b*) are based on Eq. 3 and the total uniformly dis-

tributed load may be obtained for any values of b_w and $\frac{d_w}{b_w}$ when the unit horizontal shear v_h is 240 lb per sq in. For total loads at values less than $v_h = 240$, the value taken from Fig. 2(*b*) is simply multiplied by the ratio of the new shear value to 240. Fig. 2(*b*) is based on a flange width, b_f, of 5 b_w and a flange depth, d_f, of 10 b_w.

It will not be necessary to compute web-flange shear because the depth of the flange is sufficient to keep the shear less than the allowable when the flanges are glued to the web. When the flanges are bolted or joined by connectors and bolts to the web, the number and spacing of the fastenings must be determined.

Lateral Stability

For I-beams unsupported laterally, the maximum ratio of the moment of inertia about the x-axis to the moment of inertia about the y-axis is usually 25. For the beam with a flange width b_f of 5 b_w and flange depth d_f of 10 b_w, the value of d_w could not exceed 9 b_w to satisfy this condition. However, most beams are supported laterally by purlins, joists, or heavy flooring.

Web Splices

For long spans it will be necessary to splice the plywood webs and solid wood flanges. Probably the simplest method of splicing the plywood web is to glue a plywood panel on both sides of the web joint. The thickness of the plies in the splice plates with the direction of grain parallel to the span must be the same as that for those in the web. The width b_p of the splice plate will depend on the fiber stress at the point of the splice, the web thickness, and the allowable shear. The width may be found from the following formula:

$$b_p = \frac{f\,b_w}{v_p} \qquad (4)$$

in which b_p is the width of splice plate; f is the maximum fiber stress at point of splice; and v_p is the allowable shear between web and splice plate—60 lb per sq in.

Flange splices should be at the points of minimum bending moment, and can be made by overlapping an additional piece and fastening with glue, bolts, or connectors.

Web Stiffeners

At the supports and points of concentrated loads, vertical lumber or plywood stiffeners should be glued to the web between the flanges. These stiffeners are used as bearing members and should fit tightly against the flanges. Their size may be calculated by dividing the vertical shear by the allowable stress in compression parallel to the grain.

Intermediate stiffeners are required to prevent the web from buckling and their width must be sufficient to transmit the shear. The width may be calculated from the formula:

$$b_s = \frac{v_h\,b_w}{v_s} \qquad (5a)$$

in which b_s is the width of stiffener; v_h is the unit horizontal shear; and v_s is the allowable shear between web and stiffener—60 lb per sq in.

The spacing of stiffeners depends on the thickness of the web, the number and arrangement of the plies in the web, the clear distance between the flanges, and the horizontal shear stress developed. The critical shear stress v_c may be expressed in terms of convenient design factors discussed in detail elsewhere by the writer:[5]

$$v_c = \frac{4\, u_\theta \sqrt[4]{m_1\, m_2^3}}{b_w\, d_w^2} \qquad \text{(5b)}$$

in which u_θ is a factor introduced by Edgar Seydel[6] as c_a. Values of u_θ can be selected from Fig. 3 after complex functions of m have been converted to the convenient design constants[6] β and θ. Thus, the constants m are functions of the reciprocal of Poisson's ratio μ. The moduli of elasticity of the entire panel, taken along the face grain, E_s, and across the face grain, E_d, are, respectively:

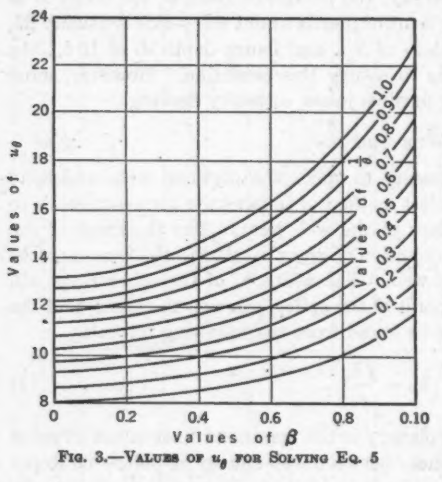

FIG. 3.—VALUES OF u_θ FOR SOLVING EQ. 5

$$E_s = E_d = \frac{1}{I} \sum_{i=1}^{i=n} (E_i\, I_i) \qquad \text{(6)}$$

in which i is the number of plies; n is a number in a mathematical expression; E_i is the modulus of elasticity of a single ply; and I_i is the moment of inertia of a single ply about the neutral axis of the cross section. As expressed by Eq. 6, E_s and E_d are summations of the product of the moment of inertia of each ply about the center of the panel and its modulus of elasticity, divided by the moment of inertia of the entire cross section.[7] In computing E_s and E_d, the modulus of elasticity along the grain for a single ply may be taken as 1,600,000 lb per sq in. and that across the grain as 0.045 times the modulus of elasticity along the grain or 72,000 lb per sq in. The modulus of rigidity in shear is equal to $G_d = \frac{1{,}600{,}000}{16} = 100{,}000$ lb per sq in. Poisson's ratio is expressed as:

$$\mu = 1 - \mu_s\, \mu_d \qquad \text{(7)}$$

In Eq. 7 the product of the Poisson's ratios along the grain (μ_s) and across the grain (μ_d) is equal to 0.01 and $\mu = 0.99$. With the foregoing definitions m_1,

[5] "Modern Timber Design," by Howard J. Hansen, John Wiley & Sons, Inc., New York, N. Y. 1943, p. 168.

[6] "The Critical Shear Load of Rectangular Plates," by Edgar Seydel, *Technical Memorandum No. 705*, National Advisory Committee for Aeronautics, Washington, D. C., 1933, p. 4, Fig. 3.

[7] "Modern Timber Design," by Howard J. Hansen, John Wiley & Sons, Inc., New York, N. Y., 1943, p. 169.

defining the flexural stiffness along the grain against flexure of the web across the grain, is

$$m_1 = \frac{E_s\, b_w^3}{12\,\mu} \qquad \text{(8a)}$$

Similarly, m_2 defines the flexural stiffness across the grain against flexure of the web along the grain, or

$$m_2 = \frac{E_d\, b_w^3}{12\,\mu} \qquad \text{(8b)}$$

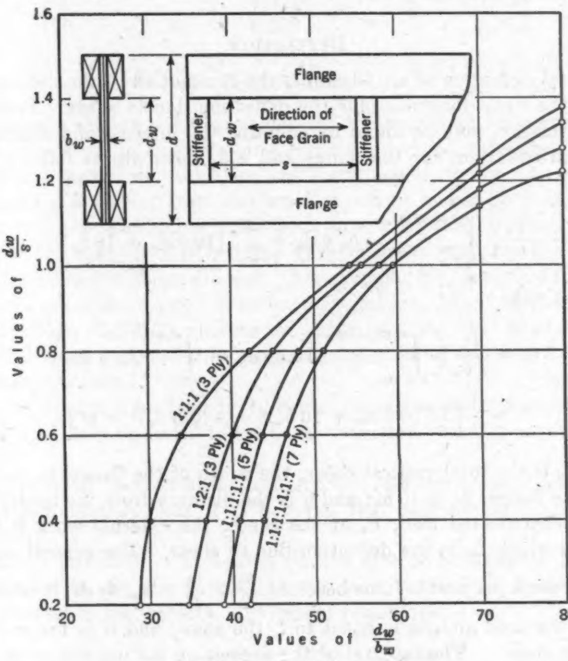

FIG. 4.—SPACING OF STIFFENERS

and m_3 defines the torsional stiffness, or

$$m_3 = \frac{E_s\, \mu_s\, b_w^3}{12\,\mu} + \frac{G_s\, b_w^3}{6} \qquad \text{(8c)}$$

Eqs. 8 apply to Douglas fir plywood, with the face grain parallel to the span. The design factors β and θ may now be written:

$$\beta = \frac{d_w}{s}\left(\frac{m_1}{m_2}\right)^{\frac{1}{4}} \qquad \text{(9a)}$$

and

$$\theta = \frac{(m_1\, m_2)^{\frac{1}{2}}}{m_3} \qquad \text{(9b)}$$

By calculating the values of E_s and E_d for the standard thicknesses of Douglas fir plywood, a solution for m_1, m_2, and m_3 is easily obtained. Then u_s can be determined for any value of $\frac{d_w}{s}$. The curves in Fig. 4 were obtained by computing values of v_e for various combinations of $\frac{d_w}{b_w}$ and $\frac{d_w}{s}$. Since the ultimate shearing stress is approximately five times the allowable, the values of v_e have been divided by five. It is recommended that the distance, s, between stiffeners should not exceed $5\ d_w$.

Deflection

The total deflection of an I-beam is the summation of the deflection computed by the usual formulas plus the deflection due to shear. Formulas for shear deformation may be found by equating the internal and external work. The general equations for the flange and web shear are as follows: For the flange—

$$v_h = \frac{V_v}{5\ b_w I} \int_y^{0.5d_w+10b_w} 5\ b_w\ y\ dy = \frac{V_v}{2\ I} [(0.5\ d_w + 10\ b_w)^2 - y^2] \ldots (10a)$$

and, for the web—

$$v_h = \frac{V_v}{I\ b_w} \left(\int_{0.5d_w}^{0.5d_w+10b_w} 5\ b_w\ y\ dy + \int_y^{0.5d_w} b_w\ y\ dy \right)$$

$$= \frac{V_v}{2\ I} [5\ (0.5\ d_w + 10\ b_w)^2 - 4\ (0.5\ d_w)^2 - y^2] \ldots\ldots\ldots\ldots (10b)$$

in which V_v is the total vertical shear; the width of the flange, b_f, is $5\ b_w$; the depth of the flange, d_f, is $10\ b_w$; and y is the distance from the neutral axis.

For a concentrated load, P, at the center the external work is equal to $0.5\ P\ \Delta_v$, in which Δ_v is the deflection due to shear. The general expression for internal work per unit volume becomes: $\frac{v_h}{2} \times \frac{v_h}{G} \times b_{w1}\ dy\ dx$, in which $b_{w1}\ dy$ represents the area and dx is equal to l, the span; and G is the modulus of elasticity in shear. The integral of the expression for internal work may be set equal to the external work so that:

$$\frac{P\ \Delta_v}{2} = 2 \frac{l}{2\ G} \int_0^{0.5d_w+10b_w} v^2{}_h\ b_{w1}\ dy \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

By substituting the values of flange and web shear in the expression for v_h and using the flange and web thickness for b_{w1}, the expression becomes

$$\frac{P\ \Delta_v}{2} = \frac{l}{G} \left\{ \frac{5\ b_w\ V^2{}_v}{4\ I^2} \int_{0.5d_w}^{0.5d_w+10b_w} [(0.5\ d_w + 10\ b_w)^2 - y^2]^2\ dy \right.$$

$$\left. + \frac{b_w\ V^2{}_v}{4\ I^2} \int_0^{0.5d_w} [5\ (0.5\ d_w + 10\ b_w)^2 - 4\ (0.5\ d_w)^2 - y^2]^2\ dy \right\} \ldots (12)$$

Values for Δ_s based on several $\frac{d_w}{b_w}$-ratios $\left(\text{to be multiplied by } \frac{P\, l\, b^8_w}{I^2}\right)$ are as follows:

$\frac{d_w}{b_w}$	Deflection Δ_s for— Concentrated load, P	Uniformly distributed load, P
40	198	99
60	644	322
80	1,578	789
100	3,271	1,635
120	6,063	3,032

Conclusions

Although the section modulus values and the maximum loads based on the allowable shear given in Figs. 2(*a*) and 2(*b*) are only applicable when the flange width is five times the web thickness and the flange depth is ten times the web thickness, there are many instances when it will be necessary to increase the flange dimensions. For higher ratios than those used, the load-carrying capacity based on the fiber stress in bending will increase rapidly, but the total load based on the allowable shear will not. For example, if b_f is equal to 10 b_w, d_f is equal to 16 b_w, and d_w is equal to 40 b_w, the total load based on shear for 1-in. plywood becomes 25,800 lb whereas the value from Fig. 2(*b*) is 23,000 lb. It appears that Figs. 2(*a*) and 2(*b*) represent a method of selecting a section for the preliminary design.

The deflection due to shear in I-beams and box sections is of considerable magnitude and must be added to the usual deflection formulas or serious errors may result.

The theoretical method of determining the stiffener spacing has not been checked experimentally, but it is believed that test results would conform rather closely.

Additional information is needed on the lateral buckling of beams and experimental data are also lacking on the load capacity of beams with the flanges attached to the webs by all types of fastenings.

APPENDIX. NOTATION

The following letter symbols, used in the paper and in its discussions, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials (ASA—Z10a—1932), prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

A = area of cross section, $b\, d$;
B = a form factor defined by Eq. 2;
b = breadth, or thickness, of a section:

b_f = breadth or width of flange;
b_p = thickness of a splice plate;
b_s = width of stiffener;
b_w = thickness of the web;
d = depth, with subscripts corresponding to b;
E = modulus of elasticity:
E_d = entire panel across the face grain;
E_i = individual ply;
E_s = entire panel along the face grain;
f = fiber stress;
G = modulus of rigidity;
I = rectangular moment of inertia; I_i = individual ply;
i = number of plies;
l = clear distance between stiffeners;
M = moment;
m = a function of Poisson's number, the reciprocal of μ;
n = a number;
P = total load, either concentrated or distributed;
Q = statical moment of area above or below the neutral axis;
S = section modulus $= I/c = M/f$;
u = a factor:
u_d = a constant depending on the ratio d_d/d;
u_θ = a factor in Eq. 5, function of m and μ;
V = total shear, subscripts h or v denoting horizontal or vertical, respectively;
v = unit shear:
v_c = critical;
v_h = horizontal;
v_p = allowable stress between web and splice plates;
v_s = allowable stress between web and stiffener;
v_v = vertical;
y = distance from the neutral axis to the extreme fiber;
β = a factor (Eq. 9a) useful in design;
Δ_v = deflection due to shear; and
θ = a factor in Eq. 9b.

DISCUSSION

Dick W. Ebeling,[8] Jun. ASCE.—There are a few points in this very useful contribution which are not entirely clear: First, the author states (see "Introduction") that the unit horizontal shear is eight times the web-flange shear; but he fails to state that the unit horizontal shear in the plywood is twice the allowable horizontal shear for the wood from which the plywood is made. Second, from Fig. 1, it would seem that the flange depths must be equal, which is not true. The form factor depends only on the depth of the compression flange. The Forest Products Laboratory in Madison, Wis., has developed a formula[9] for the most efficient section with unbalanced flanges. In using this formula, the section is first designed with equal flanges; then part of the tension flange is transferred to the compression flange keeping the total area, height, and width constant:

$$x = \frac{A\, b_f\, d^2 - \sqrt{A^2\, b^2_f\, d^4 - 4\, A\, I_s\, b_f\, d(b_f - b_w)\, d_w}}{2\,(b_f - b_w)\, d_w\, b_f\, d} \quad \text{.........(13)}$$

in which x is the thickness to be transferred from the tension to the compression side; and I_s is the moment of inertia of the symmetrical section.

Also, the spacing of stiffeners given in Fig. 4 is actually the minimum spacing. Just as the stirrup spacing in a concrete beam increases as the shear decreases, the stiffener spacing can be increased as the shear decreases. However, it is not possible to increase the spacing beyond 5 d_w because the stiffeners are needed as flange spacers in fabrication.

To increase the strength in shear and to decrease the deflection due to shear, the plywood web may be placed with the face grain at an angle of ± 45° to the span—thus doubling the allowable horizontal shear in the web. However, the strength in bending is reduced to one fourth of the value for plywood parallel to the span, although the allowable web-flange shear is not affected. The modulus of rigidity of the plywood is increased five times, which reduces the deflection.

If the plywood is placed with the grain at an angle to the span, the beam will probably have to be fabricated completely in the shop. In most cases, it is better to have the beams completely fabricated in the shop, where the trained men and proper facilities are available. Also, in shop fabrication, the splice plates can be eliminated by scarfed splice joints which develop the full strength of the plywood.

The author's theoretical method of spacing stiffeners agrees closely with that recommended by the Douglas Fir Plywood Association[3] as checked by tests.[10] Also a number of planes were designed from the Forest Products Laboratory recommendations[11] which are similar to the author's method; and, as far as the writer knows, there were no structural failures of the plywood

I-beams and box beams. Therefore, the author's method is adequate and conforms to conventional factors of safety for wooden structures.

I. OESTERBLOM,[13] M. ASCE.—To see papers on plywood construction is refreshing in a double sense. It reminds one of the not so far away past when rolled iron sections were "thrown" at an unsuspecting world; a keen search then followed to discover all their potential uses. It also affords a view of a future in which the United States will certainly go abroad begging for the iron ores she needs to maintain industrial supremacy, having tried valiantly—almost to fanaticism—to exhaust her own natural wealth as quickly as possible. This, Great Britain has done for a century or more—to her sorrow.

In this future, plywood is certain to come into its own on a tremendous scale. With moisture from the heavens, and energy from the sun, the forests will continue to grow long after domestic iron ore is a mere memory—unless man sets his mind on the task of exhausting the forests too—through economic mismanagement.

Visualizing this, it is easy to see a complex development in all directions—not only as to beams and girders but also as to every conceivable combination useful in home building and industry—and these are many. Some time ago a friend of the writer built a functional plywood home with double sheathing on 1-in. by 3-in. joists—all prefabricated and glued in his home basement during spare time, and then quickly erected. He was scorned for building a house of cards; but the proof of strength came quickly; a truck out of control ran into the house and pushed it sideways several inches without injury to the basic frame.

Experiences of similar order have multiplied recently; hence, papers on the theory and the use of plywood are highly welcome. Plywood will be of help to the builders of the future; and it will slow down the terrific rate at which iron ore is taken from the bowels of the earth.

Professor Hansen has supplied one of the chapters most needed to make plywood history. He has written about I-beams; and he has written well. He has verified his formulas by experiments. Now the engineer can design plywood I-beams with greater confidence.

There is a weakness in such beams—as he states—which one may possibly eliminate. It is not the plywood, seemingly, that determines permissible unit shear stress, but the glue between web and flange; thus the plywood itself could do a great deal more work if its own strength were governing. Why not change the section? At present there is a small glue area as compared with a large flange area. It should be the other way around to get the most out of the section. Therefore, it is proposed that the beams—at least the heavier girder types—be built up as are steel plate girders, with fillet blocks (of plywood if preferable) to take the place of the four angles connecting flange and web plates. This would greatly increase the shear area holding the web to the flanges so that even with the relatively low shear strength of the glue much greater flange stress could be transmitted to the web.

Does Professor Hansen agree? Are not such girders made? If they are not made, why not? If they are made, what new formulas are needed to use them properly in structural plywood designs?

[13] Engr., Carbide & Carbon Chemicals Corp., South Charleston, W. Va.

C. J. HOGUE,[13] M. ASCE.—An interesting contribution to the data on a useful and efficient combination of lumber and plywood, utilizing the tensile and compressive strength of sawed lumber and the shearing strength of plywood is presented by Professor Hansen. As the author notes, this development is comparatively recent; and further information and test checks are needed. The paper offers methods of determining size and spacing of intermediate stiffeners, and of calculating deflection due to shear, which differ from those in "Technical Data on Plywood."[14] Through such presentation of different methods, the best will be found.

As information on wood is developed and wood is used more technically, its anisotropic character lea ls to complicated analyses. Formerly, a designer in wood need only be equipped with a formula for bending and an empirical, straight-line column formula. With present advances, there is need for simplification of design data.

A complicated analytical formula may often be expressed in simplified form within close accuracy, and charts and tables can be prepared for convenient determination of complicated factors. This trend tends to more convenient use of wood and plywood, to quicker calculation, and to safer design where an involved formula might be misinterpreted and solved erroneously. The writer is glad to note that this is done both in the paper and in "Technical Data on Plywood."[14]

SIDNEY NOVICK,[15] JUN. ASCE.—The method for determining stiffener spacing (see heading, "Web Stiffeners") is based on the theoretical buckling behavior of plywood plates in shear. Fig. 4 appears to have been derived by finding simultaneous values of $\frac{d_w}{s}$ and $\frac{d_w}{b_w}$ for a fixed value of $v_c = 5 \times 240$, rather than "* * * by computing values of v_c for various combinations of $\frac{d_w}{b_w}$ and $\frac{d_w}{s}$" as stated by the author (paragraph following Eqs. 9). These curves, therefore, give spacings such that the theoretical factor of safety against shear buckling will be at least 5 when the horizontal shear is equal to one fifth of the maximum horizontal shear stress of the material, v_h (max)—that is, when $v_h = \frac{v_h\,(\max)}{5} = 240$ lb per sq in. The value of Fig. 4 is limited by its theoretical basis and by the failure to provide for increasing spacings when the design value v_h is less than $\frac{v_h\,(\max)}{5}$.

In 1944, the Army-Navy Civil Committee (ANC) on Aircraft Design Criteria, summarizing a more comprehensive study by the Forest Products Laboratory,[16] presented an "Experimental Buckling Curve"[17] which demonstrates that plywood beam webs cannot be assumed to buckle always at stresses close to the values predicted by theory. Actual shear stresses at buckling are equal to,

or greater than, the predicted values only when the plate dimensions are in such relation as to cause a limiting value to be exceeded; below this limit, the actual stresses are less than predicted.

In the notation of the paper, the limit above which the theoretical buckling values are valid is that $\frac{d_w}{d_{w_o}}$ is equal to 2.2, in which d_{w_o} is the theoretical depth between flanges at which the critical buckling stress v_c would be equal to the shear strength of the material, v_h (max); that is,

$$d_{w_o} = \left(\frac{4\, u_\theta \sqrt{m_1\, m_2^3}}{b_w\, v_h\,(\text{max})}\right)^{\frac{1}{2}} \qquad \text{(14)}$$

Fig. 5 has been plotted from the ANC curves[17] to show the variation of the ratio $\frac{v_c\,(\text{actual})}{v_c\,(\text{theoretical})}$ (denoted by r_v) with $\frac{d_w}{d_{w_o}}$.

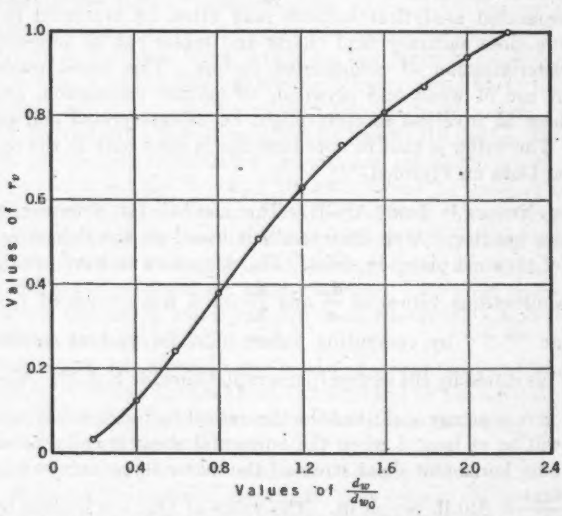

FIG. 5.—RATIO OF ACTUAL TO THEORETICAL BUCKLING VALUES

From these empirical data it appears that shear buckling will always occur before the maximum horizontal shear stress, v_h (max) is reached, regardless of stiffener spacing: The absolute maximum value of $\frac{v_c\,(\text{actual})}{v_h\,(\text{max})}$ is only 0.83 $\left(\text{for a value of } \frac{d_w}{d_{w_o}} \text{ equal to } 0.06\right)$. Therefore, if equal factors of safety against horizontal shear and shear buckling are desired, the value of the design horizontal shear, v_h, must be taken into account in determining stiffener spacing, and the maximum value of v_h must always be limited to less than $0.83 \times \frac{v_h\,(\text{max})}{5}$.

With these considerations in mind, Fig. 6 has been prepared to supplant Fig. 4. The same types of plywood and design constants as used by the author were employed; they will enable the designer to determine the spacing of stiffeners after v_h and the ratio $\frac{v_h}{v_h\,(\text{max})/5}$ $(= p_v)$ have been found. For commercial grades of plywood, v_h (max)/5 should be taken as the maximum safe horizontal shear stress recommended for that particular grade.

The curves in Fig. 6 were obtained as follows: From the theoretical shear buckling equation, the buckling stress varies inversely as the square of the depth between flanges; therefore,

$$\frac{v_c\,(\text{theoretical})}{v_h\,(\text{max})} = \left(\frac{d_{w_0}}{d_w}\right)^2 \ldots\ldots (15a)$$

If the value of v_h is such that $\frac{v_h}{v_c\,(\text{actual})/5}$ = 1, then

$$p_v = \frac{v_h}{v_h\,(\text{max})/5} = \frac{v_c\,(\text{actual})/5}{v_h\,(\text{max})/5}$$

$$= \frac{v_c\,(\text{actual})}{v_h\,(\text{max})} \ldots\ldots\ldots (15b)$$

Since $\frac{v_c\,(\text{actual})}{v_c\,(\text{theoretical})} = r_v$,

$$p_v = r_v \times \frac{v_c\,(\text{theoretical})}{v_h\,(\text{max})} = \frac{r_v}{\left(\frac{d_w}{d_{w_0}}\right)^2} \ldots (16)$$

For each type of plywood and for various ratios of $\frac{d_w}{s}$, values of $\frac{d_{w_0}}{b_w}$ were computed by a method recommended by the Forest Products Laboratory[17,18] and

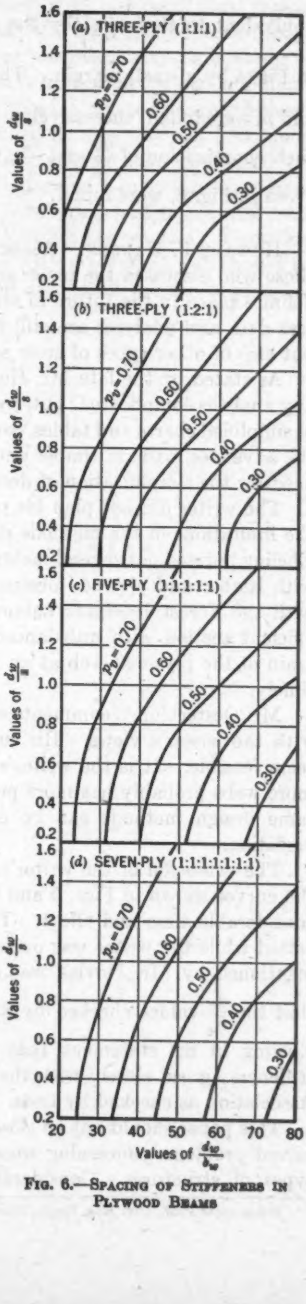

FIG. 6.—SPACING OF STIFFENERS IN PLYWOOD BEAMS

[18] "Buckling of Flat Plywood Plates in Compression, Shear, or Combined Compression and Shear," *Mimeograph No. 1316* (and supplements), Forest Products Laboratory, Madison Wis., 1942–1945.

equivalent to that used by the author. These values checked the $\frac{d_w}{b_w}$-values in Fig. 4 by a small margin. Then, for various ratios of $\frac{d_w}{b_w}$, values of $\frac{d_w}{d_{w_o}}$, r_v, and p_v were found, successively. By interpolation between the values of p_v for each combination of $\frac{d_w}{b_w}$ and $\frac{d_w}{s}$, the curves for even-numbered values of p_v, as given in Fig. 6, were found.

HOWARD J. HANSEN,[19] ASSOC. M. ASCE.—The encouraging comments of those who discussed the paper seem to indicate that plywood I-beams have a definite place in the future of structural engineering. However, considerable test data and analyses are still needed. This is true not only of the I-beam but also of other types of cross sections.

As stated by the late Mr. Hogue, the anisotropic character of wood makes any analysis complicated; but, by expressing complicated equations in the form of simplified charts and tables, convenient design factors are established. With the advances made in timber and plywood analyses in the past few years, the need for the simplification of design data is apparent.

The writer did not plan his paper to cover all the possible conditions, and the limitations of the methods presented were noted in the "Synopsis." Mr. Ebeling pointed out several factors which are known by most engineers familiar with timber and plywood design. However, for those who are unacquainted with the Forest Products Laboratory (Madison, Wis.) formula for the most efficient section with unbalanced flanges and the effects of placing the face grain of the plywood web at an angle of ±45° to the span, his comments are timely.

Mr. Oesterblom's comments concerning the future of plywood are in accord with the writer's views. His suggestions as to possible girder cross sections seem feasible. It is the writer's observation that the box beam with two or more webs probably has more possibilities than any other cross section. The same design methods can be extended to this type of section with little variation.

The extension of the writer's method by Mr. Novick and the inclusion of the curves shown in Figs. 5 and 6 are appreciated. They have already saved considerable time and effort. The paper was originally written in 1944 and edited while the writer was overseas; consequently, access to the publications mentioned by Mr. Novick was impossible. The writer was pleased to note that the $\frac{d_w}{b_w}$-values checked by a close margin. This also was noted by Mr. Ebeling in his statement that the writer's theoretical method of spacing stiffeners agreed closely with that recommended by the Douglas Fir Plywood Association as checked by tests.

This paper should not be closed without mentioning a few of the many unsolved problems concerning wood and plywood when used in this or similar types of structures. Considerable information is needed on nailed joints.

[19] Associate Prof., Civ. Eng. Dept., Univ. of Florida, Gainesville, Fla.

The paper considers flanges glued to the plywood web, but there is no reason why these cannot be nailed when sufficient test data are available on the spacing of nails. Since the flanges of an I-beam or box beam may be built up of several pieces nailed together, more information is needed on the size and quantity of nails to use. There is no question that glued laminated flanges fastened to the plywood web are more efficient than nailed flanges, but just how much more efficient is not known at present. Nailed girders have been used extensively in Europe, and, in place of plywood, diagonal 1-in. boards have been used for the web. This seems to present an interesting possibility, and tests should be made of girders of this type with American species. Complete frames or bents of this type of construction or with a plywood web should be analyzed and tested. Additional data are also needed on the use of plywood for gusset plates in timber trusses and arches.

RECHARGE AND DEPLETION OF GROUND-WATER SUPPLIES

BY CHARLES L. MCGUINNESS,[1] ESQ.

WITH DISCUSSION BY MESSRS. E. A. VAUBEL, RAPHAEL G. KAZMANN, AND CHARLES L. MCGUINNESS.

SYNOPSIS

It is widely believed that the water table is declining and that ground-water supplies are being depleted because of deforestation, drainage, improper methods of land cultivation, and pumping from wells. In addition, many fantastic explanations are offered to account for depletion of ground-water supplies. The paper describes the nature of ground-water reservoirs or aquifers, their recharge from precipitation and stream flow, and their discharge through seeps and springs and by evaporation and transpiration. It shows that changes in ground-water levels are caused by climatic changes or by human activities that affect the rates at which the ground-water reservoirs are recharged and discharged. Although additional investigation is needed, there is no reason to believe that changes in ground-water levels due to deforestation, drainage, and land cultivation have been progressive over long periods in most parts of the United States. The most pressing problems are those resulting from the withdrawal of water from wells. The paper divides the productive aquifers into two broad classes—those with high rates of recharge and large perennial supplies and those with low rates of recharge and small perennial supplies—and describes numerous examples of aquifers of both types. Artificial recharge as a method of conserving ground water is described briefly and is shown to be both practicable and necessary at certain places. The paper concludes that at some places the present rates of withdrawal from wells are excessive and will have to be curtailed sooner or later, but at many other places the rate of recharge is high and large supplies will be perennially available to wells.

INTRODUCTION

A persistent belief has arisen that the water table is declining progressively because of deforestation, drainage, improper methods of land cultivation, and

NOTE.—Published in September, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Associate Geologist, U. S. Geological Survey, Washington, D. C.

pumping from wells. The growth of such a belief has been especially rapid since 1930, and is particularly strong in the Middle West. Ground-water levels may decline as the result of deficient or poorly distributed precipitation, pumping from wells, installation of drainage ditches, or other factors. The causes of a decline in ground-water levels at any particular place are generally so complex that attempts to define them without careful investigation may lead to confusion. Thus, it is to be expected that a large number of people might believe that ground-water supplies are diminishing to such an extent that sooner or later they will be largely depleted. It is obviously impossible to present this large and complicated subject in a single paper, but an attempt will be made to give some information on the sources of ground water, the extent of depletion, and the prospects for continuing supplies. General discussions of these phases of ground-water hydrology are found in several papers by O. E. Meinzer (1a)(2)(3)(4)(5)(6)(7).[3]

Recharge and Discharge of Ground-Water Reservoirs

A discussion of recharge and depletion of ground-water supplies involves the concept of ground-water reservoirs. The rock formations of the earth—which include both consolidated rocks such as sandstone and limestone and unconsolidated sand and gravel—constitute great natural ground-water reservoirs. These reservoirs, or aquifers, are replenished by water derived directly from rain and snow or from streams, and they are discharged under natural conditions through seeps and springs and by evaporation and transpiration of plants. The water levels in the subterranean reservoirs fluctuate seasonally and with cycles of drought and excessive precipitation. Both recharge and discharge are high in wet years, and the water table is high. In dry years recharge is diminished, water is withdrawn from storage, the water table declines, and the discharge diminishes. In a sense, the water then remaining in the reservoir is in dead storage, but some of it can always be made available by wells.

The storage capacity of the major subterranean reservoirs is very great, and therefore in times of need, such as periods of drought or other emergencies, quantities of water far in excess of the current recharge, or of the perennial safe yield, can be withdrawn from storage for a few years. However, all heavily pumped aquifers should be thoroughly investigated to determine the rates at which given installations of wells can be pumped indefinitely, so that estimates can be made of the extent to which emergency rates of pumping may have to be reduced.

Under natural conditions, the aquifers are in an approximate state of dynamic equilibrium, although the water table fluctuates seasonally and from year to year. The utilization of ground water by means of wells is an additional discharge imposed on the natural system of recharge and discharge, and upsets the equilibrium (8). Before equilibrium can again be reached, the new discharge must be balanced by an increase in the rate of recharge or by a decrease in the rate of natural discharge, or by a combination of the two. Until a new equilibrium is reached, water must be pumped from storage with a consequent

[3] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (see Appendix).

decline in water levels. Ground-water reservoirs, or aquifers, differ widely in areal extent, opportunity for recharge, ability to transmit and store water, and conditions of natural discharge. The properties of the individual aquifers determine how much water can be withdrawn from them by wells and the relative extent to which withdrawal from storage, increase in recharge, and decrease in natural discharge are involved.

A decline in water levels caused by withdrawal of water from wells increases the hydraulic gradient from the areas of recharge and reduces the gradient toward the areas of natural discharge. A decline of the water table in the areas of recharge may result in an increase in the rate of recharge, but only if there is "rejected recharge" (8). Recharge is rejected if the potential rate of recharge exceeds the rate at which water can flow laterally through the aquifer, so that the water table stands at or near the surface and water is disposed of by evaporation and transpiration and by flow into streams. Lowering the water table in such an area reduces the rate at which water is lost, and thus increases the rate of recharge. If the rate of recharge is normally less than the rate at which the aquifer can carry the water away laterally, recharge is not rejected and the rate of recharge is governed (*a*) by the rate at which water is made available by precipitation or by the flow of streams, or (*b*) by the rate at which water can move vertically downward through the soil to the water table and thus escape evaporation. Lowering the water table by withdrawing water from wells does not cause an increase in the rate of recharge in such an area.

A decline of the water table in the areas of natural discharge caused by withdrawal of water from wells reduces the discharge by evaporation and transpiration and also by seepage into streams. Water that is derived not from a loss in storage but from increased recharge or decreased discharge has been termed "salvage" (9).

Over a long period under natural conditions, depletion of the water supply of an aquifer can occur only as the result of a climatic change or a geologic process that causes a reduction in recharge or an increase in discharge. For example, a reduction in recharge might be caused by a blanket of loess deposited by wind over the recharge area of a permeable formation, or by deposition of silt in the bottom of a stream that contributes water to an aquifer. An example of a process that might cause an increase in discharge would be the lowering, by downcutting, of the level of a stream into which ground water is discharging. Depletion of the supply can occur as the result of the activities of man, who not only withdraws water from wells but also performs other actions that may affect the rates of recharge and discharge.

A "Symposium on Fluctuations of Ground-Water Levels" that appeared in 1936 (1) contains papers giving long-time records of ground-water levels at several places in the United States and one place in England. Some of these records illustrate the principle that, under natural conditions, ground-water levels fluctuate with the amount and distribution of precipitation. The well whose hydrograph is shown in Fig. 1 is in the northeastern tip of Oneida County, New York (1*b*), and penetrates glacial sand and gravel. The observations were made by the Black River Regulating District. The graph shows no progressive decline in water level during the period of record. The graph of the water level

in this well (Fig. 1(*a*)) in the latter part of 1944 was about the same as in the latter part of 1935, although before the end of 1944, because of drought, the water level declined a little lower than in 1935.

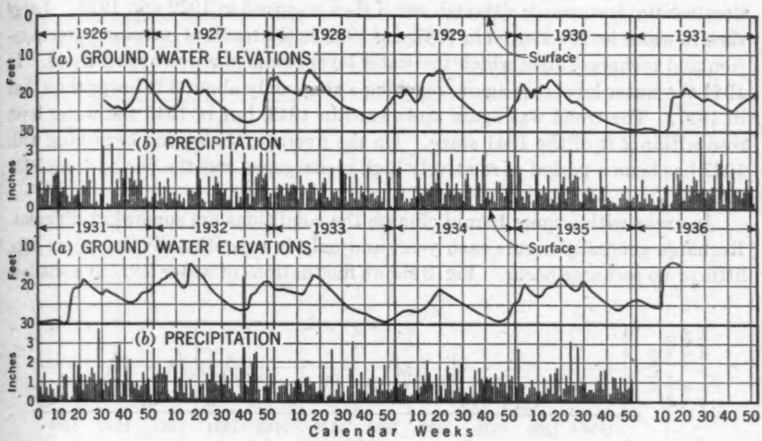

FIG. 1.—HYDROGRAPH OF WELL 6 AT WOODGATE, N. Y., 1926–1936

Fig. 2 illustrates a feature of ground-water recharge that is typical of some areas, particularly in the West, in which the pumpage from irrigation wells is in excess of the rate of recharge in years of normal or low precipitation, resulting in withdrawal of water from storage. However, the water is replenished during

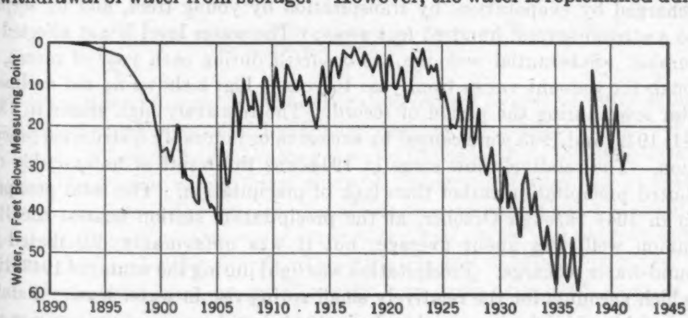

FIG. 2.—FLUCTUATIONS OF WATER LEVEL IN THE WILLIAMS WELL, SAN BERNARDINO AREA, SANTA ANA RIVER BASIN (CALIFORNIA) 1892–1940

the infrequent periods of excessive precipitation. The Williams well (Fig. 2) is near the Santa Ana River, northwest of Redlands, Calif., and penetrates alluvium in the San Bernardino Valley (10). The observations were made by the Gage Canal Company.

Following a period of deficient precipitation in the late nineties, the water level in the Williams well—the fluctuations in which are reasonably typical of those in wells in the San Bernardino Valley—declined to a low stage in 1904, and then rose persistently until 1917. From 1917 to 1937 the trend was predominantly downward, although small rises occurred in 1922 and 1923. Large rises in water level occurred in 1937 and 1938 as the result of increased precipitation and recharge, after which the water level resumed a downward trend. In 1941 the water level rose again, reaching a stage only about 3 ft lower than that in 1917. The trend was again downward in 1942, but in 1943 the water level rose within 2 ft of the 1941 stage. On the average, the period beginning with 1937 has been a period of relatively high recharge, as was the period from 1904 to 1917.

In areas with a more humid climate the conditions are somewhat different. Recharge generally occurs each year, and only in exceptionally dry years does little or no recharge occur. Fig. 3 shows fluctuations of water level in a shallow

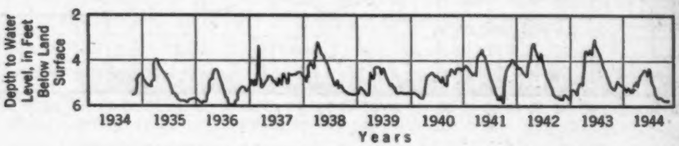

FIG. 3.—HYDROGRAPH OF THE ROSCOMMON WELL IN MICHIGAN, 1934–1944

observation well penetrating glacial outwash sand near Roscommon, in the north-central part of the lower peninsula of Michigan. In the vicinity of the well the ground-water supply is recharged by melting snow and rainfall, and is discharged by evaporation, by transpiration by young trees, and by seepage into a stream several hundred feet away. The water level is not affected by pumping. Substantial recharge has occurred during each year of record, although the amount varies from year to year. Fig. 3 shows no net decline in water level during the period of record. The relatively high stages in 1938, 1941, 1942, and 1943 were caused by excessive or favorably distributed precipitation. The relatively low stage in 1944 was the result of unfavorably distributed precipitation rather than lack of precipitation. The total precipitation in 1944 through October, at the precipitation station nearest the Roscommon well, was about average; but it was unfavorably distributed for ground-water recharge. Precipitation was light during the winter of 1943–1944—which accounts for the relatively small spring rise in water level. Rainfall was considerably above normal in June, 1944; but, because of evaporation and transpiration, only a small rise in water level resulted.

The abrupt rise and decline in water level in the Roscommon well in February, 1937 (shown in detail in Fig. 4), was obviously exceptional. It was caused mostly, if not entirely, by local recharge from melting snow. Water from melting snow was observed to collect in a surface depression near the well. Although recharge undoubtedly occurred throughout the region as a result of

the thaw, the recharge in the surrounding area was not as great as that at the well, and the water was able to drain away quickly into the adjacent areas.

In some places large and sudden rises, followed by rapid declines, in water-table wells have been attributed to pressure effects produced when the soil becomes saturated; but the data do not show whether such a mechanism may have accounted for part of the February, 1937, rise in the Roscommon well.

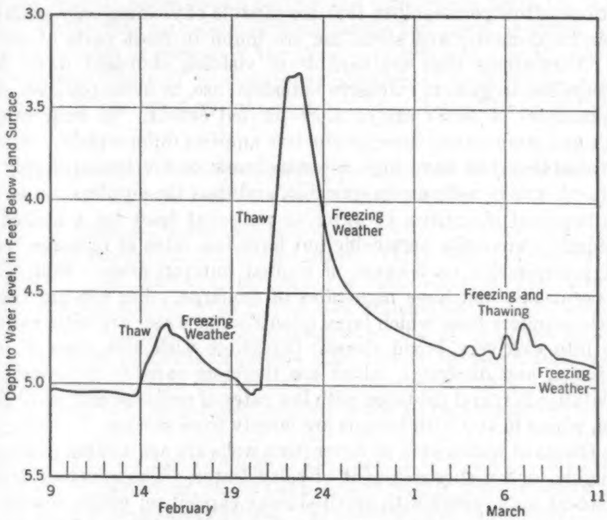

FIG. 4.—ENLARGEMENT OF HYDROGRAPH, FEBRUARY AND MARCH, 1937; THE ROSCOMMON WELL IN MICHIGAN

The relation of forests and the cultivation of land to ground-water supplies has received much discussion, but further rigorous investigation of the subject is needed. It seems inevitable that changes in the land such as deforestation and crop production should have produced changes in the average annual infiltration, changes in the average annual loss by evaporation and transpiration, and hence changes in the average stage of the water table and average annual amount of ground-water runoff. There is no reason to believe, however, that such effects have been progressive over long periods in most parts of the United States.

Drainage ditches, of course, accomplish their purpose of lowering the water table in the areas drained, with a resultant loss in ground-water storage. However, this effect may be expected to be complete within a relatively short time after the drains are installed (a year or a few years at the most) so that a progressive decline of the water table over a long period is not to be expected as the result of the installation of a given system of drains.

Effects of Withdrawal of Water from Wells

Although much investigation will be necessary to establish fully the effects on ground-water supplies of such activities as deforestation, land cultivation, and drainage, the most pressing problems are those created by withdrawal of large quantities of water through wells.

Water-bearing formations differ greatly in their capacity to transmit water and in the quantity of water that they yield from storage with a decline in head. Formations of low permeability that are capable of yielding only small supplies of water for domestic and stock use are found in most parts of the United States. Formations that are capable of yielding sufficient water for large public supplies, irrigation, extensive industrial use, or other purposes requiring large quantities of water are of more limited extent. In their capacity to transmit and store water, these productive aquifers differ widely. Some are of low permeability but have high artesian heads or are buried deeply so that large drawdowns in wells are practicable, and thus the aquifers can be made to yield substantial quantities of water to wells—at least for a limited period. Other aquifers are quite permeable but have low rates of recharge because of lack of precipitation or because of limited outcrop areas. Still others are highly permeable and have high rates of recharge. For the purpose of this paper, the aquifers from which large quantities of water are withdrawn can be divided into two very broad classes: (a) Those with high rates of recharge, transmission, and discharge, which are therefore capable of furnishing large perennial supplies; and (b) those with low rates of recharge and small perennial supplies, where heavy withdrawals are largely from storage.

The effects of withdrawal of water from wells are aggravated in some places by droughts, or by encroachment of salty water. The effect of droughts is most evident on aquifers with small storage capacities, which depend on sustained recharge to support heavy withdrawals. Aquifers with low rates of recharge and small perennial supplies, where heavy withdrawals are largely from storage, are relatively unaffected by droughts.

Encroachment of salty water affects aquifers of both classes but especially those of the second class. It occurs when the head of the fresh water is lowered by withdrawal of water through wells sufficiently to permit the salty water to move toward the wells. Some aquifers in the interior of the United States are subject to encroachment of water of poor quality; but most aquifers in danger of salt-water encroachment are near the coast, where water from the sea, or salty water from part of an aquifer that has not been flushed out by fresh water, tends to move toward the wells as the water levels are lowered by pumping or natural flow. In areas threatened by salt-water encroachment, the best method of detecting the approach of salty water is by means of so-called outpost wells, and the only method of guaranteeing a perennial supply of uncontaminated water is to permit the establishment of a ground-water divide between the salty water and the wells, by reduction or redistribution of pumpage or artificial recharge. In places where contamination has already occurred, the value of the ground-water supply can be salvaged to a considerable extent by using the water for purposes in which quality is not so important, such as cooling.

Examples of aquifers with high rates of recharge and discharge are the productive Tamiami limestone in the Miami (Fla.) area, the Ocala limestone of central and northern Florida and coastal Georgia, and some deposits of glacial outwash sand and gravel in the northern states—for example, (a) those in the valleys of the Ohio River and several of its northern tributaries; and (b) some highly productive glacial gravels in the Pacific Northwest. Aquifers with low rates of recharge (where heavy withdrawals are largely from storage) include the Ogallala formation in parts of the High Plains (as in the Panhandle of Texas), the Dakota sandstone of the Dakotas and adjacent states, and some of the desert basins or bolsons of the West—for example, the Mimbres Valley in New Mexico. Several representative aquifers of both classes will be described to show the great variety of ground-water conditions in the United States.

Examples of Aquifers with High Rates of Recharge and Large Perennial Supplies

The water-bearing limestone in the Miami area is one of the most permeable and productive aquifers in the United States (11). The rate of recharge from precipitation is high, and of course so is the rate of natural discharge through seeps and springs and by evaporation and transpiration. The coefficient of transmissibility (expressed as the number of gallons of water per day that will move through a section of the aquifer 1 mile wide under a hydraulic gradient of 1 ft per mile) has a value of 2,000,000 to 3,000,000 in the vicinity of Miami, whereas in many heavily pumped aquifers in the United States the value is less than 50,000.

In some places the water supply of the productive aquifer in the Miami area is jeopardized by salt water, which has access to certain areas of heavy pumping, especially by way of drainage canals. The well field of the Miami public water supply was actually affected by salt water that gained access through a canal, and it has been necessary to install a movable dam in the canal to prevent salt water from reaching the well field during periods of low flow in the canal. Also, a "tongue" of salty water is moving slowly toward the well field underground along the canal, and eventually will reach the well field unless a certain minimum fresh-water head, established by redistribution of pumpage or by some other method, is maintained continuously in the area between the salt-water tongue and the well field (11). However, the investigations of the U. S. Geological Survey have shown that, with proper management, the cities of Miami, Miami Beach, and Coral Gables (in Florida) have a very large perennial supply of fresh water.

Areas of productive glacial outwash deposits include those in the Spokane Valley-Rathdrum Prairie area, in Washington and Idaho. The glacial outwash deposits, at least 500 ft thick in many places and very permeable, serve as the underground outlet for water from an arm of Lake Pend Oreille, and the underflow is estimated to be not less than 1,000 cu ft per sec, or about two thirds of a billion gallons per day (unpublished reports by A. M. Piper and L. C. Huff in the files of the U. S. Geological Survey). An average of about 100 cu ft per sec, or about 65 mgd is withdrawn for use in the Spokane Valley.

Glacial outwash deposits in the valleys of the Ohio River and some of its tributaries yield large supplies of water to wells at many places. There is much recharge from rainfall and melting snow, but the river forms a major source of recharge at some places where wells have been constructed near the river and are pumped heavily enough to lower the water table adjacent to the stream. Examples of such supplies (unpublished reports in the files of the U. S. Geological Survey) include the public water supply at Parkersburg, W. Va., and the water supplies at large war plants at Point Pleasant, W. Va., and Charlestown, Ind. At one war plant as much as 50 mgd has been pumped from seven wells in a 2-mile stretch along the banks of the Ohio River. Similar conditions exist in many other valleys. Many large industrial and municipal water supplies have been developed from wells that are so situated as to induce recharge from the streams, and many others undoubtedly will be developed in the future.

In the Mill Creek Valley Water Supply Project, installed by the Federal Works Agency, water is pumped from wells penetrating permeable glacial outwash sands and gravels in the Miami River Valley south of Hamilton, Ohio, and is piped to a large plant in the Mill Creek Valley to the southeast. The designed capacity of the system is 15 mgd. The wells are located so as to take advantage of recharge from precipitation in the immediate vicinity and to intercept ground water flowing westward from a ground-water divide at the head of the Mill Creek Valley; but considerable water will be recharged from the Miami River when wells near the river are pumped heavily (12).

In the Louisville (Ky.) area, large quantities of water are pumped from wells, mostly from wells penetrating glacial outwash deposits in the Ohio Valley. The average pumpage increased from about 37 mgd in 1937 and 1938 to about 62 mgd in 1943 (13). A large part of the total recharge, which is estimated to be from 30 mgd to 40 mgd, is believed to come from the Ohio River.

The pumpage at Louisville has been in excess of recharge for some years, and water has been withdrawn from storage with resulting declines in water levels. In 1943 from 20 mgd to 30 mgd was withdrawn from storage. Inasmuch as the outwash deposits are only about 100 ft thick, the storage has been greatly depleted, and substantial reduction in the rate of pumping will be necessary unless the supply can be greatly increased by wells near the river or by artificial recharge.

In the Platte River Valley of Nebraska, which is cut into deposits of sand, gravel, silt, and clay of glacial and fluviatile origin, recharge of the ground-water supply is largely from precipitation. There is some recharge from the river, however, when increased flows occur following the dry season and also during floods, whenever they occur (14)(15). During most of the year, however, the water table is above stream level and water moves underground toward the river rather than away from it. The contours of the water table show that water recharged from precipitation moves toward the river and discharges into it. However, the movement has a downstream component because of the slope of the valley, and thus the individual particles of water have an oblique path with respect to the river. The downstream component can be considered underflow; but it is small in comparison with the total amount of water re-

charged and discharged and can scarcely be compared with true underflow such as that in the Spokane Valley.

An example of productive water-bearing formations in which droughts may aggravate the effects of heavy pumping is the Indianapolis (Ind.) area. The principal aquifer consists of glacial outwash deposits, but these deposits overlie and furnish water to limestones from which a large quantity of water is also pumped. The effects of two successive years of drought, 1940 and 1941, combined with the effects of record pumping in 1941 to produce critical ground-water conditions in some parts of the area (16). The average pumpage in 1941 was about 52 mgd. During 1942, however, the precipitation was about normal, the pumpage of ground water decreased to about 47 mgd, and the over-all ground-water conditions improved considerably (16).

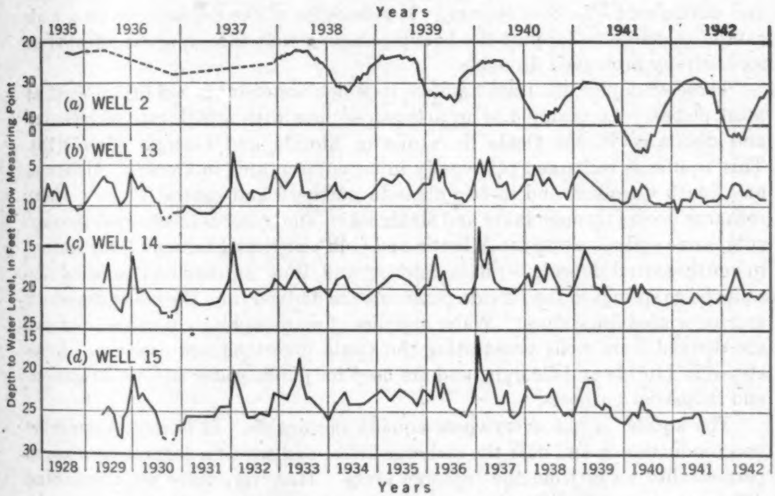

FIG. 5.—HYDROGRAPHS OF SELECTED WELLS, 1928–1942; INDIANAPOLIS, IND.

Wells 13, 14, and 15, Fig. 5, show fluctuations of the water table in an area where recharge is high and where pumping from wells is fairly heavy. The wells penetrate glacial outwash sand and gravel. A total of several million gallons per day is pumped from a gravel pit and from a number of drilled wells. The water levels in the wells were low in 1940 and 1941 as the result of drought and pumping. However, they were not as low as during the drought of 1930–1931. The water levels recovered considerably in 1942, but were much lower than in years of large recharge, such as 1932 and 1937. It is apparent that, because of a high average rate of recharge, the effects of pumping in this area are relatively slight except in years of drought.

Fluctuations in an area where the rate of recharge is relatively low are shown in Fig. 5(*a*). Well 2 penetrates glacial outwash sand and gravel in the

downtown district of Indianapolis, where percolation of water from above is reduced or prevented by pavements and buildings and recharge largely results from lateral percolation from surrounding areas. As the result of heavy pumping, the water levels in wells showed net declines for several years and reached a low stage in 1941, when recharge was reduced by drought. In the summer of 1941 the pumping water levels in some of the wells (about 100 ft deep) penetrating sand and gravel in the downtown district were not far above the bottoms of the wells. As a result of increased recharge in 1942 the water levels rose somewhat but, because of continued heavy pumping, were considerably lower than in 1940 and previous years.

It is estimated that, since pumping began in the Indianapolis area, a total of 400,000,000,000 gal to 500,000,000,000 gal of water has been pumped from wells. Of this volume, about 97% is estimated to have come from recharge and only about 3% from storage. It is because of the dependence on a high rate of recharge to support the heavy pumping that the supply is affected so seriously by prolonged droughts.

These examples illustrate aquifers in which water-table conditions exist at most places. An example of an artesian aquifer with a high rate of recharge and discharge in the Ocala limestone of Florida and Georgia (9)(17)(18). This aquifer is recharged principally in its outcrop area in Georgia, Alabama, and South Carolina, and in two areas in northern and central Florida where recharge occurs through lakes and sinkholes. The water is discharged through submarine springs along the Atlantic and Gulf coasts and through large springs in north-central Florida. Silver Springs and Blue Springs and most of the other large springs in the Florida peninsula are derived from the Ocala limestone and associated limestones. Water supplies of many millions of gallons per day are derived from wells penetrating the Ocala limestone and associated limestones in Florida and Georgia, and are used for public water supply, irrigation, and industrial purposes.

The aquifer is not everywhere equally permeable. It is most permeable and productive in and near the recharge areas, and shows a general decrease in permeability away from the recharge areas. However, there are substantial differences in permeability in areas at approximately equal distances from the recharge areas. For example, at Brunswick, Ga., and Jacksonville, Fla., the Ocala limestone is relatively productive, but at Fernandina, Fla., between Jacksonville and Brunswick, the aquifer is somewhat less productive. In 1943, the draft at the three places ranged from 34 mgd to 40 mgd, as shown in Fig. 6(*a*), which also shows the pumpage at Savannah, Ga. In Fig. 6, the contours (interval, 10 ft) represent approximately the height to which water would rise above mean sea level in tightly cased wells penetrating the principal artesian aquifer in 1943 (Fig. 6(*a*)) and in the first wells ever drilled into the Ocala limestone (Fig. 6(*b*)). The piezometric surface was still above the land surface at Jacksonville and Brunswick, except in the immediate vicinity of pumped wells, whereas, at Fernandina, the piezometric surface was below the land surface in the heavily pumped area. The contrast between conditions at Fernandina and those at Brunswick and Jacksonville is shown strikingly in Fig. 6(*a*). The pumping at Brunswick has caused only a slight lowering of the

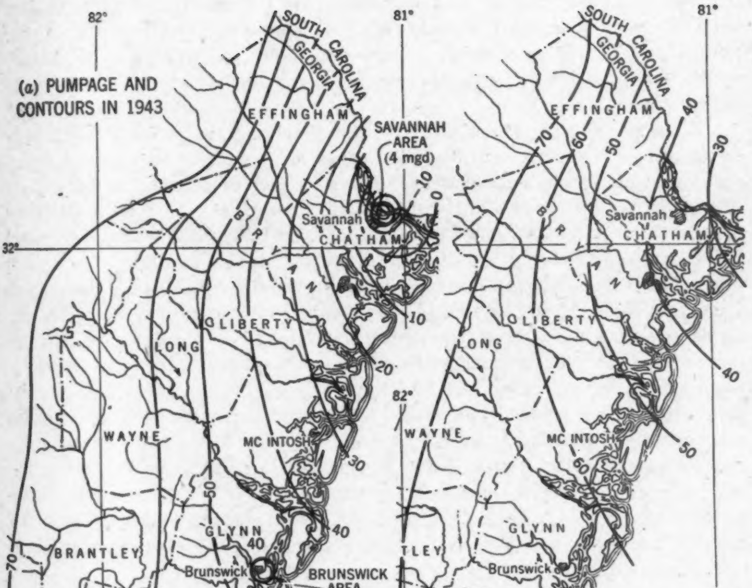

FIG. 6.—PIEZOMETRIC SURFACE OF THE OCALA LIMESTONE IN THE COASTAL AREA OF GEORGIA AND NORTHEASTERN FLORIDA

piezometric surface, whereas at Fernandina it has created a substantial cone of depression. The pumping at Jacksonville has created a cone of depression slightly deeper than that at Brunswick, but considerably shallower than that at Fernandina. A substantial cone of depression has formed at Savannah, where the productiveness of the aquifer is roughly comparable to that at Fernandina.

Where problems of depletion by pumping, not aggravated by drought, have developed in productive aquifers, the cause has generally been concentrated pumping from closely-spaced wells. In many such areas the remedy consists in wider spacing of wells and redistribution of pumpage. In the Baton Rouge (La.) area, as much as 50 mgd has been pumped from the so-called 400-ft and 600-ft sands in an area of about 6 sq miles—much of it in an area of not much more than 1 sq mile (unpublished reports in the files of the U. S. Geological Survey by J. C. Maher and G. C. Taylor, Jr.). Although the water-bearing sands are very productive, the concentrated pumpage in a small area has lowered the water levels in the wells to such an extent that it has been necessary to adopt emergency conservation measures at some of the important industrial plants to insure continued production. Among these measures is the development of supplementary water supplies from the Mississippi River. The ground-water problem in the Baton Rouge area can be solved by distributing the wells that penetrate the 400-ft and 600-ft sands over a larger area and by developing additional water from other sources, including deeper sands in the heavily pumped area and the virtually untouched deposits of alluvium adjacent to the Mississippi River.

Examples of Aquifers with Relatively Small Perennial Supplies

An example of a less productive aquifer which has a fairly high potential rate of recharge but which is strongly affected by drought is the shallow aquifer in the Elizabeth City (N.C.) area (19). The aquifer consists of surficial sands of Pleistocene age, about 30 ft thick. The climate is humid, the average rate of recharge is fairly high, and a moderately large quantity of water can be developed from a system consisting of numerous wells with small individual yields distributed over a large area. A supply of this kind has been developed for Elizabeth City. Because of the small saturated thickness of the aquifer, the successful development of a large supply depends on sustained recharge from precipitation. During prolonged droughts, the small amount of storage is quickly depleted, but with the return of wet weather the available storage space is refilled.

Among the aquifers with a low average rate of recharge, where heavy withdrawals are largely from storage, is the Ogallala formation, the principal aquifer underlying the High Plains. The formation consists largely of a sheet of alluvium deposited in Tertiary time, overlying older dissected rocks. It ranges in thickness from a featheredge at the border of the plains to more than 500 ft in some places. The formation, especially the lower part, consists largely of sand and gravel and contains an enormous amount of water in storage.

Investigations of the hydrology of the Ogallala formation by the U. S. Geological Survey and cooperating agencies are under way in most of the area

underlain by the formation (20)(21)(22)(23)(24)(25)(26)(27)(28)(29). In general, they show that the formation is recharged by precipitation but that the rate of recharge is low. In different places the annal recharge from precipitation probably ranges from a fraction of an inch to a few inches of water.

A report by W. L. Broadhurst and W. H. Alexander, Jr. (20), in 1944, shows the situation that exists in the High Plains in Texas. From 1935 to the end of 1943 the number of irrigation wells in this region increased from about 300 to about 2,950, and the area irrigated increased from 35,000 acres to 400,000 acres, or about 13% of the total area within the boundaries of the irrigated districts. From 1937 to 1941, a period of subnormal precipitation, the increase in irrigation was accompanied by a persistent decline of the water table (Fig. 7). During 1941 the precipitation was heavy, the greatest on record in parts of the region. Consequently, the requirements for irrigation were small, recharge to the underground reservoirs was unusually large, and observation wells in each pumping district showed a pronounced rise in water level. During 1942 the precipitation was again above average, pumping was again light, and the water levels in most of the wells either remained nearly stationary or rose slightly. During 1943 the precipitation was light, the pumping was greater than ever before, and practically all the wells showed a decline in water level (Fig. 7).

It should be stated that the rainfall in 1941 was exceptional and the pumping for irrigation in both 1941 and 1942 was light. The recharge that occurred in 1941 was probably greater than in any year since 1915 and several times the recharge in most years (21). Nevertheless, net declines in water level occurred in the Plainview and Hereford districts; and, although net rises occurred in the Lubbock-Littlefield and Muleshoe districts, the water levels generally resumed their downward trend in 1943. It is evident that the rate of pumping will eventually have to be curtailed greatly in this region.

The Dakota sandstone (which underlies most of North Dakota and South Dakota and considerable parts of near-by states, extending to the south as far as New Mexico) is an aquifer in which water is confined under pressure by thick beds of younger rocks, mostly shale (30). The sandstone crops out at relatively high altitudes in the foothills of the Rockies and those of the Black Hills, and is recharged in these areas. The artesian pressure was 200 lb per sq in., or even more, at some places when the first wells were drilled, and the wells had initial flows of several hundred gallons per minute (31)(32)(33)(34)(35). However, the average permeability of the sandstone is rather low, the specific capacity of the wells—that is, their yield per unit of drawdown—is small, and most of the water represented by the large initial yields was derived from storage by compaction of the beds as the head was lowered.

The high initial yields of the wells gave a false impression of the productiveness of the aquifer and encouraged the drilling of many wells and the withdrawal of excessive quantities of water throughout the Dakota artesian basin. However, as the artesian head was lowered, the yield of the wells decreased; and in some areas the yield is slowly approaching the perennial rate of recharge. For example, in one row of townships in the Ellendale-Jamestown area of North Dakota, the total yield of flowing wells penetrating the Dakota sandstone was about 520 gal per min in 1938. The estimated perennial recharge is about 500

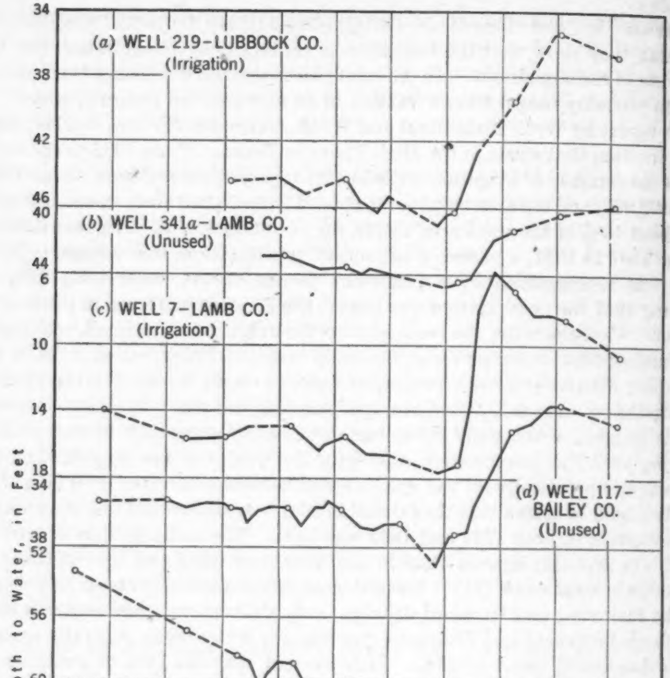

FIG. 7.—HYDROGRAPHS OF WELLS IN THE HIGH PLAINS OF TEXAS

gal per min (30). The yield of the wells in this row of townships in 1923 was about 1,000 gal per min, and the total yield when the wells were being drilled, largely between 1900 and 1920, was doubtless much greater.

Somewhat analogous conditions are found in the region in Illinois, Iowa, and Wisconsin underlain by Cambrian and Ordovician sandstones, although the artesian head was never as high as that in the Dakota Basin, partly because of a smaller difference in altitude between the outcrop areas and the areas of withdrawal. Comparatively few detailed investigations have been made of these aquifers, but great declines in water level have occurred in large parts of the region and much of the water withdrawn has been derived from storage (36)(37). The head of a well drilled at Chicago, Ill., in 1864 was 80 ft above the surface and about 692 ft above sea level (36). This well penetrated the

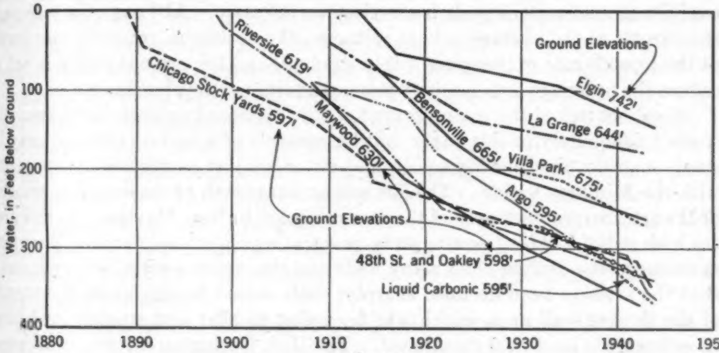

FIG. 8.—DECLINE OF WATER LEVELS IN WELLS IN AND NEAR CHICAGO, ILL., 1899–1943.

Galena-Platteville limestone, which doubtless had a head lower than that of the deeper Cambrian sandstones that have since been developed so heavily. In 1943, according to data issued by the Illinois State Water Survey, the water levels in some wells at Chicago, penetrating the Cambrian sandstones, were at altitudes as low as 230 ft above sea level, and the decline undoubtedly continued during 1944 (Fig. 8).

The Mimbres Valley in New Mexico has a very large quantity of water in subterranean storage and many productive wells. It was assumed to have a large perennial supply until critical investigation showed that the average annual recharge is actually quite small. The valley consists of a structural basin, floored with relatively impervious consolidated rocks and filled with alluvial deposits of gravel, sand, silt, and clay, derived from the adjacent mountains (38). The ground-water supply is recharged largely by the Mimbres River, which sinks into the alluvium after leaving the mountains. Rainfall on the floor of the valley and return flow from irrigation contribute relatively minor quantities of water. The average annual recharge was estimated to be about 10,000 acre-ft for the period from 1908 to 1928—an average of about 9

mgd. Records of water levels in wells, and of stream flow, show that recharge was slight during the period from 1929 to 1940, inclusive. Even in 1941, an exceptionally wet year, the recharge was not very great. Recharge from the Mimbres River is probably less than it was formerly because of the greater use or river water for irrigation in the headwater areas.

The total pumpage, largely for irrigation, increased from about 10,000 acre-ft per yr during the period from 1929 to 1933 to about 25,000 acre-ft in 1940 (an average of about 22 mgd), and decreased only to about 21,000 acre-ft in the exceptionally wet year of 1941. The records of water levels in wells show that most of the water pumped has been derived from storage in the subterranean reservoir. Even in 1941 there was a net loss in storage of several thousand acre-feet in the valley as a whole.

The Mimbres Valley is one of the areas in New Mexico in which legal control over the ground-water supply is exercised by the state. Although the pumpage is in excess of the average rate of recharge, the decline in ground-water levels at the present rate of pumping will be gradual, and the present policy is not to reduce the pumpage but simply to restrict additional developments.

Legal control of the use of ground water is a broad subject that cannot be treated adequately in this paper, but an example of a sound approach may be cited—namely, the New Mexico ground-water law just mentioned in connection with the Mimbres Valley. The law was an outgrowth of the overdevelopment of the artesian water supply of the Roswell basin in New Mexico. In this area the high initial yields of flowing wells penetrating cavernous Permian limestone encouraged the drilling of so many wells and the withdrawal of so much water that the artesian head declined sharply; wells ceased flowing along the margin of the flowing well area, which was becoming smaller and smaller; and large investments in land were threatened. The U. S. Geological Survey, in cooperation with the state engineer, made a thorough investigation of the region, determined the perennial safe yield of the artesian aquifer, and assisted state officials in drafting a law for the control of the ground-water supply. The law was enacted and has been enforced effectively by the state engineer with the cooperation of the ground-water users; thus the valuable artesian water supply is both efficiently developed and secure (39)(40). Conservation of water is effected by preventing wasteful use of water for irrigation and by reducing loss of water from the limestone into the overlying valley fill by locating and plugging leaky wells.

The New Mexico ground-water law is regarded as a model. Its development was made possible by the thorough investigation of the ground-water supply of the aquifer concerned and the determination of the rate at which water could be withdrawn perennially. Unless a good estimate of the perennial water supply of an aquifer has been made available through adequate investigation, a law enacted for control of the water supply of the aquifer is likely to be difficult or impossible to enforce.

Probably the most serious problems of ground-water depletion will arise in the areas underlain by aquifers that have low rates of recharge but from which wells can obtain initial yields of several hundred gallons per minute—or even 1,000 gal per min—giving the impression of perennial supplies more abundant

than they actually are, and leading to overoptimistic and excessive development. The impression of abundance may be caused by high permeability, as in the Mimbres Valley, or to high artesian head, as in the Dakota artesian basin.

Artificial Recharge

A method of conserving ground-water supplies that will be used more and more in the future is artificial recharge, in which water from streams or water pumped from wells is recharged to the ground-water reservoirs (41). Artificial recharge has been practiced on a large scale for some years in California, where recharge has been accomplished by passing water from streams or other bodies of surface water over the ground—in ditches, in furrows, in basins, or in a thin sheet, by a method commonly known as "water spreading." The infiltration galleries from which the public water supply of Des Moines, Iowa, is obtained are recharged artificially from shallow basins excavated over the galleries. Similar projects are in operation at a few other places in the eastern part of the United States, including Dayton, Ohio. Recharge from an artificial lake is accomplished in the Duhernal water-supply development near Old Bridge, N. J.

A method that has been used on a large scale in relatively few places is artificial recharge through wells. The most notable example is on western Long Island in New York, where water pumped for cooling from wells at more than a certain minimum rate must be returned to the ground through wells constructed for the purpose (42)(43). The New York State Water Power and Control Commission has the authority to require similar practices elsewhere on Long Island if necessary.

At Louisville where the present pumpage of ground water is in excess of the recharge and the ground-water levels are declining, artificial recharge of certain wells was undertaken at the suggestion of the U. S. Geological Survey and through the efforts of the War Production Board and the industries concerned. This recharge permitted continued production of industrial alcohol at certain plants whose production otherwise would have had to be curtailed because of lack of water (44). Wells are also being recharged on a fairly large scale at Indianapolis (16), at a large industrial plant in Virginia, and probably at several other places. It is to be expected that, at many places, wells will be recharged with cold filtered surface water in the winter, where the value of ground water for cooling purposes makes this practice economically feasible. This type of recharge is practiced at Louisville and at the industrial plant in Virginia.

Methods of Investigation

The hydrology of ground-water reservoirs is a somewhat complicated subject, and each reservoir has its own peculiar characteristics, due both to natural conditions and to the extent and distribution of the ground-water developments. Thus, each reservoir must be given individual study. The science of ground-water hydrology has advanced greatly in recent years, and methods are becoming available for the comprehensive study of the major ground-water reservoirs that will show the quantities of water that are perennially available and how to develop and utilize them efficiently.

The U. S. Geological Survey is engaged actively in the development of methods for making pumping tests and analyzing the results with respect to: (*a*) The quantities of ground water that are available in specific areas, (*b*) the extent of interference between different wells or groups of wells, and (*c*) the additional supplies that can be developed by proper distribution of the pumpage (45)(46)(47). Important developments have been made in recent years on the basis of the Theis nonequilibrium method, which permits the determination, from simple pumping tests, of the coefficients of transmissibility and storage of an aquifer—that is, the rate at which water is transmitted under a given gradient and the quantity of water released from storage with a given lowering in head. These two fundamental coefficients are then utilized to predict the effects of pumping given installations of wells penetrating the aquifer. Refined methods are coming into use for analyzing the results of pumping tests in aquifers that are limited by relatively impermeable boundaries within a short distance from the wells or in aquifers whose sources of recharge are near by. Under favorable conditions the results of pumping tests can even be used to determine the presence of geologic structures, such as a fault or other barrier that may not be apparent from surface observation or well records.

Conclusion

Deforestation, cultivation of land, drainage, and similar practices have undoubtedly affected ground-water supplies to some extent in the areas involved, but there is no reason to believe that the effects have been progressive over long periods of years in most parts of the United States. The effects of pumping or natural flow from wells are of great concern; and, as has been shown by the numerous examples of aquifers of different kinds that have been described, the conservation and development of ground-water supplies in the future will require thorough investigation of each major aquifer and effective legal control of the withdrawals from the more heavily developed aquifers. In some places heavy withdrawals from wells are depleting the ground-water supply and cannot be continued indefinitely; in many other places recharge is large and therefore large supplies will be perennially available to wells.

DISCUSSION

E. A. VAUBEL,[3] Assoc. M. ASCE.—The thought that depletion of ground-water supplies does not occur suddenly but results from hydrological withdrawal from storage at rates greater than recharge is strikingly presented in this paper. Because many variables enter into a decline in water levels and differ somewhat even at two points in a restricted area of a few square miles, it is reasonable that many people might assume that declining levels would spell exhaustion of ground-water supplies within a few years.

As the author states, the properties of the individual aquifers determine how much water can be drawn from them by wells. When progressive declining levels occur due to a concentrated pumping requirement in a limited area, it is certainly proper to consider and to put into effect certain engineering concepts which promote effective utilization and conservation of ground-water resources. These concepts are:

1. Proper well spacing, projected by use of the Theis nonequilibrium formula applied to measured production and pumping levels of existing adjacent wells and pilot wells, can enable large municipal and large industrial users to secure their ground-water requirements without fear of depletion.

2. Sometimes in an existing well field, a redistribution of pumpage to equalize the effect of the water levels will help to forestall a rapid decline in a given sector of the field. This is attained by taking production from outlying wells in order to enlarge and equalize the withdrawal per given unit of area. The piezometric surface then tends to be devoid of the depression cones created by excessive pumpage in a small area in a well field. In terms of operation procedure, it may be stated that the quantities withdrawn from outlying wells should be equivalent to those withdrawn from strategically located wells in the center of the well field.

3. In many areas additional exploration will reveal the exact depth and thickness of aquifers and permit withdrawal of water for piping from a relatively virgin area to the point of use, without undue economic expense. A planned test drilling program is advisable when considering a long range ground-water supply requirement so as to be certain that the extent of the aquifer is definitely known.

4. Where known sands afford water of different mineral quality, it is expedient and within good conservation practice to utilize the better quality of water for boiler and domestic use. By this is meant water of low hardness and with chlorides generally within the United States Public Health Service standards. Where supplies of greater hardness and chloride content occur, these can generally be better utilized for certain industrial processes and cooling.

5. In serving the water supply needs of a large community the fact must not be overlooked that certain surface streams may supplement a ground-water supply program or vice versa. Sometimes there is a tendency to balance production, storage, and distribution costs of one against the other, although both

[3] Engr., The Layne Texas Co., Ltd., Houston, Tex.

may be required to supply the present and future needs of a large and growing center of population adequately. Surface and ground water each have inherent advantages and disadvantages; the advantages of each are sometimes necessary to complete the water supply picture.

The points outlined, which are suggested procedure for attacking a ground-water supply depletion problem, were covered in part by the author, but item 5 supplements his presentation. Delineation by items serves to emphasize the points covered in detail and by example in the paper.

The Houston, Tex., area presents an example of an aquifer which has a high rate of recharge due to heavy precipitation, a large outcrop area with average permeability, and a series of sands totaling approximately 600 ft in thickness; and which, as a result, affords a large perennial supply. However, the discharge required from the aquifer is becoming increasingly greater due to industrial and municipal growth and irrigation usage. Therefore, the previously enumerated factors will have to be utilized to provide ample quantities for future water supply requirements.

RAPHAEL G. KAZMANN,[4] ASSOC. M. ASCE.—An excellent summary of the present status of prevailing thought on the permanence and productivity of ground-water supplies is contained in this paper. Unfortunately the paper is too short to do more than summarize various situations. To focus the attention of the profession on the economic implications resulting from just one study of a specific ground-water situation, reference is made to the High Plains of Texas where, in 1943, 400,000 acres of land were irrigated from wells. Under the heading, "Examples of Aquifers with Relatively Small Perennial Supplies," the author states: "It is evident that the rate of pumping will eventually have to be curtailed greatly in this region."

Although the author does not state how long "eventually" may be, it is probable that within the next generation violent changes in the agricultural activity of the area will result from a shortage of ground water. A number of farmers will lose the major part of their capital investments in pumping plants, distribution systems, and farm buildings as a result of ground-water depletion; yet a sound, controlled program of ground-water development would enable a smaller amount of irrigation farming to continue indefinitely in the High Plains area.

In the other direction are the economic implications of the possibilities of increasing the usable ground-water supplies by improved methods of ground-water extraction. Mr. McGuinness states (under the heading, "Examples of Aquifers with High Rates of Recharge and Large Perennial Supplies"):

> "There is much recharge from rainfall and melting snow, but the [Ohio] river forms a major source of recharge at some places where wells have been constructed near the river and are pumped heavily enough to lower the water table adjacent to the stream. Examples of such supplies * * * include the public water supply at Parkersburg, W. Va., and the water supplies

[4] Hydrologic Engr., Ranney Method Water Supplies, Inc., Columbus, Ohio.

at large war plants at Point Pleasant, W. Va., and Charlestown, Ind. At one war plant as much as 50 mgd has been pumped from seven wells in a 2-mile stretch along the banks of the Ohio River. * * * Many large industrial and municipal water supplies have been developed from wells that are so situated as to induce recharge from the streams, and many others undoubtedly will be developed in the future."

Mr. McGuinness did not mention that the "wells," referred to at the war plants, were a relatively new development in ground-water engineering—that is, the radial, horizontal water collectors which are the equivalent of infiltration galleries laid on the bottom of an aquifer. The special virtue of these units is their capacity to operate with utmost efficiency in relatively thin aquifers where conventional wells are impracticable because of the smallness of the available drawdown. Horizontal collectors have their screens projected, horizontally, as close as possible to the bottom of the aquifer. Thus, they operate with equal efficiency as long as a little water remains in the aquifer. In the installations supplied by the infiltration of river water, the potential size of the differential head between the river and the collector or infiltration gallery is a maximum, thus making the supply as large as possible, and permanent as well.

Probably the outstanding installation of horizontal infiltration collectors was made in 1942 at the Wabash River Ordnance Works near Clinton, Ind., where an average production of 72 mgd and a maximum production of almost 89 mgd was obtained from six units (48).

The value of the additional, permanent ground-water supplies to municipalities and industries is incalculable. However, the horizontal infiltration collector, or any other type of infiltration gallery, although it will develop many new ground-water supplies, is certainly not the last technical advance which will affect the economic availability of ground water. The history of ground-water development shows that improved drilling and pumping methods have increased available ground-water resources. The horizontal water collector too has increased the potential ground-water supply by making thin infiltration aquifers economically available. Finally, a lessening of power costs through the use of new sources of energy would tend to agument available ground-water supplies.

Thus, from an engineering viewpoint, the principal addition needed in Mr. McGuinness' excellent paper is a short section dealing with the effect of technology in increasing the potentially useful quantity of ground water. Applied hydrology must consider engineering techniques.

Charles L. McGuinness,[8] Esq.—Mr. Vaubel makes several interesting and useful comments from the standpoint of the development and operation of water supply systems based on wells. He points out that proper well spacing, using the nonequilibrium formula as adapted by Charles V. Theis, is necessary. It might be emphasized that the use of the unmodified Theis formula is quite successful in many parts of the Coastal Plain in Texas and other coastal states, where extensive aquifers are typical. In many places where the aquifers are

[8] Geologist, U. S. Geological Survey, Washington, D. C.

bounded—or where sources of recharge exist—at short distances from the wells, modification of the formula by intricate mathematical methods may be necessary.

The statement that water of poor chemical quality should be used for purposes in which quality is relatively unimportant deserves great emphasis, especially in the many areas where water of the best quality is limited in quantity. Equally important is the statement concerning the need to consider both ground-water supplies and surface-water supplies in designing each installation.

Mr. Kazmann points out that it was not specified how long was meant by "eventually" in stating that curtailment of irrigation pumping in the High Plains of Texas will eventually be necessary. The length of time depends on the extent to which irrigation pumping, so far entirely uncontrolled, continues to increase. Obviously, adequate legal control by the states of ground-water withdrawals, based on quantitative estimates of the long-term yield obtained by thorough investigation, would go a long way in preventing undue hardship and excessive financial losses in such situations as that in the High Plains.

Mr. Kazmann also points out that the original paper was deficient in not containing a discussion of the effects of technological developments on the availability of ground-water supplies. Such developments in the past, especially the improvement of pumps, have greatly increased the amount of water economically available from wells. They have even led to overpumping in some areas where the aquifers are permeable but the rate of recharge is low. However, with the constant development of improved methods for determining the safe yields of aquifers and with the growth of effective and equitable legal control of ground-water withdrawals, technological progress in methods of extracting ground water may be expected to be entirely beneficial in the future.

MODEL STUDY OF BROWN CANYON DEBRIS BARRIER

By Karl J. Bermel,[1] Assoc. M. ASCE, and
Robert L. Sanks,[2] Jun. ASCE

With Discussion by Messrs. Clifford A. Betts, Roger E. Amidon, Ettore Scimemi, J. W. Johnson, and Karl J. Bermel and Robert L. Sanks.

Synopsis

The principal hydraulic tests of a 1:50 scale model of a debris barrier and the contiguous channel, with some corroborative prototype data, are included in this paper. Tests of the barrier include those for determining the spillway capacity, the performance of the overflow, the development of a stepped overflow crest, and the operation of the barrier with and without detrital material impounded upstream from the barrier. Tests in the channel cover the problems of scour downstream and deposition upstream from the barrier. Because of meager field data, especially regarding bed load and rates of transportation, the initial tests of deposition upstream from the barrier were based on bed load and rates of transportation as developed in the laboratory. These results were reasonably verified in subsequent tests, based on data obtained from the first major storm after completion of the prototype structure.

A discussion of these data was presented before the Waterways Division at the Los Angeles (Calif.) Meeting of the Society in July, 1943.

Introduction

As part of the effort to reduce flood damage in the heavily populated and highly developed metropolitan area of southern California, the U. S. Forest Service selected the Arroyo Seco watershed to inaugurate a comprehensive program of upstream flood control. The work in general is based on the findings and recommendations in a report by the U. S. Department of Agriculture dated January 14, 1939.[3]

Note.—Published in May, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[3] "Partial Plan for Runoff and Water-Flow Retardation and Soil Erosion Prevention for Flood Control Purposes, Arroyo Seco Flood Source Area," Survey Rept., Los Angeles River, U.S.D.A., January 14, 1939.

The watershed, north of Pasadena, Calif. (see Fig. 1), is approximately 30 sq miles in area, ranges from 1,100 ft to 6,000 ft in elevation, and is composed for the most part of a much fractured, deeply weathered, and disintegrating rock mass. The slope of the main channel in the lower part of the arroyo varies from 1.9% to 3.2% and the slopes of the tributaries vary from 10% to 67%. Records from twenty-two precipitation stations for a period from

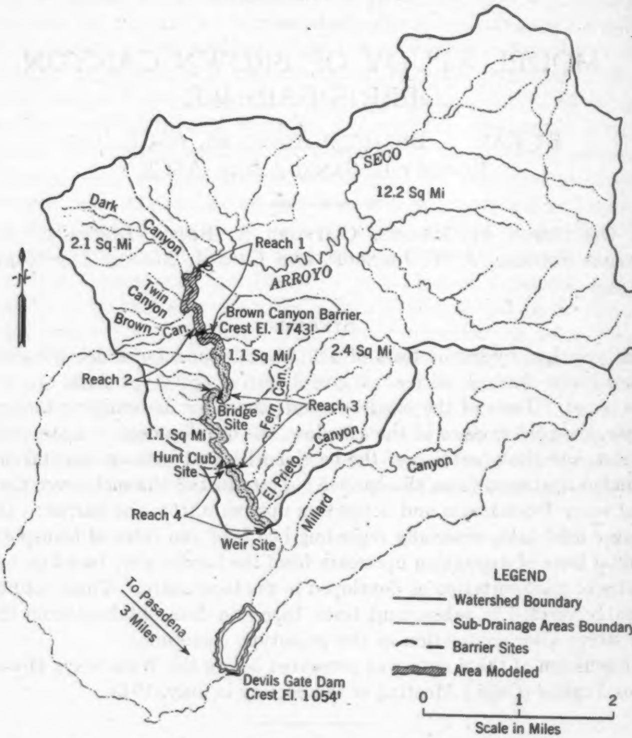

FIG. 1.—ARROYO SECO WATERSHED SHOWING BARRIER LOCATION, SUBDRAINAGE AREAS, AND THE PARTS OF THE AREA TO BE MODELED

two to thirty-eight years indicate that seasonal rainfall varies from 6 in. to 34 in. near the mouth of the canyon, and from 11 in. to 60 in. at the higher elevations. The flow varies from 0 to a maximum recorded amount of 11,400 cu ft per sec (380 cu ft per sec per sq mile) near the mouth of the arroyo.

These factors of geology, precipitous slopes, and rains of high intensity, in combination with the loss of much of the protective vegetal covering because of fires and road construction, make this watershed a serious flood problem area.

Since 1825, eighteen known floods have occurred in this locality. Devil's Gate Dam, downstream from the mouth of the Arroyo Seco, in operation since

1920, has lost approximately one third of its storage capacity, of 4,500 acre-ft, because of detrital material from this watershed.

The Problem

As part of the plan to reduce the silting rate of Devil's Gate Reservoir and flood destruction along the stream, the U. S. Forest Service has contemplated the construction of a series of four debris barriers to be spaced approximately a mile apart, starting at a point about one mile upstream from Devil's Gate Dam (see Fig. 1). Because of the large fluctuations in discharge and debris load in the Arroyo Seco, adequate information for designing these barriers and data on the influence of the barriers on the regime of the stream were not available. To provide such information, a series of model studies was undertaken by the Forest Service in cooperation with the University of California, at Berkeley.

In brief, the plan of model studies for each of the contemplated barriers is as follows:

1. To test the proposed spillway designed and to develop, if necessary, modifications in design to obtain adequate flow capacity and proper operation;

2. To determine the location and type of structure required to dissipate the energy of the maximum design flow over the spillway, and to prevent or minimize the resultant scour in the downstream channel bed which would impair the stability of the barrier;

3. To determine whether protection to the downstream canyon walls is necessary to prevent excessive erosion during major floods; and

4. To determine the slope of the debris surface and the approximate volume of debris that would be impounded by the barriers.

Since the Brown Canyon Barrier, which is the uppermost of the four barriers (see Fig. 1), is the only barrier constructed, this paper is concerned with the description of the model tests of this structure.

Fig. 2.—Model of the Arroyo Seco, Reach 1, Facing Upstream

The Model

The model of the reach of the Arroyo Seco containing the Brown Canyon Barrier was constructed to an undistorted scale of 1:50. The part modeled is indicated by the hatched area marked "reach 1" in Fig. 1. The channel was shaped in a sand-clay mixture, using male templets as a guide in forming

the topography. The shaped channel was then covered with a thin protective coat of cement mortar, brush finished. Additional roughness for the canyon bottom was obtained by pressing model bed-load material into the fresh mortar. Fig. 2 is a view of the completed model of reach 1.

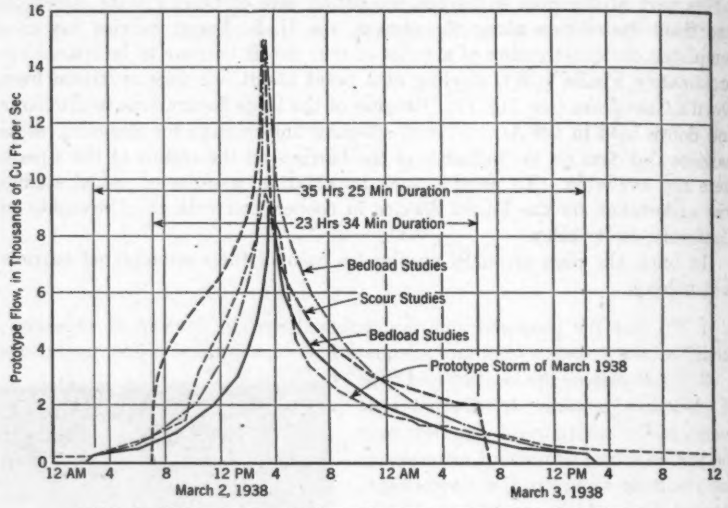

FIG. 3.—HYDROGRAPHS AND MODEL STUDIES OF THE ARROYO SECO STORM

The barrier model was constructed of wood with a smooth varnish finish, reduced to one fiftieth of actual size without distortion. The crest and wing walls were built separately to allow for possible changes in design.

Discharge in the model was measured by a 45° V-notch weir. A continuous record of the head-discharge relationship was obtained by the use of a water-stage recorder, and was supplemented by a point gage for more accurate measuring and for checking the adjustment of the recorder.

The factor for converting discharge in the model to discharge in the prototype was based on Froude's law since it was considered that the most important measurements of flow Q would be made at the barrier, and the factor of gravity would be more important than that of friction.

The formula used was as follows:

$$Q = A\,V = L^2_r\, D^{1/2}_r = L^{5/2}_r \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which A is the cross-section area; V is the average velocity in the section; L_r is the ratio of model length L_m to prototype length $L_p \left(L_r = \frac{1}{50} \right)$; and D_r is the ratio of model diameter D_m to the prototype diameter $D_p \left(D_r = \frac{1}{50} \right)$.

The hydrographs used in the model studies, and the hydrograph of the March, 1938, storm on which they were based, are shown in Fig. 3. Flow in

the prototype was measured over the Devil's Gate Dam (for the March, 1938, storm) and by the gaging station of the United States Geological Survey in the Arroyo Seco.

Crest Studies

The Brown Canyon Barrier is a constant-angle arch dam approximately 65 ft high and 220 ft long, with its spillway made roughly three fourths of this length to accommodate the maximum design flow. Since part of the flow is used for domestic purposes, the barrier was provided with a "grizzly" (an outlet 2 ft in diameter, adequately protected to prevent clogging) and numerous 6-in. weep holes to allow continuous flow passage.

The design crest (see Fig. 4) was provided with a 10-in. air duct, with 6-in. outlets spaced at 10-ft intervals under the lip of the crest, for aeration of the

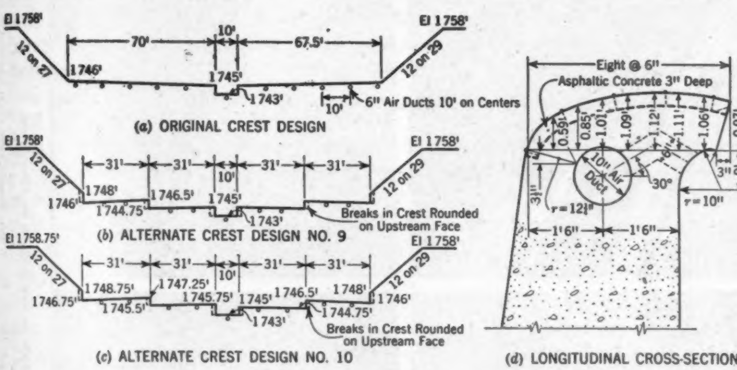

Fig. 4.—Crest Profiles and Section, Brown Canyon Barrier, Facing Upstream

nappe. Tests indicated that for flows as great as 1,500 cu ft per sec, which were accommodated in the flat part of the spillway, complete aeration was not obtained (see Fig. 5(*a*)). The depth and velocity of flow at the outside edges were insufficient, causing the nappe to adhere to the downstream face, and preventing aeration other than that provided by the air ducts.

For flows larger than 1,500 cu ft per sec, aeration was more complete, flow at the outside edges intermittently opening and then sealing off complete aeration, but not materially altering the profile of the nappe. At the maximum flow of 15,000 cu ft per sec, however, the area available for aeration on the right abutment was quite small (see Fig. 5(*b*)). Since measurements indicated ample freeboard, a minimum of 3 ft being stipulated, it was felt that reduction of the spillway length, by movement of the right wing wall, would be desirable to improve aeration and to decrease the flow over the right or east canyon wall. A total reduction in crest length of 12.5 ft improved conditions considerably. Further reduction was limited by the undesirability of increasing the stresses developed in the barrier by displacement of the right wing wall. Reduction of crest length produced no improvement in aeration for flows of less than 1,500

FIG. 5.—VIEWS OF THE MODEL IN OPERATION
(a) Original Designed Crest, Q = 1,500 Cu Ft per Sec
(b) Original Designed Crest, Q = 15,000 Cu Ft per Sec
(c) Final Crest, Q = 295 Cu Ft per Sec
(d) Final Crest, Q = 15,000 Cu Ft per Sec

cu ft per sec. Modifications of original design, such as increasing the flow section in the center or increasing the slope of the crest, were also unsatisfactory.

By resorting to a stepped crest, the low flows were confined to a narrower section, with improvement in aeration. With the steps level, considerable lag was encountered before flow over the side steps attained sufficient depth to spring free of the downstream face—the time of lag, of course, depending on the rate of rise or fall of flow.

Further improvements in crest design were directed toward reducing the time during which this undesirable condition was operative. Several variations in crest design were tested. The most effective was one in which the steps sloped up to the center of the barrier, thus making the flow on a step deeper toward the bank and shallower toward the center. As a result, a well-developed nappe falling free of the barrier was developed at the outside of a step by the time water was flowing over the highest part and joining with the water in the adjoining lower step. Therefore, the nappes under both steps were fully aerated at all times except at the instant when the flow over both was joined. At this instant a curtain of water was formed between the barrier and the nappe as before but was almost instantly broken, leaving the entire nappe well developed and falling free of the barrier.

Later tests, with the barrier filled with detritus, indicated that the flow had a marked tendency to pile up on the west side of the barrier. This condition was considered undesirable because of the excessive scour on the downstream canyon wall. To counteract this condition, the entire west half of the crest was raised 9 in. The modification was also beneficial for clear water flows (no detritus above barrier) by alternating the operation of the steps, thereby ensuring complete aeration of the nappe at all times (see Fig. 5(*c*) for operation of the final crest design at a flow of 295 cu ft per sec).

At the maximum flow of 15,000 cu ft per sec, steps in the barrier crest had no objectionable effect on the nappe. With this final design, considerable reduction in flow over the right abutment has been obtained (compare Fig. 5(*d*) with Fig. 5(*b*)). For comparison of head-discharge relationship of the various crests tested refer to Fig. 5. The extent of flow over the abutments was plotted on a grid system. In the prototype this area will be protected with gunite.

Scour Studies

For a barrier approximately 65 ft above bedrock, with flow about 7 ft deep over the crest at the maximum design discharge and with the bedrock fairly erosive, it was apparent that some form of protection to the downstream channel would be necessary. Observations as to the location and extent of scour that would occur without benefit of the various proposed types of protective structures were made before testing.

For this purpose five rates of clear steady flow were used, increasing from 1,500 cu ft per sec to 15,000 cu ft per sec (prototype values). With a sand-clay mixture for bedrock, overlain with loose bedrock material, each rate of flow was continued until scour conditions appeared stabilized. These tests indicated that the extent of scour, the maximum depth of scour, and the dis-

tance downstream to the point of maximum depth increased with increase in flow (see Fig. 6). Since the flow durations to achieve stability, especially for the two higher rates of discharge, are beyond any conceivable durations which might obtain in the prototype, the magnitude of depth of scour was considered indicative only of that which ultimately might develop.

Tests using an assumed hydrograph of the design storm, having a peak of 15,000 cu ft per sec, eliminating flows of less than 2,000 cu ft per sec and enduring for 171 hours (prototype time), produced a maximum depth of scour

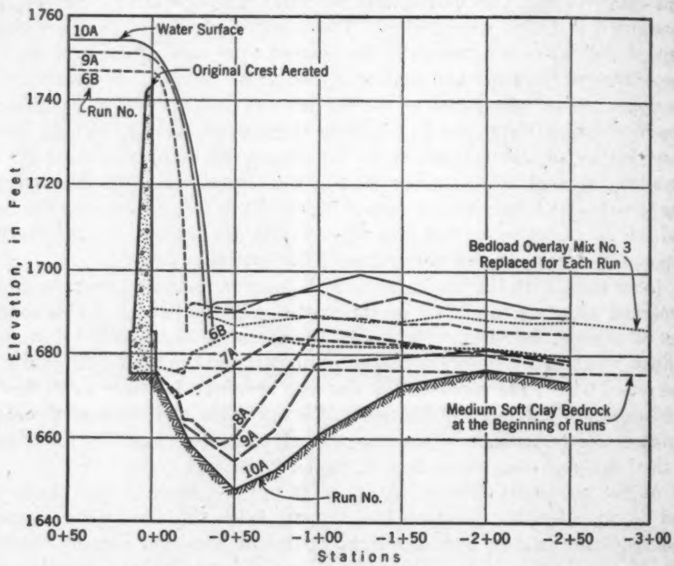

FIG. 6.—PROGRESSIVE SCOUR BELOW BROWN CANYON BARRIER

of 4.5 ft between 25 ft and 35 ft downstream. As a result, the use of the sand-clay mixture as bedrock was considered satisfactory, yielding results comparable to those which might occur in the prototype under similar flow conditions. With fixed bedrock, overlain with loose bedrock material, the results indicated that, where no scour hole could develop in the bedrock, more of the bedrock was exposed and, for the maximum flow of 15,000 cu ft per sec, the exposed bedrock extended downstream 290 ft.

In an attempt to determine the extent and duration to which the bedrock might be exposed, tests were made using hydrograph flow, of the design storm, capable of transporting bed load over the barrier. At the peak of the flow the extent of bedrock exposed was practically the same as that exposed for the maximum steady flow without bed load. However, with the recession of flow, bed load was redeposited over the bedrock. Bedrock between 100 ft and 285 ft downstream from the barrier was exposed for a little more than a third of the total flow duration.

Preliminary tests of an ogee sill (crest elevation 1,690), approximately 14 ft above bedrock, tested at 80 ft and 170 ft downstream from the barrier indicated that, to be effective, the height and the distance downstream would have to be increased considerably. Tests of two trapezoidal sills 380 ft downstream from the barrier (crest elevations 1,693 ft and 1,697 ft) reduced the depth of scour by approximately the amount that they increased the backwater elevation. The main objection to these structures was their large size and the scour problem they developed.

Tests of an apron 70 ft long showed good protection against development of a scour hole; but the effect of this apron was to expose the downstream bedrock as in the previous fixed bedrock studies. Thus, as far as dissipating energy was concerned, the development of a scour hole was desirable provided that the barrier itself was not endangered. An apron 13 ft long, designed primarily as a cutoff wall (which would act as an apron for flows less than 500 cu ft per sec), allowed a scour hole to develop, reduced the undercutting effect, and was considered the most desirable of any of the structures tested (see Fig. 7).

Deposition Studies

Field examination of bed load impounded by the Devil's Gate Dam, as well as of that remaining in the arroyo (excluding any material that was considered

Fig. 7.—Combination Apron and Cutoff Wall That Was Considered the Most Desirable of Those Tested

residual), gave a fair approximation of the size and grading of material transported. In the absence of any actual measurements of rate of bed-load transportation, it was believed that past measurements of the loss of storage capacity

of the Devil's Gate Dam could be correlated with flow measurements to yield approximate loading rates. Unfortunately, however, upon investigation there were many confusing factors. Measurements of loss of storage capacity in-

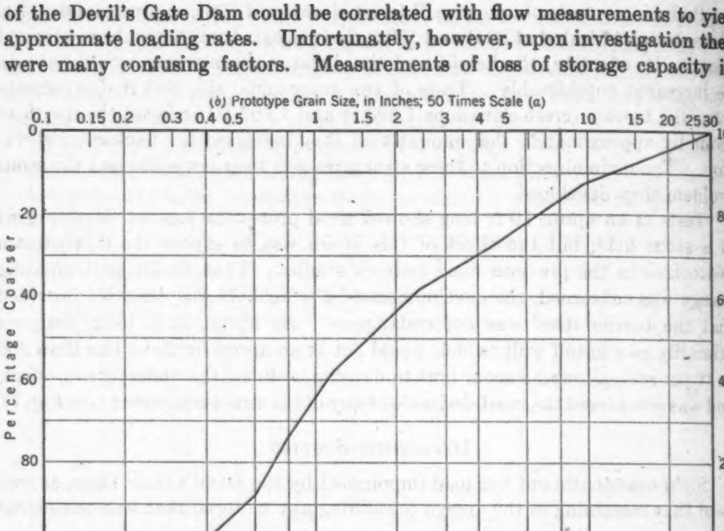

FIG. 8.—GRADING CURVE FOR MODEL BED-LOAD MATERIAL, SERIES A, B, C, E, AND F

cluded material contributed by a tributary, and did not include a substantial amount of material deposited above the crest elevation of the dam and the mouth of the arroyo. This was further complicated by the lack of complete flow data.

As a result, it was felt that more satisfactory information could be obtained from the model. A series of steady flow runs were made in reach 1 of the model without the Brown Canyon Barrier in place. For each flow, bed load was introduced at the upper end of the reach at a rate that would not create excessive deposition or scour at the point of introduction. Observation of deposition throughout the reach and measurements and analysis of the bed load introduced and carried away provided a method for adjusting the size, grading, and rate to obtain a bed load that would attain general movement and have approximately equal rates of inflow and outflow. The bed load finally used in the model was composed of commercial sands and gravels, varying in prototype size from $\frac{1}{8}$ in. to 28 in. in diameter (see Fig. 8 for grading curve). By determining steady rates of flow, loading curves were established for hydrograph flows.

For the model studies of bed-load deposition, two hydrographs were used—one, a hydrograph similar to that of the maximum recorded flow in the arroyo (9,000 cu ft per sec), and the other, a hydrograph of the design storm with a peak of 15,000 cu ft per sec.

With the barrier in place, the first series of runs to fill the barrier were made with the design storm, and bed load was introduced at the established rate—

177,100 cu yd per run (prototype value). At the conclusion of the first run, the detrital front extended downstream from the upper end of the reach to within approximately 900 ft of the barrier. With succeeding runs, the front continued to move downstream until, during the tenth run, the initial filling of the barrier was sufficient to cause about 100 cu yd of bed load to be carried over the barrier. With additional runs the detritus slopes, upstream from the barrier, continued to increase, but at a decreasing rate. The volume of stored material likewise increased. With each succeeding run the volume of bed load transported over the barrier increased until, at the end of the twenty-second run, when little change was observed in the channel slope, stability was assumed to exist. The average slope of the detrital material, as based on the canyon center-line length, was 1.75% with a storage of 1,014,000 cu yd (see series A, Fig. 9, and Table 1). This compares favorably with computed estimates of 1,013,000 cu yd and a slope of 1.88%. The estimate was based on measurements of debris slopes behind existing small barriers where the measured slope averaged approximately seven tenths of the original channel slope.

It was felt that size of flow, rates of loading, and size of bed-load material would vary in the prototype and would have some

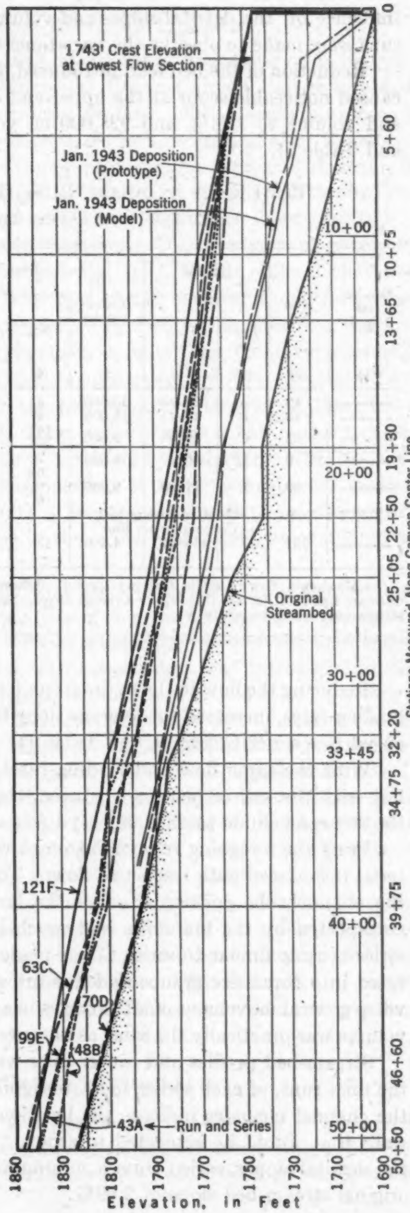

FIG. 9.—PROFILES OF STREAM CENTER LINE UPSTREAM FROM BROWN CANYON BARRIER, SHOWING FINAL PROFILE OF THE BARRIER FILLING THAT RESULTS FROM USING THE JANUARY, 1943, STORM (SEE LEGEND IN TABLE 1)

influence on the detrital slopes and volume. As a result three other series of runs were made to observe the variations that might occur.

Reduction of the bed load introduced, to one third of the volume in series A, caused noticeable scour at the upper end of the channel and reduced the slope and volume to 1.71% and 928,000 cu yd, respectively (see series B, Fig. 9, and Table 1).

[a] Maximum flow in cubic feet per second. [b] Storage volume between Brown Canyon Barrier and ordinate line N 4,202,300 (Fig. 9). [c] Average stream-bed slope based on the canyon center line and the stream center line, respectively.

Reducing the flow to the hydrograph for 9,000 cu ft per sec, using the original loading rates, increased the average slope to 1.88% and the volume to 1,085,300 cu yd (see series C, Fig. 9, and Table 1).

With the same flow and loading rates, as in the preceding series of runs, but with the size of bed load reduced, the slope was decreased to 1.29% and the storage volume to 681,000 cu yd (see series D, Fig. 9, and Table 1).

In all the foregoing runs, no attempt was made to vary the size of the material introduced with respect to flow. To check whether, at the upper end of the channel, the accumulation of the larger sized particles which were not transported by the low flows had much influence on the slope of the bed, a series of runs similar to series C was made. However, the bed load was separated into three size groups and was introduced in flow ranges that could develop general movement of all particles in a given group. The resultant storage volume was practically the same as in series C (see series E, Fig. 9, and Table 1).

Stream-bed profiles and center lines were plotted for each run. Those for the final runs, of each series, indicate significant changes in slope and those for the channel meander indicate the locations of those parts of the side canyon walls that would be subjected to scour. For the range of conditions tested, the detrital slopes varied from a minimum of 0.5 to a maximum of 0.7 of the original stream-bed slope of 2.69%.

Verification Studies—Bed-Load Deposition

The occurrence of the January, 1943, storm (peak flow 4,400 cu ft per sec, see Fig. 3) shortly after the completion of the Brown Canyon Barrier afforded an excellent opportunity to verify the model studies. With a negligible amount of detritus being carried beyond the barrier, surveys before and after the storm indicated that 243,000 cu yd were impounded by the barrier. Mechanical analysis of samples of some 10,000 lb of bed load from twelve pits throughout the reach above the barrier showed that the bed load varied from fines to occasional boulders larger than 12 in. in diameter. The average was weighted on the basis of representative volume (see Fig. 10). If this range in material size was reduced to model scale, a large part of the material would be so fine that it would be transported in suspension. To rectify this difficulty, the size range was reduced to a grain size varying from $\frac{1}{16}$ in. to 14 in. (prototype values).

Loading rates were determined as before, using steady flows. Manipulation of the time scale in connection with the hydrograph of the storm allowed the required bed load to be introduced. Three series of runs of the January, 1943, storm were made before results were considered satisfactory. Better conformity was achieved mainly by manipulation of the time scale and loading rates and also by the closer conformity of backwater elevations maintained by the barrier. The final average slope in the model was 2.26% as compared to 2.03% in the prototype.

Using the same loading rates and time scale (1 to 4.42) as in the last test with the January, 1943, storm, an analysis of five storms was made to achieve stabilized slopes above the barrier. Even though the rates of bed load transported over the barrier did not attain the rates of bed load introduced at the upper end of the model, a small change in slope was concluded to represent, approximately, the maximum slope that would be developed by storms similar to the January, 1943, storm. The storage volume (1,140,000 cu yd) and the average slope (2.01%) of this final stream bed (see series F, Fig. 9, and Table 1) are both 0.13% greater than the maximum of the previous tests. If the original discrepancy in model verification of the January, 1943, storm is considered, it can be concluded that previous results, based on model determination of loading rates and bed-load size, were applicable to the prototype.

As a result of these bed-load studies, since the probability of having identical storms as to flow, bed-load size, and amount available for transportation is rather remote, true stability of slopes or volume will never be achieved, but will vary depending on these and other factors. Also, the range of results obtained in the model studies appears to predict the reasonable variations that can be expected in the prototype.

Prototype Crest Performance

Measurement of depth of flow over the barrier, for the peak of 4,400 cu ft per sec, during the January, 1943, storm, accounting for flow through the weep holes and the "grizzly," compared favorably with head-discharge relationships as determined in the model.

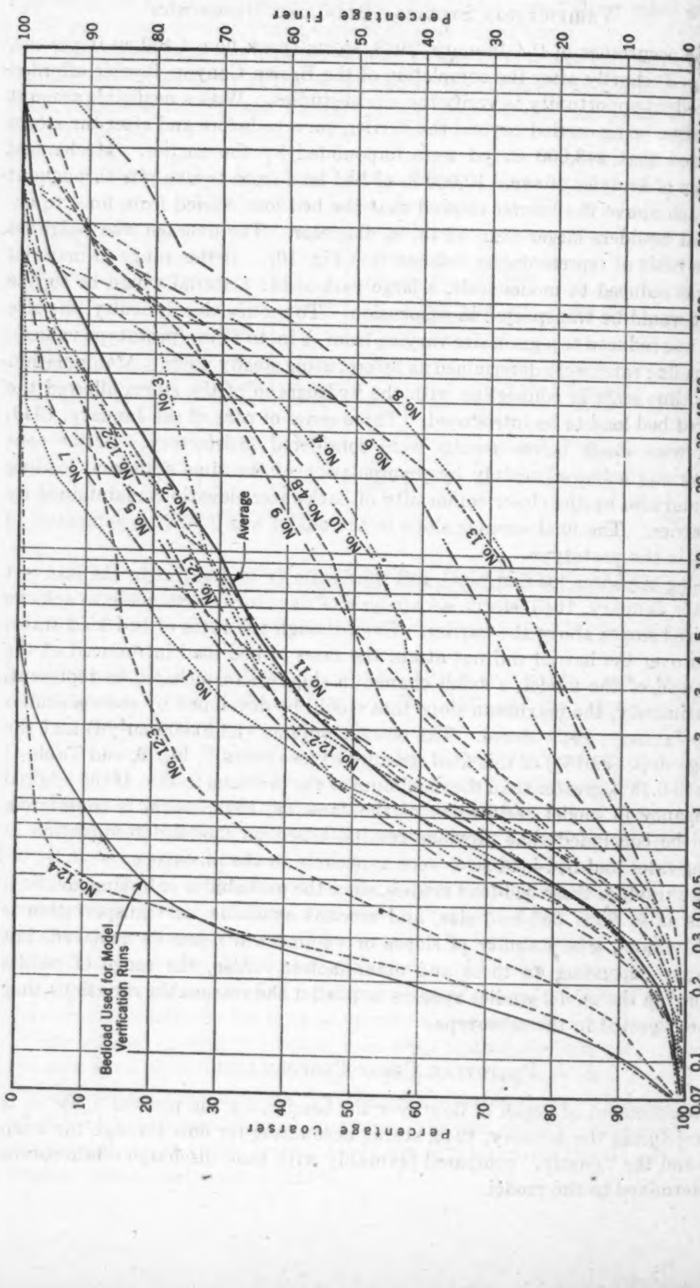

FIG. 10.—GRADING CURVES, FIELD SAMPLES OF DEBRIS DEPOSITS, STORM OF JANUARY 21 TO 23, 1943

With a flow of approximately 300 cu ft per sec, part of the spillway is in operation, as shown in Fig. 11. The most noticeable difference between model and prototype performance occurs with shallow depths of flow over the crest. In the prototype there is less tendency of the nappe to adhere to the lip of the crest.

Fig. 11.—Operation of the Brown Canyon Barrier at a Flow of Approximately 300 Cu Ft Per Sec Over the Crest

Prototype Scour Downstream from the Barrier

The storm of January, 1943, occurred before the combination apron and cutoff wall were constructed. As a result no comparison can be made with the installation as recommended by the model studies. The scour that did occur, however, without the benefit of any structure, was similar to that obtained in the model where the bedrock was fixed and overlain with loose bedload material. In the prototype, the channel downstream from the barrier was mostly scoured to bedrock and extended downstream for several hundred feet.

With the removal of the overlying loose bed-load material, a stilling pool developed immediately below the barrier. This pool extended approximately 40 ft downstream, with the greatest depth of 10 ft at approximately 25 ft downstream from the barrier. Field inspection of the development of this depression in the bedrock profile indicated that it was not caused by wear of the bedrock but rather by the removal of the loose overlying material.

Concluding Remarks

Observation of discharge over the crest of the barrier, while covering less than a third of the maximum design flow, provides reasonable reliance in the results as obtained from the model.

Scour downstream from the barrier (the combination apron and cutoff wall had not been installed at the time of the storm) produced conditions similiar to those that occurred in the model—that is, the overlying detrital material was scoured and bedrock was exposed for a considerable distance downstream.

Although a comparison of the detrital slopes that eventually will exist upstream from the barrier cannot be made at this time, the slopes and disposition of the initial filling are comparable to those attained in the model.

As a result of the studies involving the transportation and deposition of bed-load material, it becomes increasingly evident that, before much confidence can be placed in the use of models to reproduce or to predict changes in existing conditions, much more effort will have to be made to determine what takes place in nature.

ACKNOWLEDGMENTS

These experiments were undertaken during 1942 by the Department of Agriculture, U. S. Forest Service, Region 5, in cooperation with the Department of Mechanical Engineering of the University of California. General supervision, frequent consultation, and the use of hydraulic laboratory facilities were furnished by the University, under the direction of Morrough P. O'Brien, M. ASCE, assisted by J. W. Johnson, Assoc. M. ASCE, and by E. H. Taylor, Jun. ASCE. Close collaboration was maintained throughout the experiments with E. R. Huber, M. ASCE, and W. L. Minaker and John F. Serex.

DISCUSSION

Clifford A. Betts,[4] M. ASCE.—The debris bed-load investigations constitute an interesting phase of the model studies of the Brown Canyon Barrier. They furnish information that may be helpful in the design of other structures or series of barriers for channel control. Particularly significant is the 1.73% to 2% slope of the debris upstream from the barrier. It indicates an ultimate valley storage of three quarters of a million cubic yards of debris upstream from the structure and above spillway level, or nearly double the crest level storage capacity. This occurs in a foothills arroyo having an average stream bed slope of 2.7%. The fact that the flood (4,400 cu ft per sec) of January, 1943, subsequent to construction, corroborated the model study predictions, adds to their value.

The use of channel barrier dams in narrow canyons, to stabilize mountain sides by holding the channel regimen and thereby preventing channel undercutting, is not new. However, there is need for more authoritative data on the complicated problem of predicting the behavior of bed loads of various materials under different volumes of flow.

In this case the bed load consisted of Lowe grandiorite, San Gabriel formations, and Wilson diorite, graded from fines to boulders, 3 ft or 4 ft in diameter, with sizes less than 6 in. predominating. As was to be expected, deposition in one bar might be localized fines or all coarse gravel; but the over-all distribution from the upper to the lower end of the canyon was relatively uniform, with the proportion of large-size material decreasing downstream. Differences between the behavior of the model and the prototype resulted from the artificial fixed channel, lack of tree-root obstructions, and the fact that no attempt was made to introduce material smaller than would be retained on a 200-mesh sieve ($\frac{1}{8}$ in. and smaller in the prototype) because of suspension. Nevertheless, there has been sufficient evidence in the subsequent behavior of the prototype channel to confirm the findings that the slope of the stream bed becomes greater (1) when debris-carrying flows are reduced, (2) when debris quantities are increased, and (3) when the size of bed-load debris is increased.

The introduction of the bed load to simulate actual watershed conditions seems to be an important factor. It requires meticulous study and calibration in order that the quantities applied to the various flows approximate the quantities of material actually transported.

Since these quantities increased with the rate of flow, it is obvious that extensive tests covering wide ranges of hydrographs would have added greatly to the information in this field had the project requirements justified the extra cost. As usual, however, this load will have to fall on some larger project.

Roger E. Amidon,[5] Assoc. M. ASCE.—The interesting model study of the Brown Canyon Debris Barrier is well presented in the paper under discus-

[4] Hydr. Engr., U. S. Forest Service, U. S. Dept. of Agriculture, Washington, D. C.

[5] Civ. Engr., U. S. Forest Service, California Forest and Range Experiment Station, Berkeley, Calif.

sion. Valuable information pertaining to the spillway and downstream scour action was obtained. However, it is regrettable that more definite data did not result relating to the movement of debris and to the probable ultimate debris slope to be stabilized by the structure.

The original estimate that debris would assume an ultimate slope above the structure approximately equal to 70% of the original channel slope was based on measurements made above existing structures. These measurements were made during the period 1939 through 1941 at sites of approximately one hundred debris dams and check dams with small drainage areas above, seldom exceeding 5 sq miles. The age of the structures varied from 1 to 15 years. In most cases the channel gradient was affected from the site of the dam to the toe of the next upstream barrier. In some cases deposition at the toe of the next upstream structure was several feet deep. The dams included in the study vary from 2 ft to 35 ft in height, and are spaced from 20 ft to 2,500 ft apart. The original channel slopes varied from 4% to 35% and the debris slopes varied from 0% to 21%. The debris slopes varied from 0% to 100% of the original channel slopes, and averaged 52% for all barriers surveyed. The average debris slope above sixty-seven dams, where the original channel slope was 14% or less, was 66% of the original channel slope. On this basis it seemed reasonable that over a much longer period of time, on the lower gradient channels, the debris slope would at least approach 70% of the original.

The great number of variables that affect the slope which debris will assume above barriers forestalls the possibility of making precise estimates based on generalized curves for any specific structure. The size and quantity of material available for transportation, slope of the channel, volume of flow, obstructions in the channel, and period of years are some of the influencing factors.

In planning debris barriers it is extremely important to estimate correctly the volume of slope storage that will result in order to determine the economic feasibility of the structure. Detailed studies of field conditions and accurate measurements of progressive barrier storage, over a period of time, will provide data from which reasonably accurate estimates of debris slope can be made.

The increasing importance of the control of erosion and debris movement above reservoirs designed for flood control, water conservation, and hydroelectric power generation justifies serious consideration of this problem.

Ettore Scimemi,[6] Esq.—Among the problems treated in this most interesting paper is the depth of the scour at the foot of a spillway dam such as Brown Canyon.

Experiments were performed on a model and since, in the prototype, the material encountered was a fairly erosive bedrock, the authors were obliged to substitute for this material, in the model, some other material with similitude characteristics reduced in the scale 1:50. Such a transformation presents considerable difficulties, not only in the selection of a suitable material, but in obtaining or developing one that will have the proper size and size distribu-

[6] Prof., Hydr. Inst., Univ. of Padua, Padua, Italy.

tion. In a reduction of 1:50 it is inevitable that the effect of some of the finer material in the prototype will be lost entirely in the model. In addition to these difficulties (which could make the results questionable), there are some general considerations in the design of a spillway dam.

A nappe that falls vertically from the top of a dam, and which can scour the bottom of the river, cuts the channel to a depth that depends on the balance of the forces engaged; that is, equilibrium between energy of the nappe and the energy destroyed in the whirlpool. Therefore, the volume and the depth of the scour are not more rigorous functions of the size of the material on the bottom, but only a function of the difference in the elevation of

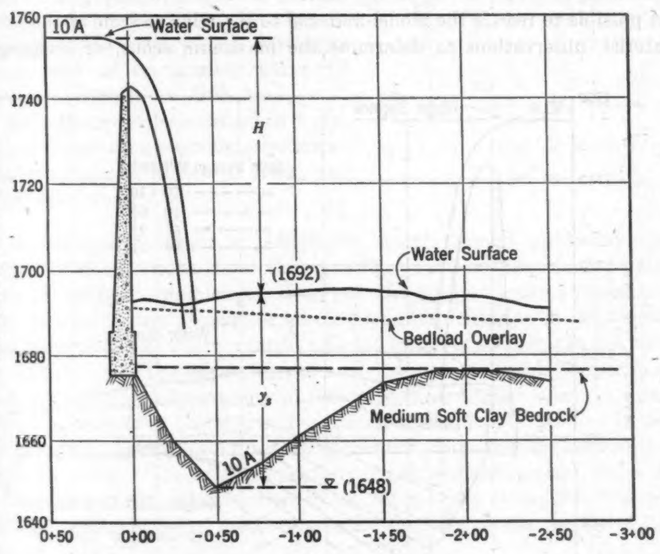

FIG. 12

the overflowing nappe and that of the stilling pool below. Alessandro Veronese[7] examined this problem, and gave the following formula for the depth (in metric units) of the scour y_s:

$$y_s = 1.90\, H_f^{0.225}\, q^{0.54} \quad \text{(2a)}$$

in which y_s is the depth of the scour, under the downstream water surface; H_f is the effective drop (see Fig. 12); and q is the discharge per linear unit of

[7] "Erosioni di fondo a valle di uno scarico," by A. Veronese, *Annali dei Lavori Pubblici*, Roma, Settembre, 1937, p. 717.

the dam. This formula is translated into English units as

$$y_s = 1.32\, H^{0.225}{}_f\, q^{0.54} \qquad (2b)$$

in which y_s and H_f are in feet; and q is in cubic feet per second per foot of dam.

In Fig. 12, which is analogous to Fig. 6: $H_f = 1{,}755 - 1{,}692 = 63$ ft; $q = 15{,}000/134 = 112$ cu ft per ft; and, therefore, $y_s = 1.32 \times 63^{0.225} \times 112^{0.54} = 43$ ft. According to Fig. 6, $y_s = 1{,}692 - 1{,}648 = 44$ ft. In other words, Eqs. 2 conform perfectly to the experiences observed in the Brown Canyon model.

When formulas such as Eqs. 2 cannot be used for the design of hydraulic structures, at locations where the tailrace is subject to scour, and where it is not possible to reduce the model material to the relative scale of the prototype material, observations to determine the maximum scour, or scouring limit,

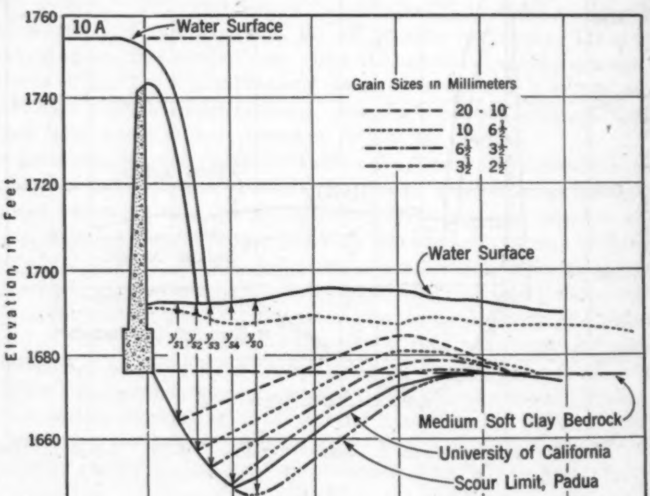

Fig. 13

can be made by another experimental method. This consists in making successive observations on the model with smaller and smaller grain sizes without regard to the grading of the prototype material. Trials must be begun with rather large gravel and then repeated with successively smaller gravel. The scour will be deeper and deeper with each reduction in grain size until a limiting depth is soon reached.

This method has been used by the writer on a model of Brown Canyon Dam (scale 1:50) similar to that used by the authors, constructed in the

hydraulic laboratory of the University of Padua in Padua, Italy. The results of these trials are plotted in Figs. 13 and 14. Fig. 14 gives the relation between depth of scour and grain size. At grain size zero the scour limit, $y_{\infty} = 47$ ft, is obtained. This value is near enough to that found by the authors (44 ft) so that the difference may be said to be due to errors in reproducing various accessories and parts of the model to an accurate scale ratio.

This method should lead to good results for any type of hydraulic structure, without necessarily conforming to any reduction, in scale, of the prototype material, and of its grading curve (if available). Results of this kind, with some limitations, were described in a previous paper regarding scouring experiences at Conowingo Dam, at Sennar Dam, and at other structures.[8]

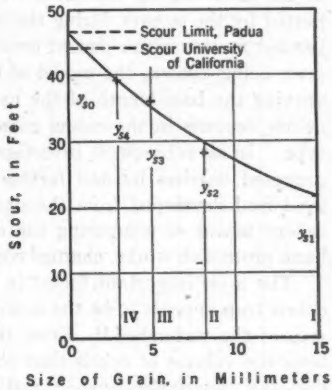

Fig. 14

J. W. Johnson,[9] Assoc. M. ASCE.—A search through published reports on hydraulic model studies shows that investigations have been made on a large number of hydraulic problems. However, the study by the authors of the Arroyo Seco structures appears to be the first comprehensive model investigation on the problem of the movement and deposition of sediment in the vicinity of debris barriers. The advantages of model studies for debris barrier investigations are many; a large variety of factors such as barrier spacings, order of constructing a series of barriers, and sediment loading can be studied in detail. Observations on field installations would require years to yield information of comparable value. The experiments reported by the authors and those made at a later date on the other barriers of the Arroyo Seco system[10,11,12] have permitted the formulation of certain general principles of the action of debris barriers.[13]

The section of the paper concerning the deposition studies is of particular interest to the writer. It was fortunate that the studies on sediment deposition were in the early stages of the model work when the January, 1943, storm occurred on the Arroyo Seco watershed. During, and following, this storm, prototype data were obtained on: (a) The total volume and slope of the debris

deposited behind the Brown Canyon Barrier, (*b*) a hydrograph of stream flow at a gaging station a short distance downstream, and (*c*) a record of water levels in the basin during the flood. Thus, with the total volume of debris transported by the stream during the flood (except for the volume of very fine suspended matter which passed over the spillway) and the slope of the final deposit being known, the model of the Brown Canyon Barrier was operated by varying the base length of the hydrograph until the volume and slope of the debris deposits in the model corresponded with those observed in the prototype. In all subsequent investigations of the Brown Canyon Barrier and the proposed barriers located farther downstream, the hydrograph and rate of sand feed developed from the data of the January, 1943, storm gave an excellent means of comparing the effectiveness of the various barrier systems, bank protection works, channel correction measures, and other proposed works.

The most important factor in estimating the efficiency of a reservoir as a debris trap appears to be the ratio of original capacity for debris storage to the area of the watershed.[14] From the model studies of the various barrier systems the volume of debris that could be stored in each system was estimated and the capacity-watershed ratios were computed and are summarized in Table 2 (the various systems include the Brown Canyon Barrier, a high barrier at the Weir Site (Fig. 1), and two possible systems of low barriers in reach 4 instead of the high barrier at the Weir Site).

The ratios of capacity versus watershed area (capacity-area ratio) for the various barrier systems are of interest in connection with the relationship between annual storage loss and capacity-area ratio as computed for existing water-supply reservoirs in Southern California, as shown in Fig. 15; the plotting data for this figure being obtained from published data on reservoir silting.[15] Carl B. Brown, Assoc. M. ASCE,[14] states that in reservoirs used for water storage an annual storage loss of one half of 1% is considered serious enough to require measures to control silting. A comparison of the data in Table 2 with Fig. 15 indicates that the Brown Canyon Barrier and the proposed high barrier at the Weir Site might be expected to have an annual loss of storage capacity near this critical rate; however, the 7-ft and 15-ft barriers in reach 4 (see Table 2) definitely would be expected to have excessive silting rates. The model studies, in fact, indicated that the basins in these two low-barrier systems would become almost completely filled during a single flood of

the magnitude of that of January, 1943. It is admitted, of course, that the data used in plotting Fig. 15 are too meager to give a definite relationship between annual storage loss and capacity-area ratio; however, the general mag-

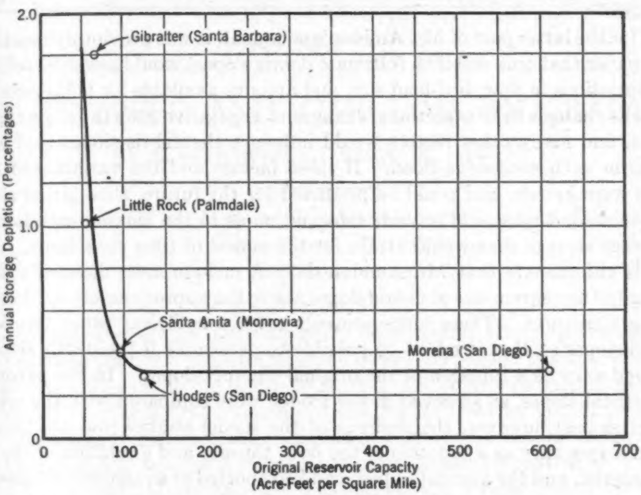

FIG. 15.—RELATIONSHIP BETWEEN ANNUAL DEPLETION OF RESERVOIR CAPACITY AND CAPACITY-WATERSHED-AREA RATIO FOR VARIOUS SOUTHERN CALIFORNIA RESERVOIRS

nitude of the critical value of the ratio appears reasonable. Future sedimentation surveys of water and debris storage basins in Southern California will provide needed data on reservoir silting rates in that area.

KARL J. BERMEL,[16] ASSOC. M. ASCE, AND ROBERT L. SANKS,[17] JUN. ASCE.—The writers wish to express their appreciation of the interest taken by those who submitted discussions; for the valuable contributions, substantiating data, and constructive criticisms of this paper.

Mr. Betts, discussing that phase of the studies dealing with detrital slopes upstream of the barrier, states, "* * * extensive tests covering wide ranges of hydrographs would have added greatly to the information in this field had the project requirements justified the extra cost." Although cost is certainly a consideration, justification of more extensive testing was limited primarily by the lack of sufficient data or knowledge as to the laws governing flood flows and the transport of bed-load material. To obtain this information, aside from the attendant difficulties, is both time consuming and costly and is certainly beyond the scope of these studies; however, until such time as measurements of this type are made and laws established governing both model and prototype

[16] Senior Engr., Div. of Mech. Eng., Univ. of Calif., Berkeley, Calif.

[17] Asst. Engr., Univ. of California, Berkeley, Calif.

behavior, models at best only can be relied upon to indicate general tendencies. This also applies to the first part of the comment by Mr. Amidon, that "* * * it is regrettable that more definite data did not result relating to the movement of debris and to the probable ultimate debris slope to be stabilized by the structure."

As for the latter part of Mr. Amidon's comment, it was previously mentioned in the paper that true stability (ultimate debris slopes) would never be achieved since variations in flow, bed-load size, and amount available for transportation, as well as changes in flow sections, changes of vegetative growth in the channel bottom, and many other factors would influence the debris slopes that would exist after each successive flood. If these factors and the variation of these factors were known, and could be predicted for the future, then model studies could be made that would provide information as to the maximum, minimum, or average storage that would attain for the period of time considered.

It is unfortunate that Mr. Amidon did not include more detailed data regarding the measurements of debris slopes above the approximately one hundred existing structures. These measurements cover a sufficient range of original channel slopes so that it might be possible to determine if the debris slopes as measured vary as a function of the original channel slopes. In the paper, the final detrital slopes, as achieved in the model, were compared with the original channel slopes; however, the findings of the model studies indicate that the detrital slopes vary as a function of the flow, the size and gradation of the bed-load material, and the amount of bed load transported or available for transport.

For the experiments performed to determine the extent of scour, the maximum depth of scour, and the distance downstream to the point of maximum depth of scour, the authors used the experimental method as suggested by Mr. Scimemi, with the exception that a graded bed-load material was used instead of material successively smaller in grain size. This material was the same as that used for the deposition studies upstream of the barrier; that is, it varied from 0.1 mm to 15 mm in size. The discrepancy of 3 ft less depth of scour, as compared to the experiments performed at the University of Padua, Italy, is no doubt due to the retention of the larger sized particles. Whereas the latter experiments are more exact as to the limiting depth of scour, the use of the bed-load material was considered more indicative of the conditions that would exist after bed-load material was transported over the barrier, which would be the conditions of operation for the greatest part of the life of the structure.

TRUCK SPEED AND TIME LOSS ON GRADES

BY J. W. STEVENS,[1] ASSOC. M. ASCE

WITH DISCUSSION BY MESSRS. JONATHAN JONES, ELLIOTT J. DENT, F. B. OGLE, AND J. W. STEVENS.

SYNOPSIS

In the design of grades it is frequently necessary to ascertain the delay to traffic resulting from the decrease in speed of heavily loaded trucks on adverse grades. On routes involving heavy traffic it is particularly important to determine the effect of speed reduction and time loss incurred by loaded trucks on hill and overpass grades upon the operation of traffic at a constant design speed. Where the time loss is large it may be necessary to use preventive or remedial measures, such as an alternate route in rough terrain, a reduction of the rise in grade at an overpass, or in an extreme case the construction of an additional traffic lane, in order to avoid congestion for the anticipated traffic density.

A procedure for calculating the velocity curve and determining the time lost by a given vehicle traveling over an adverse grade is described in this paper. It is possible to determine the relative advantages of alternate grade designs with regard to the operation of truck traffic. The method outlined was developed in the design of a freeway project, and the examples used in the paper are concerned with overpass grades on that project. However, the application of the method is wider than that covered by the examples. The entire range of problems involving time loss on grades can be handled by the outlined methods, modified as suggested in the paper.

In the freeway design problem, certain conclusions were reached concerning the effect of variations in grade rise and grade rate at overpasses upon time loss. These conclusions and some general comments regarding the effect of truck speed reduction upon highway traffic capacity are included in the paper.

1. BASIC DATA AND PRINCIPLES

Basic data for computing truck velocities on grades were published in 1942 by Carl C. Saal,[2] including tests made by the U. S. Public Roads Administration

NOTE.—Published in September, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Bldg. Insp. Engr., City of Amarillo, Amarillo, Tex.

[2] "Hill-Climbing Ability of Motor Trucks," by Carl C. Saal, *Public Roads*, May, 1942, p. 33.

(USPRA) to determine the velocities that could be maintained on various grades by trucks carrying various loads, and to determine the decrease in performance of trucks due to age. Although the direct conclusions to be drawn from Mr. Saal's findings pertain to the maximum sustained speed of loaded trucks on long grades, the tests also included the determination of various data which are required for the computation of truck speeds on short grades and on combinations of up-and-down grades under different conditions of loading and power.

In the calculation of velocity and time curves for trucks, operating over a given profile, it is possible to utilize principles which have been used for some time in studies of railroad train operation. Since the operating characteristics of motor vehicles are considerably more flexible than those of railway trains, it is probable that the results of calculations for trucks are subject to errors which would not be encountered in railroad work. Also, since experimental data on the tractive resistance of trucks are scarce, it will often be necessary to use assumed values for this factor. Furthermore, the difference in driving habits of vehicle operators and the total lack of knowledge regarding what may be expected as an average procedure for the application of the available tractive effort of the vehicle in question necessitate the use of rather broad assumptions relative to the manner of applying the motor power, especially on descending grades. It is desirable that additional test data on tractive resistance and driver habits be obtained, in order that the limitations which these features impose on velocity-curve determination will be removed.

2. Fundamental Equations of Motor Vehicle Dynamics

The forces that affect the speed of a motor vehicle may be grouped under three main classifications: (1) The tractive effort exerted by the motor through the driving wheels; (2) the total tractive resistance of the vehicle, including rolling and air resistance; and (3) the accelerating or decelerating force created by the grade on which the vehicle is operating. The first two classes of forces are subject to determination by more or less elaborate tests; the third is easily computed from the gross weight of the vehicle and the rate of grade.

The familiar equation, $F = m\,a$, with modifications for the problem under consideration, is used for calculating velocity changes with varying forces. Mr. Saal uses the equation:[3]

$$P_e = a\,(m + k) + W_g\,(f) \qquad (1)$$

in which P_e is the net tractive effort, in pounds, at drive wheels; a is the acceleration of vehicle, in feet per second per second; m is the mass of vehicle $= W_g/32.2$, in pounds mass; k is the mass equivalent constant for rotating parts of vehicle, in pounds mass; W_g is the gross vehicle weight, in pounds; and f is the coefficient of tractive resistance, in pounds per pound.

Eq. 1 is applicable for level grade, and it may be modified to the following form, which is applicable, with only small error, for inclined grades:

$$P_e = a\,(m + k) + W_g\,(f) + W_g\,(S) \qquad (2)$$

in which S is the rate of grade, in feet of rise per foot of horizontal distance.

[3] "Hill-Climbing Ability of Motor Trucks," by Carl C. Saal, *Public Roads*, May, 1942, p. 49, Eq. 15.

Eq. 2 may be rearranged in the following form:

$$a = \frac{P_e - [W_g\,(f) + W_g\,(S)]}{m + k} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

and the acceleration a thus evaluated may be used in calculating the change in velocity of the vehicle in a given distance or time interval, when the initial velocity is known.

3. Use of Numerical Integration for Calculating Velocity Curves

The method described herein for computing velocity curves for motor vehicles involves the use of a numerical integration process, which is based on the following principles:

Fig. 1 shows velocity, acceleration, and time curves, referred to distance plotted along the abscissa. If the velocity v_1 is known, an approximation to v_2 may be obtained by means of the relation,

$$v_2 = v_1 + a_m\,(t_2 - t_1) \quad \ldots . (4)$$

in which a_m is the mean value of the acceleration between s_1 and s_2. It is evident that the time interval, $(t_2 - t_1)$, is equal to the distance interval, $(s_2 - s_1)$, divided by the mean velocity between s_1 and s_2. If sufficiently small intervals of distance are used, any desired degree of accuracy may be obtained in the approximation; the arithmetic mean values, $(v_1 + v_2)/2$ and $(a_1 + a_2)/2$, may be used, instead of the actual mean values, for velocity and acceleration, respectively, obtained by dividing the areas under the corresponding curves in the interval (s_1 to s_2) by the length of the interval.

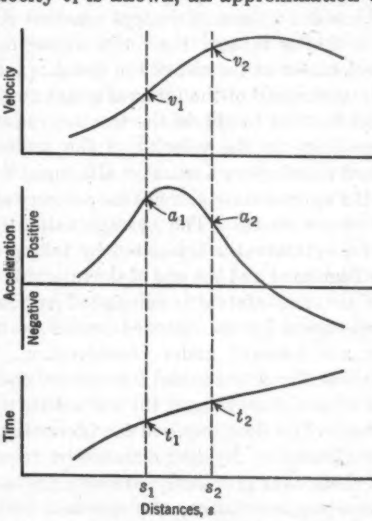

Fig. 1.—Characteristic Velocity, Acceleration and Time Curves

4. Outline of Method for Computing Velocity Curves

The method for computing the velocities of a given vehicle at successive points along a given profile may be stated briefly as follows:

Uniform distance intervals, sufficiently short to afford the desired degree of accuracy in velocity and time values, are marked off on the profile throughout the section under consideration. The uniform intervals may be subdivided if necessary at points where one or more of the forces acting on the vehicle changes abruptly. The change in velocity in each distance interval is calculated by the procedure outlined in the next paragraph; and the velocity at the end of each interval, the mean velocity in the interval, and the time required to traverse

the interval are computed. From the series of values obtained for the successive intervals through the section of profile being studied, the velocity curve may be plotted, and the time lost by the vehicle, compared to the time required for traveling over the section at a given uniform velocity, may be determined.

The forces acting on the vehicle at a given point, such as the beginning or the end of a distance interval, are determined by the power developed by the motor, the rate of grade at the given point, and the velocity of the vehicle. These forces are the tractive effort P_e in Eq. 3 which may be computed from the motor power by a method explained in Section 7, the grade resistance W_g (S) in Eq. 3, and the tractive resistance W_g (f) in Eq. 3 (which varies with the vehicle velocity). The acceleration or deceleration of the vehicle at the beginning of the distance interval under consideration is computed by means of Eq. 3; that is, by dividing the resultant force (which is the algebraic sum of the three forces, P_e, W_g (S), and W_g (f)) by the sum of the mass (m) of the vehicle and a mass equivalent constant (k) for the rotating parts of the vehicle. In a similar manner the forces acting on the vehicle and the acceleration or deceleration at the end of the distance interval are computed. Since the velocity at the end of the interval is unknown at this stage, an assumed value of f must be used to obtain the tractive resistance. The use of the value of f corresponding to the velocity at the beginning of the interval in question will afford satisfactory accuracy; although, if desired, the value of f corresponding to the approximate anticipated velocity at the end of the interval may be used for closer results. The average value for acceleration or deceleration in the distance interval is computed by taking the arithmetic mean of the values at the beginning and the end of the interval. Then the change in velocity through the distance interval is calculated by multiplying the average acceleration or deceleration by an assumed period of time for the vehicle to traverse the distance interval under consideration. This change in velocity is added algebraically to the initial velocity for the interval to obtain the velocity at the end of the interval, and the arithmetic mean velocity for the interval is computed. The time required for traversing the interval at this average velocity is computed by dividing distance by velocity. If the time thus obtained does not check that previously assumed, the computation of velocity change and the succeeding calculations are repeated until corresponding values for time and mean velocity are obtained. Fair accuracy usually may be secured on the first trial, since the time can be estimated closely from the initial velocity, and from a knowledge of whether the acceleration is positive or negative. When satisfactory agreement between time and mean velocity is obtained, the corresponding values for these items and for the velocity at the end of the interval are taken as final for the interval under consideration. The foregoing series of operations are repeated for the successive distance intervals.

5. Vehicle Data Required for the Computations

The vehicle data required for the computations consist of the tractive effort available at the driving wheels, the tractive resistance of the vehicle for the entire range of velocities involved in the problem, the mass of the vehicle, and the mass equivalent constant for the inertia of the wheels and other rotating

parts of the vehicle. Fairly complete data for the trucks and truck-trailer combinations tested by the USPRA are given by Mr. Saal.[3] The tractive resistance of a vehicle varies considerably for different types of pavement or road surface. The values which he gives are applicable for concrete pavement, and should be used only for concrete and closely similar types of surfacing. The tractive-resistance data presented by Mr. Saal are applicable to the low-type bodies used in the tests, and higher values should be used for large van-type bodies.

6. Application of Available Tractive Force

There is great uncertainty as to the manner in which the available tractive force of a vehicle will be applied by an individual driver; and there are little or no observed data to indicate an average habit pattern for the application of the tractive force. Therefore, it is necessary to use a driving procedure, for velocity-curve computations, based almost entirely upon assumption. For the 15-ton truck and the type of profile considered in this study, involving relatively low rises in grade in level terrain, it was decided to consider operation in high gear only. For a heavily loaded truck on ascending grade, it appears entirely logical to assume that the tractive force applied will be at or near the maximum available value, as long as the speed of the vehicle is decreasing. Such an assumption was used in the various cases covered in this study. It was also assumed that the tractive effort is increased uniformly from the value required for constant initial speed on level grade to the maximum available value as the vehicle traverses the sag vertical curve at the beginning of the grade rise. Thus it is assumed that other traffic prevents the operator of a heavily loaded truck from increasing speed prior to reaching the rising grade to compensate for the expected loss in speed, and that full power is applied by the time the maximum rate of grade is encountered.

It is more difficult to state what procedure can logically be assumed for application of the available motor power on a descending grade, or even after the vehicle has begun to accelerate in passing over a summit at full throttle. The most serious limitation upon the accuracy of computed velocity curves results from this feature. On a descending grade the vehicle may be operated in a great variety of ways—with the throttle fully open, partly open, or closed, in gear, or in neutral, and with or without application of the brakes. Any combination of these operating conditions in succession may be encountered. It is evident that very complicated tests would be required in order to determine, under such a variety of possibilities, a typical or average driving pattern of procedure. Lacking such test data, one can only attempt a fairly logical assumption for driving procedure on descending grades.

In the cases for which velocity curves were computed in this study, it is assumed that the truck is moving on a level grade at a speed of $V = 40$ miles per hr prior to entering the grade up to an overpass; and that the tractive effort is uniformly increased from the value required for operation on level grade to the maximum available value as the vehicle moves through the vertical curve from level to ascending tangent grade. The maximum tractive effort is maintained until the vehicle has begun to accelerate near the summit of the grade

rise. Then it is gradually reduced to zero and maintained there until the truck is near the end of the descending grade, when it is gradually increased to the value for operation on level grade at the initial speed of 40 miles per hr. It is the intention to apply the power or tractive effort in accordance with the foregoing procedure in such a way that the vehicle speed will be restored to exactly 40 miles per hr at the end of the descending grade. This procedure does not result in the minimum possible time loss on the grades, for it does not take account of a possible increase in speed to a value greater than 40 miles per hr on the descending grade. Operation on the descending grade at a speed greater than 40 miles per hr might require the use of the brakes to avoid running too close to the vehicle ahead of the truck. In such a case, a time gain rather than a time loss is involved. Operation over the profile with minimum time loss could be effected only by the most skilful drivers, and certainly not by the average driver. The assumptions used in the problems are chosen to represent average conditions.

The objective of restoring the speed to 40 miles per hr at the end of the descending grade can be attained only by a trial procedure; but it is possible to use the acceleration curve as a basis for assumptions regarding the use of the tractive effort, so that this curve encloses approximately equal areas above and below the zero axis, within the limits of the rising and descending grades. In other words, the speed at the end of the overpass grade will be restored to the original value if the product of the deceleration and the distance through which it operates is made approximately equal to the product of the acceleration and the distance through which it operates. This technique is subject to a minor error resulting from the fact that the acceleration curve is plotted to a distance abscissa, rather than to a time abscissa.

For the grade problems discussed herein, it is assumed that the vehicle remains in high gear at all times when power is applied. This assumption is legitimate for the range of speeds involved, since about 30 miles per hr is the minimum speed encountered in normal overpass grade problems. On a given grade, the characteristics of the truck and the habits of the driver will determine the speed at which gear changes will be made. It is considered very unlikely that a change from high gear to second would be made under ordinary circumstances at a speed above 30 miles per hr. For the grade conditions considered herein, it appears probable that operation in high gear will result in a minimum time loss, since the time and speed lost in shifting gears twice would most likely counteract any possible saving in time realized by the utilization of the higher tractive effort available at a higher gear ratio.

In problems concerning long steep grades, of course, it will be necessary to consider changes in gear ratio in computing the velocity curves. This feature affects the tractive-force diagram and the mass equivalent constant for rotating parts of the vehicle, but it does not introduce serious complications in the calculations.

7. Formulas for Maximum Tractive Effort

The maximum tractive effort available at the drive wheels for a given vehicle may be calculated for various engine speeds and gear ratios, from data

relative to the engine horsepower or torque and the over-all mechanical efficiency of the transmission and the rear end drive mechanism. For conversion of truck speed to engine speed, or vice versa, the following formula[4] is applicable:

$$\omega = \frac{168\ G\ V}{r} \qquad (5)$$

in which ω is the engine speed, in revolutions per minute; G is the ratio of total gear reduction; V is the road speed, in miles per hour; and r is the effective radius of drive wheels, in inches.

When the net engine horsepower for a given engine speed for full throttle operation is known, the net engine torque may be computed by means of the following relation:

$$T = \frac{33{,}000\ E}{2\ \pi\ \omega} \qquad (6)$$

in which T is the net engine torque, in pound-feet; and E is the net engine horsepower. If the net engine torque curve for a given truck is available, the tractive-effort curve for a given gear ratio may be derived from it by using the following formula (given in slightly different form[5] by Mr. Saal):

$$P_e = \frac{12\ T\ G\ \eta}{r} \qquad (7)$$

in which P_e is the net tractive effort, in pounds, available at drive wheels, corresponding to a given engine speed, at full throttle; and η is the ratio of over-all efficiency of drive mechanism, for given speed and gear ratio.

Substitution of the expression for torque, Eq. 6, in Eq. 7 gives the following formula for tractive effort:

$$P_e = \frac{12\ E \times 33{,}000\ G\ \eta}{2\ \pi\ r\ \omega} = \frac{198{,}000\ E\ G\ \eta}{\pi\ r\ \omega} \qquad (8)$$

8. Performance Data for Truck-Trailer Combination

The truck-trailer combination selected for example purposes in the computed velocity curves included in this study is a medium truck and a high van-type semi-trailer, having a gross weight (W_g) of 30,000 lb. Average performance data, rather than actual data for any one make and model of truck, are used. The maximum net horsepower output of the motor (E) is taken at 90 at a speed (ω) of 2,800 revolutions per min, and the over-all efficiency of the drive mechanism (η), exclusive of the motor, is assumed to be 90% throughout the range of speeds involved. Actually, the efficiency factor for a given gear ratio varies slightly with speed; however, sufficiently accurate results for the purpose of this study will be obtained by the use of a constant efficiency factor. Also, the tractive effort available at full throttle at a given gear ratio varies with the speed, but it was considered satisfactory to use a constant value for this factor, for the range of speeds involved. Using Eqs. 5 and 8, with a total gear reduction (G) of 7.15 and an effective drive wheel radius (r) of 18.5 in.,

[4] "Hill-Climbing Ability of Motor Trucks," by Carl C. Saal, *Public Roads*, May, 1942, p. 45, Eq. 10.
[5] *Ibid.*, p. 49, Eq. 16.

the tractive effort (P_e) available at the wheels for full throttle operation was found to be 750 lb for a truck speed (V) of 40 miles per hr and 780 lb for a speed of 30 miles per hr. These values correspond to horsepower values (E) of 89.0 and 69.3, respectively, taken from a typical power curve for a 90-hp engine. A maximum tractive-effort value of 760 lb is used in the computations.

Values for the mass equivalent constant (k) used to represent the energy stored in rotating parts of the truck and trailer combinations were determined experimentally and are shown, in charts, by Mr. Saal.[6] For the truck and trailer type considered in this study, operating in high gear at a gear ratio of 7.15, Mr. Saal indicates that a mass equivalent constant of about 70 is applicable. The total mass of the vehicle effective in resisting acceleration or deceleration is computed as follows: Total mass $= m + k = \frac{W_g}{32.2} + 70 = \frac{30,000}{32.2} + 70 = 1,002$. To simplify the computations in this case, it is sufficiently accurate to use a value of 68 for k, which makes the total mass equal to 1,000 lb.

Two tractive-resistance curves are shown in Fig. 2. These curves represent data for the average tractive resistance of medium tractor trucks with low-bed semi-trailers, operating on concrete pavement in very good condition.[7] These curves represent the data for a combination with gross loads of 30,000 lb and 20,000 lb, as shown. In the computations of Section 11 the tractive resistances used are based on the 20,000-lb curve, on the assumption that it is approximately correct for the van type of bed with a load of 30,000 lb, since the air resistance will be higher than that for a low bed.

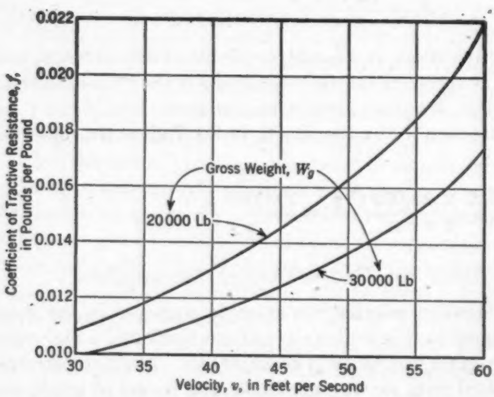

FIG. 2.—TRACTIVE-RESISTANCE CURVES, LOW-BED TRAILER ON CONCRETE PAVEMENT

The foregoing data constitute all the information relative to the vehicle required for computation of the velocity curve. Information regarding the profile is necessary to complete the data for the calculations.

9. DATA RELATIVE TO PROFILE

In the present study, made in connection with a divided highway in an urban area, where the average speed will be about 40 miles per hr, it is con-

[6] "Hill-Climbing Ability of Motor Trucks," by Carl C. Saal, *Public Roads*, May, 1942, p. 47, Figs. 17 and 18.

[7] *Ibid.*, p. 43, Table 15.

sidered that a vertical sight distance of 500 ft should be provided, based on a line of sight 4.5 ft above the pavement surface at each end. This design requirement governs the length of summit vertical curves for various rates of grade on each side of the summit. The grade lines used in the speed-loss computations for rises of various heights were made symmetrical about their high point, the midpoint of the summit vertical curve, except in the case involving a rise without an equal grade drop. The lengths of the short vertical curves connecting to level grade at each end of the grades over the overpass were chosen in most cases so that a grade change of 5% per station results. For a given rise in grade above a level line there is a certain maximum rate of grade that can be used under the aforementioned conditions. This maximum grade will be that for which the ends of the summit vertical curve coincide with the ends of the sag vertical curves connecting to the level grade. Generally, this maximum rate of grade will provide the most economical solution from the standpoint of construction cost. There is a possibility, however, that it may involve excessive delay to traffic, on account of steep grades, if a heavy volume of truck traffic is involved. It might even be excessive for any type of traffic.

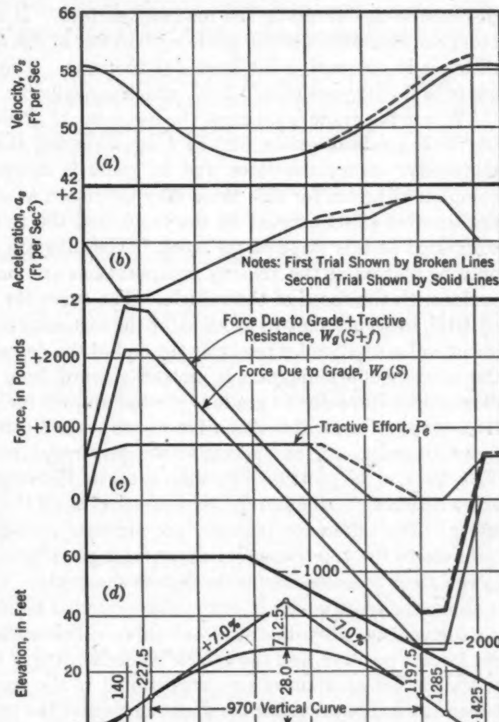

FIG. 3.—FORCE, ACCELERATION, AND VELOCITY CURVES (GROSS WEIGHT, 30,000 LB; 90-HP MOTOR; HIGH GEAR)

The grade line for the illustrative problem, for which detailed computations are outlined, provides a rise of 28 ft above the level approach grades, which is approximately the height required for a railroad overpass. A rate of grade of 7.0% was chosen as being about the maximum that is satisfactory for the type of highway under consideration. The length of vertical curve required to provide a sight distance of 500 ft between the +7.0% and −7.0% grades is 970 ft. The length of sag vertical curves required to connect the 7.0% grade

and the level grade is 7.0/5.0 = 1.4 stations or 140 ft. The essential features of the profile are now known, and the grade line is plotted in Fig. 3, for convenience in visualizing the problem in the computations of Section 11.

10. Force Diagrams and Acceleration Curve

The next step is to plot the force diagram for the given profile. The force created by the grade, acting to change the velocity of the vehicle, is the product of the gross vehicle weight and the rise or fall of the grade in feet per foot of distance measured along the roadway surface. It is sufficiently accurate and more convenient to use the grade ratio of feet of rise or fall per foot of horizontal distance in computing the force due to grade. The error involved for a 7.0% grade is slightly less than 0.25%, which is negligible.

Where the grade is tangent, the force due to grade is constant. On vertical curves the rate of grade, and as a consequence, the force due to grade, vary uniformly. Since the force due to grade is determined by the profile, the complete diagram for this force may be drawn at once; but the diagrams for the tractive effort exerted by the truck and the tractive resistance cannot be computed at this stage of the work. The diagram for tractive resistance can only be plotted as the velocity computations are made, because the resistance varies with the speed of the vehicle. The curve for tractive effort is projected by trial, in an attempt to provide for the restoration of the vehicle speed to the initial value of 40 miles per hr at the end of the descending grade. In Fig. 3(*c*) the tractive-effort diagram is plotted upward from the zero force axis. The diagram for force due to grade is plotted upward for plus grades and downward for minus grades; and the tractive resistance is plotted upward from the grade-force diagram, as the successive tractive-resistance values are determined. This method of plotting provides a curve representing the resultant of the external forces acting on the vehicle—that is, all the forces except the tractive effort. The difference between the ordinate to this resultant curve and the ordinate to the tractive-effort curve, at a given point on the profile, is the net force acting to accelerate or decelerate the vehicle. When the resultant curve is above the tractive-effort curve, the computed net force is negative, decelerating the vehicle; when the resultant curve is below the tractive-effort curve, the net force is positive, and the vehicle is accelerating. Furthermore, the ordinates to the acceleration curve are proportional to the corresponding differences between the ordinates to the resultant curve and the tractive-effort curve. With this arrangement, it is easy to visualize the effect of changes in the applied tractive effort. By studying the acceleration curve from time to time after the vehicle is on the descending grade, the tractive-effort curve may be projected in such a manner that fewer trials will be required to attain the desired vehicle speed at the end of the grade.

11. Description of Detailed Computations

With the data in Sections 8 and 9, the numerical computations can be arranged in the form shown in Table 1, or in any shorter form suitable to the computer. The normal interval of distance is 50 ft, but, wherever the force

acting on the vehicle changes sharply inside the normal 50-ft interval, the normal interval is subdivided. For instance, the normal interval is divided at the end of the sag vertical curve, distance $s = 140$, where the force due to grade reaches a maximum. The use of short intervals in this manner improves the accuracy of the approximation.

For the profile under consideration, the grade is level at distance $s = 0$ and the grade resistance, therefore, is zero. The velocity of the truck is 40 miles per hr or 58.667 ft per sec at distance $s = 0$. The coefficient of tractive resistance (f), taken from the curve in Fig. 2, is 0.0206 lb per lb of truck weight. The tractive resistance (R_t) corresponding to the initial velocity, and used also for

the interval from distance $s = 0$ to distance $s = 50$, is the gross vehicle weight (W_g) multiplied by the coefficient, or $30{,}000 \times 0.0206 = -618$ lb. Since the truck speed (V) is constant on the level approach grade, the tractive effort (P_e) at distance $s = 0$ is just sufficient to balance this resistance; that is, +618 lb. In the numerical work, the forces tending to decelerate the vehicle are marked negative and those tending to accelerate the vehicle are marked positive. The foregoing data are then recorded at $s = 0$ ft in Table 1.

The tractive resistance (R_t) used at distance $s = 50$ is −618 lb, as stated in the preceding paragraph. The engine tractive effort (P_e) at distance $s = 50$ is equal to $618 + (760 - 618) \times 50/140 = +669$ lb. The grade resistance (R_g) is equal to $30{,}000 \times 0.07 \times 50/140 = -750$ lb (see $s = 50$ ft under Cols. 1 to 4, Table 1). Taking the algebraic sum of the engine tractive effort, the tractive resistance, and the grade resistance, the net force P_n is found to be −699 lb; the acceleration (a_e) at the end of the interval between $s = 0$ and $s = 50$ is computed by dividing the net force by the total mass of the truck, $-699/1{,}000 = -0.699$ ft per sec per sec; and the average acceleration (a_a) during the passage of the truck from distance $s = 0$ to distance $s = 50$ is the arithmetic mean of the accelerations at the beginning and the end of the interval, $(0.000 - 0.699)/2 = -0.350$ ft per sec per sec (see $s = 50$ under Cols. 5, 6, and 7, Table 1).

The velocity change (Δv_e) in the interval from $s = 0$ to $s = 50$ is computed by multiplying the average acceleration by the time (Δt) taken for the truck to pass through the distance interval at an average velocity (V) equal to the

arithmetic mean of the velocities at the beginning and the end of the interval. It is necessary to assume an average velocity (V); then find the time for this velocity; compute the velocity change and the velocity at the end of the interval; and observe whether the mean velocity checks that assumed. Using an assumed average velocity of 58.500 ft per sec, the time is 50/58.5 = 0.855 sec, and the velocity change is $-0.350 \times 0.855 = -0.299$, giving a velocity of $58.667 - 0.299 = 58.368$ ft per sec at distance $s = 50$, and an average velocity in the interval of $(58.667 + 58.368)/2 = 58.518$ ft per sec. This velocity is used for the second trial, since it does not check the value previously assumed. The time for the second trial is $50/58.518 = 0.854$ sec, and the velocity change is $-0.350 \times 0.854 = -0.299$ ft per sec. The velocity at the end of interval is $58.667 - 0.299 = 58.368$; and the mean velocity is the same as computed in the first trial (see $s = 50$, under Cols. 8, 9, 11, and 12, Table 1).

The time for the distance interval, 0.854 sec, is added to the previous value for total time. The coefficient of tractive resistance for the velocity at the end of the interval is read from the curve in Fig. 2, and found to be 0.0205 lb per lb (see $s = 50$, under Cols. 10 and 13, Table 1). The complete data for the second line of the table have thus been computed.

These several steps are repeated for the computation of the data for distance $s = 100$, and for the subsequent distance intervals. The computations for time and velocity may be performed very easily and quickly with a slide rule, with sufficient accuracy for the purpose. On certain types of rules, only one setting of the slide is required for each trial; the second trial is usually sufficiently close to the correct value, so that, in reality, the computations are much simpler than the description indicates.

In Fig. 3 the curves for the complete computations shown in Table 1 are plotted. The tractive-effort curve indicated by a broken line in Fig. 3(c) represents the first trial to increase the speed of the vehicle to the initial value of 40 miles per hr at the end of the descending grade. The corresponding velocity curve (Fig. 3(a)) is also indicated by a broken line. The tractive-effort curve shown by the solid line in Fig. 3(c) was projected as the second trial, and the corresponding velocity curve is also shown by a solid line in Fig. 3(a). The numerical values for the second trial are indicated in Table 1(c).

12. Time and Distance Loss

The time lost by the assumed vehicle for a given distance is the difference between the computed time for traversing this distance and the time required to cover the same distance at a constant speed equal to the initial speed, which is 40 miles per hr in the illustrative problem. Fig. 4 shows the time and distance lost for any point on the profile of the example. The computed time curve represents the total time, shown in Col. 13, Table 1, plotted against the distance for each 50-ft interval point on the profile, the plotted curve being that of the values for the second trial computation for points beyond distance $s = 800$ (see Table 1(c)). The time curve for uniform velocity is a straight line, with a slope of one second on the time scale to 58.667 ft on the distance scale.

The time loss at a given point on the profile, as compared with a uniform speed of 40 miles per hr, may be scaled from Fig. 4, as the difference between

the ordinates to the computed time curve and the time curve for uniform velocity, for the distance in question. For distance $s = 1,425$ the time loss scales 3.7 sec. Since this point is the end of the descending grade of the profile used in the example, the time loss at this point may be called the total for the profile.

The total time loss is the answer sought in most overpass grade problems, since it may be used as a basis for comparison with other grade lines between control points, and intermediate values for time loss are not important. For such cases, the total time loss can be calculated directly without plotting the time curves. In the example, the total computed time for the distance of 1,425 ft, in the second trial, is 28.03 sec. The time required to cover this distance at a constant speed of 40 miles per hr is $1,425/58.667 = 24.29$ sec. The total time loss is $28.03 - 24.29 = 3.74$ sec.

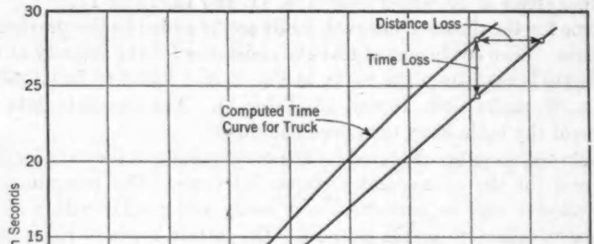

FIG. 4.—TIME-DISTANCE CURVES CORRESPONDING TO FIG. 3

The distance lost by the truck at a given point on the profile is defined as the product of the time loss in seconds at the given point and the governing initial velocity, using the unit of feet per second to obtain the distance loss in feet. In the example, the total distance loss for the profile, at $s = 1,425$, is $3.74 \times 58.667 = 219$ ft. In other words, when the truck in the example reaches $s = 1,425$, it is 219 ft back of the position it would have reached in the same time at a constant speed of 40 miles per hr. The distance loss may be scaled from Fig. 4, as the distance between the two time curves—that is, by measuring horizontally from a point on the computed time curve, corresponding to the actual distance or time in question, to the time curve for uniform velocity.

For determining time or distance, lost or gained, by scaling from a time-distance curve, the measurement should be made in all cases from the point in question on the computed curve to the curve for uniform velocity.

13. Use of Time Intervals, Rather than Distance Intervals, for Velocity-Curve Computations

It is practicable to use a computation procedure involving time intervals, instead of distance intervals, as used in the illustrative problem. This procedure would simplify the detailed computations for velocity slightly, since it would eliminate the necessity for trial determination of the time interval during which a certain average acceleration operates; but the use of this procedure would complicate the determination of the forces acting upon the vehicle at the end or the beginning of the constant time interval, and would make the plotting of the acceleration and velocity curves more difficult.

14. Graphic Methods for Determining Velocity Curves

Graphic methods for the construction of velocity curves, providing satisfactory accuracy for the type of problem under consideration, have been used in connection with similar studies in railway work, and there are apparently no circumstances that would prevent the adaptation of these graphic methods for studies of truck velocities. The description of such a method, including a bibliography, was presented in 1941 by A. I. Lipetz.[8] It is considered unlikely that the graphic method would prove advantageous, from the standpoint of saving time and labor, as compared with the numerical method described herein, for the short profiles under consideration in this study. In the comparison of different grade lines, such as might be encountered on different routes between control points in mountainous terrain, the use of a graphic method might be distinctly advantageous.

15. Effect of Height of Rise and Rate of Grade on Time Loss

In an effort to determine the factors that would provide the best designs for grade lines over grade separation structures on a freeway, computations of the velocity curves and the time loss for the truck described in Fig. 3 were made for a variety of grade lines. Values between 5 ft and 28 ft were used for the rise in grade. The velocities were not restored to exactly 40 miles per hr at the end of the descending grade in some cases, since it appeared that variations up to about 0.3 mile per hr would permit sufficiently accurate computation of time loss. An endeavor was made to use procedures for applying the tractive effort on the descending grade for the different profiles which followed the same general principles in all cases.

In Fig. 5 the time losses for the various profiles are plotted against the rise in grade. The curve drawn through points A to I is a quadratic parabola. From the relation between the plotted points and the parabola it is evident that the time loss is approximately proportional to the square of the rise in grade, and the four profiles studied for the 28-ft value of rise indicate that the time loss is not greatly affected by the rate of grade. These conclusions are based on the assumed truck-trailer combination described in Section 8, and on a definite general procedure for the application of the tractive effort of the truck;

[8] "Graphical Methods for Plotting Time-Speed-Distance Curves for Railway Trains," by A. I. Lipetz, *Transactions*, A.S.M.E., October, 1941, p. 603.

and they should not be applied directly for other truck designs or loads, or for grades that require a shifting of gears. However, it appears that the assumptions that time loss is approximately proportional to the square of the rise and is independent of the rate of grade may be used as a general basis for designing overpass grades, provided the same standard for vertical sight distance governs for the different profiles considered.

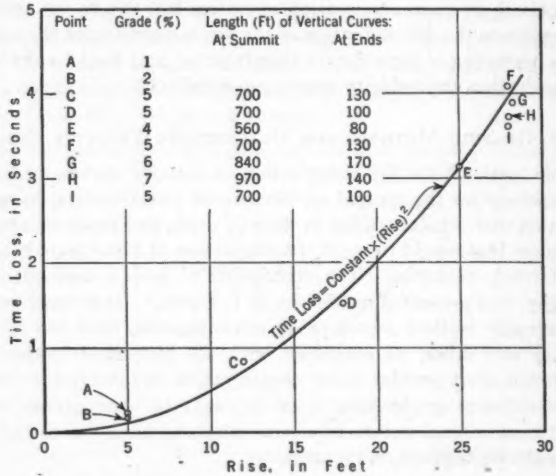

FIG. 5.—TIME LOSS FOR A TRUCK ON OVERPASS GRADES (90-HP MOTOR, HIGH GEAR; W_g = 30,000 LB; VERTICAL SIGHT DISTANCE, 500 FT)

16. EFFECT OF OVERPASS GRADES ON HIGHWAY CAPACITY

The time lost by a single truck on an up-and-down grade such as that discussed herein is a fairly definite quantity, subject to the aforementioned limitations on accuracy. The effect of a rise in grade to overpass a railroad or street on the carrying capacity of a single traffic lane or on the capacity of a complete highway facility is somewhat more difficult to evaluate. It is possible, however, to give some general comments relative to this question, which may be useful in the study of specific problems.

In 1942, O. K. Normann[9] presented a paper containing data and comments pertaining to the maximum theoretical capacity and the practical working capacity of various types of highways. In the remarks that follow, use is made of ideas expressed by Mr. Normann, with only a brief explanation of the fundamentals involved. Reference to the original source will provide the reader with a broader background for review of the remarks contained herein.

There is an average minimum spacing, which depends upon velocity, for vehicles moving in a single lane of a given highway, and this spacing may be determined by the proper test methods when traffic conditions on the highway

[9] "Results of Highway-Capacity Studies," by O. K. Normann, *Public Roads*, June, 1942, p. 57.

are suitable. On the basis of the average minimum spacing between vehicles for various speeds, it is possible to calculate the maximum theoretical traffic capacity of the traffic lane under consideration. Under actual operating conditions, the traffic volume will rarely reach the maximum theoretical capacity, since this capacity is based on continuously maintaining the minimum spacing. There is a definite practical working capacity for a given traffic lane of a given highway, however, and a working capacity for a given traffic facility, taken as a whole. The practical working capacity of a given section of highway is a relative value depending on various local conditions.

If a truck travels over a certain section of a highway which includes an overpass grade, and there is no other traffic on the section of highway at the time, the reduction in speed of the truck in moving over the grade rise affects the truck alone. That is, no other vehicle is delayed as a result of the reduction in speed of the truck. On the other hand, if the same section of highway is carrying its maximum theoretical traffic volume, for the assumed speed of 40 miles per hr (which condition may exist for a short time) and one of the vehicles moving over the section is a truck such as that of Section 8, it is evident that each vehicle following the truck over the grade rise will lose time in an amount equal to the time lost by the truck, provided the average minimum spacing is maintained through the section, since under the condition of maximum theoretical capacity there will be no passing. If a stream of traffic feeds into a section of highway containing an overpass grade at a speed of 40 miles per hr, at the average minimum spacing for this speed, and a considerable percentage of trucks is involved, the time lost by a truck at the grade rise will result in delay for each vehicle following the truck. The loss of time incurred by each additional truck will cause additional delay for the vehicles behind it, and congestion will eventually result at some point on the highway back of the grade rise. The maximum theoretical traffic capacity of the section of highway for a speed of 40 miles per hr will be reduced as a direct result of the presence of the grade rise, provided, of course, the trucks and cars do not regain the time lost at the overpass grade by operating at a speed in excess of 40 miles per hr at any place in the section.

The conditions outlined in the preceding paragraph are extreme. The practical working capacity of a lane of a divided multilane highway will probably be less than two thirds of its theoretical maximum capacity; and, although two, three, or more vehicles will be encountered in a group, spaced at or near the minimum distance, such groups will be separated by spacings greater than the minimum. Under these conditions, the reduction in speed of a given truck passing over a grade rise would result in delay for the vehicles following the truck and not separated from it or the preceding vehicle by a spacing sufficiently long to obviate the effects of speed reduction by the vehicles ahead.

This last point may be clarified by an example, in which it is assumed that, on one lane of the section of road approaching the grade rise, vehicles are traveling in groups of five, at 100-ft average minimum spacing for the initial speed of 40 miles per hr; and these groups of five vehicles are spaced 1,000 ft apart, net. Then, if a truck included in one of the groups incurs a time loss and corresponding distance loss on the given profile, only the vehicles behind

the truck in its group will be delayed as a result of the truck time loss, unless the distance loss for the last vehicle in this group amounts to more than 900 ft; that is, the original group spacing of 1,000 ft, less the average minimum spacing between vehicles for the speed involved. If the latter condition occurs, vehicles in the group following that containing the truck will incur delay; if the delay to this second group is sufficiently great, a third group also will be delayed, and so on. A succession of grade rises in the profile under consideration would involve cumulative time losses. From these considerations, it appears that in a practical problem the number of vehicles that would be delayed by a reduction in speed of a truck on a given profile can be determined only on the basis of mathematical probability, taking proper account of the average minimum spacing between vehicles, the average number of vehicles in a group, the average spacing between groups, and the proportion of vehicles that are unable to maintain speed on the given profile.

Furthermore, under working conditions, vehicles following the truck would not necessarily be prohibited from passing the truck while its velocity is less than 40 miles per hr, or from increasing speed to a value above 40 miles per hr and passing the truck after traveling over the grade rise; so it is possible that, on a sufficiently long section of highway involving one overpass grade, some of the vehicles in a group following a truck at the grade rise might pass the truck and thus permit the remainder of the vehicles to make up their lost time, with the result that none of the vehicles except the truck would incur a time loss for the section of highway under consideration. Finally, it is possible that the truck might operate at a speed greater than 40 miles per hr after passing the overpass grade and thus overcome the loss of time on the grade.

The foregoing remarks indicate the wide range of conditions that may be encountered in a study of the effect of grade rises on the capacity of a highway. Ordinary conditions of the profile and ordinary proportions of truck traffic apparently are not likely to justify the construction of an extra traffic lane on overpass grades to permit passing of heavily loaded vehicles. However, such extra lanes are often justified and have been built at many locations on rural highways where fairly long and steep grades are involved, to eliminate excessive delays to traffic.

17. Time Loss on Rising Grade Without Compensating Falling Grade

As may be seen from a study of Fig. 3, the force due to grade is large in comparison with the tractive effort available from the engine for heavily loaded vehicles on ordinary overpass grades. In cases where the grade rise is not accompanied by a corresponding drop in grade beyond the overpass, a considerable increase in time loss prior to a restoration of the velocity to its initial value is to be expected, as compared to time loss in the case where the rise is compensated by an equal fall. Fig. 6 shows complete force, acceleration, velocity, and time curves for two profiles involving a rise of 12 ft. The broken lines represent values for a profile with a 12-ft drop in grade beyond the overpass, and the solid lines represent values for a profile with a level grade beyond the overpass. The total time loss for the first case is 0.83 sec and the distance loss

49 ft. For the second case the time and distance losses are 1.50 sec and 88 ft, or about 80% greater than for the first case.

The rise of 12 ft involved in these cases is an ordinary value for urban grade separations between streets, and the value of 1.5 sec for time loss is small. For a rise of 25 ft or more, not compensated by a drop in grade, it appears that excessive time loss might result. To permit the use of a convenient scale, the time curves between the beginning of the profile and distance $s = 500$ are not shown in Fig. 6.

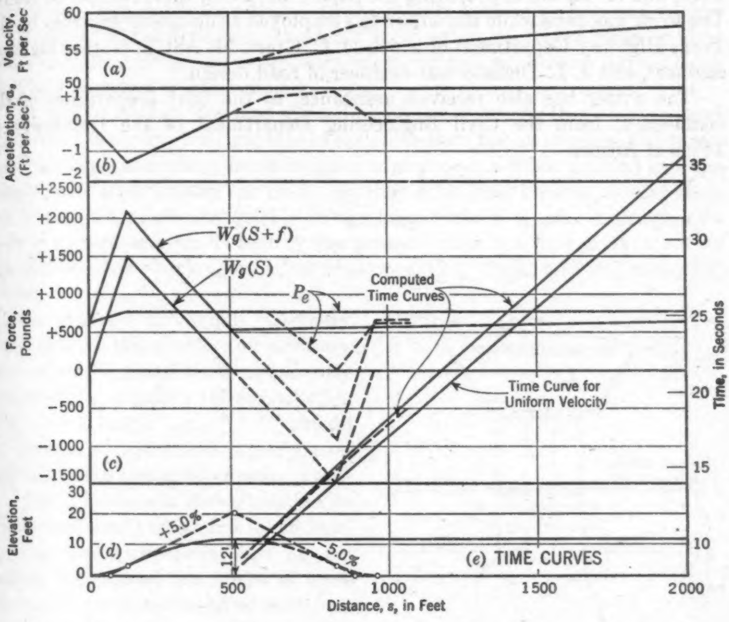

FIG. 6.—TRUCK OPERATION CURVES FOR A GRADE RISE WITH OR WITHOUT A COMPENSATING FALL

18. CONCLUSION

This paper is presented with the primary purpose of calling attention to the method of obtaining the velocity curve for a given vehicle traveling over a given profile. Although the original studies on which the paper is based concern overpass grades, and the examples are taken from those studies, the applicability of the outlined methods to a wide variety of grade problems is evident.

It is felt that the comments regarding the effect of low rises in grade, on truck speed and highway traffic capacity, may be useful in a field wider than that of the overpass grades for which they were originally formulated, and that they are of sufficient interest to warrant their inclusion with the exposition of the method for velocity-curve computation.

It is hoped that the method and corollary ideas will provide the engineer with improved means for selecting the best grade line, from the standpoint of operation of trucks and mixed highway traffic, not only for short adverse grades, but for longer profiles as well.

19. Acknowledgment

The methods outlined were developed under the direction of H. G. Bossy, of the Texas Highway Department. For his numerous suggestions during the work, and for his aid in preparing the paper, Mr. Bossy deserves special credit. The work was done while the writer was employed as designing engineer by the Texas Highway Department of which D. C. Greer, M. ASCE, is state highway engineer, and J. L. Dickson was engineer of road design.

The writer has also received assistance, in the final preparation of the manuscript, from the Civil Engineering Department of the University of Texas at Austin.

DISCUSSION

JONATHAN JONES, M. ASCE.—The impression a layman receives from reading this paper is that the adverse effect upon general traffic of the slowing down of trucks on ascending grades is not a very serious matter; this impression is summarized in the two concluding sentences of Section 16. The author may be justified in reaching this conclusion for his locality, and for overpasses required in otherwise flat terrain. He considers, however, that his study is more widely applicable than that. In the rapidly succeeding hills and valleys of the state of Pennsylvania, the backing-up effect of trucks upon general traffic on ascending grades is seriously exasperating and, human nature being what it is, a source of great danger.

All may be well on four-lane divided highways, assuming that all slow-moving trucks will occupy the right lane in each direction; but on two-lane and three-lane highways, ascending, faster vehicles cannot pass a truck without extreme danger; nor, after passing the crest, can they often pass because at that stage the trucks will accelerate quickly to the legal limit of speed. Consequently there is no greater boon desired by the general driver in a hilly state, than the elimination of the backing-up effect of slow-moving trucks on steep ascending grades.

The author's statement "Ordinary conditions of the profile and ordinary proportions of truck traffic apparently are not likely to justify the construction of an extra traffic lane * * *" should be taken as applying to overpass grades and not to the means of crossing a natural rise. There is in such situations an alternative means which has taken hold, to what the writer considers an excessive degree; and the intent of these remarks is to express a belief that here the construction of the extra lane, where relief is needed, will usually be superior to the alternative practice of making a deep cut to reduce the grade.

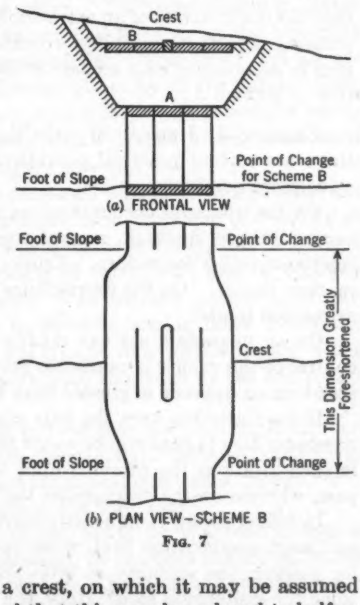

FIG. 7

Fig. 7 will serve to illustrate this point in terms of a highway practice of which the writer is well aware through observing the construction of improved highways in his vicinity. This diagram shows roughly the frontal view and the plan view of an incline from a valley to a crest, on which it may be assumed that the natural grade would be severe, and that this may be reduced to half or less by making the deep cut indicated as scheme A. So doing does not, however, enable all trucks to climb the grade without reduction of speed, but only

some of them. The others reduce their speed somewhat, although not so much as on the original grade. The delay to following traffic is therefore somewhat mitigated; the danger is not removed. Passing on the center lane is dangerous and in many instances forbidden by law. The cost of the cut is extreme; in one observed instance it added at least three months to the construction time, during which traffic was detoured, because of the necessity for blasting solid rock.

If, however, this road were constructed from valley to crest as shown as scheme B, and in the plan view, Fig. 7(*b*), providing an additional lane on the right side of the ascending pair, and separating the ascending and descending pairs with a raised element, then all passenger and light truck traffic could negotiate the steep grade in high gear, without any danger from oncoming traffic, and therefore without the need for special sight distance. The cost (because the ground would be only barely scratched instead of deeply cut) should be little more, and frequently would be less, then alternative A. The required right of way would be reduced. The pleasure of the average passenger would be enhanced, because he would be viewing a landscape instead of the side of a cut. Trucks on the right-hand lane would naturally be traveling at considerably slower speed by scheme B than by scheme A; but their loss in this respect would be the gain of all others.

As a user of the highway both for business and pleasure, the writer believes that the construction of an extra traffic lane over natural rises is very frequently justified, and that the fullest consideration should be given to providing this lane in accordance with scheme B rather than seeking to avoid it by the adoption of scheme A.

Elliott J. Dent,[10] M. ASCE.—In discussing this interesting subject there are certain practical considerations that the writer believes should receive more emphasis.

On the upgrades encountered on main highways the modern passenger car can, ordinarily, maintain normal speed; in fact, there is often a considerable reserve of power for pickup. Trucks, on the other hand, are slowed down to a marked degree. On the downgrades trucks can, and do, maintain the legal or safe speed limits.

On an upgrade a car can readily slow down or stop; on a downgrade the control of the vehicle is much less efficient. Other things being equal, the safe speed on an upgrade is greater than that on a downgrade.

If the foregoing were the only considerations, the easy and safe places for passenger cars to pass trucks would be on the upgrades. It is unfortunate that in such locations the summits limit the sight distances and make it unsafe to pass, whereas on the downgrades the visibility is much better.

In rolling country, on heavily traveled two-lane highways, it is inconvenient and most exasperating that, when the safe and available speeds are favorable for passing, the visibility so often inhibits such action. On the other hand, when the visibility is satisfactory, the available relative speeds are unfavorable.

In the majority of cases the logical solution is the provision of an additional traffic lane on the upgrade side of the crest.

[10] Cons. Engr., Washington, D. C.

F. B. Ogle,[11] Assoc. M. ASCE.—The proper maximum grades for highways, required to meet a specific set of conditions, can be determined by the long-needed method presented in this paper. Certain variable factors, particularly driver habits and truck operating characteristics, will be minimized by driver training and by the standardization of truck building and maintenance, which will be forced by competition. This development is foretold by the experience in railroad operation of the past. The method proposed by Mr. Stevens is sound, simple, and easily applied.

The first designers of the modern highway were primarily concerned with providing an all-weather surface for light, self-propelled vehicles of relatively low speeds. The alinement usually followed existing roads; and the grade line followed the existing grade closely. Based on present-day standards, this alinement was poor, and the adverse grades were excessive in many cases.

As the traffic load increased, improvements consisted primarily of widening pavements, inserting curves at angle turns, flattening existing curves, and reducing excessive grades to an assumed maximum rate of rise. The assumed maximum grade rates were low enough to avoid any serious reduction in speed of the then predominately automobile traffic. Highway traffic capacity did not appear as a problem.

The appearance of the freight hauling truck in substantial numbers in the past few years has changed the picture materially; and highway capacity has become an important problem in highway design. The trend clearly indicates that in the near future, certainly within the normal life span of the highways now being designed, truck traffic will predominate. This trend will be accelerated by the adoption of uniform traffic regulations by all the states. Such regulations will come in time, and their adoption will increase interstate movement greatly. For economic reasons, commercial trucks in interstate haul must operate with heavier loads and at higher speeds.

Grades that can be negotiated by the passenger automobile at 50 miles per hr or more will force the trucks into lower gears, requiring them to crawl up at 10 miles per hr, or less. On long grades where traffic is heavy, this produces a serious condition, both from the standpoint of safety and loss of highway capacity. This is apparent to all drivers. One method proposed by Mr. Stevens for relieving this congestion is to provide passing lanes which will release the faster moving vehicle; but it will give no relief to the trucks, which can be relieved only by proper grade design with the truck as the controlling factor.

Grade design based on truck operation will increase the construction or first cost; but it will reduce the unit cost of truck operation and increase the highway capacity. The net result will be to reduce the actual cost based on number of vehicles accommodated; and these are, in fact, the true costs.

It appears that the expenditure of public funds for the convenience of trucks operated for private profit is not justified, as has been contended by the railroad companies. This is unquestionably true in so far as the benefits accrue to the truck operator; but the movement of freight on the highways has become

[11] Senior Resident Engr., Texas Highway Dept., Lubbock, Tex.

vital to the economic life of the United States, and any reduction in the cost of freight movement will accrue to the public.

J. W. Stevens,[12] Assoc. M. ASCE.—The discussions indicate an opinion which is evidently held by many private drivers: That trucks on hills delay traffic to an annoying extent. The writer heartily agrees with the comments pointing out the need for passing lanes on many existing highway grades. It is easy to determine whether there is serious need for a passing lane on an existing highway grade merely by observation of traffic in the field and without analysis of the profile and possible truck speed.

Passing lanes should be provided in the original design, instead of waiting until the pavement is built before determination of their need. Therefore, the application of the speed and time loss studies is most valuable in the general design of a project on new location. In many cases the need for passing lanes will be evident without detailed study, and the necessity for such study will be reduced to the doubtful or borderline cases.

Special emphasis should be given to the limitation of the conclusion at the end of Section 16 (which applies strictly to overpass grades in otherwise flat terrain) as pointed out by Mr. Jones. It is probable that passing lanes might be amply justified on fairly steep grades involving rises of the order of 50 ft on highways where a rise of 25 ft would not require an extra lane.

Mr. Ogle's discussion indicates that the question of permitting automobiles to pass slow-moving trucks is only part of the designer's problem. The need for grade design to provide for efficient operation of truck traffic is increasing, and will continue to increase as the proportion of truck traffic grows.

The writer feels that the published discussions are valuable for their additions to the ideas covered in the paper, and wishes to express appreciation for these discussions.

Attention should be called again to the possibility of combining arithmetical operations to shorten the computations, as mentioned in the first sentence in Section 11. Any user of the method will find additional short cuts particularly suited to his procedure. It is interesting to note that both the shape and height of the velocity curve in Fig. 3 show considerable resemblance to the profile curve. This resemblance, of course, depends on the scales of the two curves and on the applied power of the vehicle, and possibly is purely coincidental. However, remarkable similarity of the velocity and profile curves was noted in all cases covered by Fig. 5. It is conceivable that the similarity of these curves might be established for short sections of profile in many cases, so that the velocity curve could be drawn with satisfactory accuracy by inspection of the profile, thus eliminating computations.

It is hoped that the remarks in Section 14 will discourage no one from making full use of graphic methods in speed and time loss problems. The writer's attention has been called to the possibility of graphic solutions shorter than those of which he was aware when the paper was prepared. The graphic methods for time loss determination might well form the subject of a valuable paper for the benefit of engineers concerned with this phase of highway design.

DRAWDOWN TEST TO DETERMINE EFFECTIVE RADIUS OF ARTESIAN WELL

By C. E. Jacob,[1] Assoc. M. ASCE

With Discussion by Messrs. N. S. Boulton, Carl Rohwer, R. M. Leggette, M. R. Lewis, and C. E. Jacob.

Synopsis

The drawdown in an artesian well that is pumped has two components: The first, arising from the "resistance" of the formation, is proportional to the discharge; and the second, termed "well loss" and representing the loss of head that accompanies the flow through the screen and upward inside the casing to the pump intake, is proportional approximately to the square of the discharge. The resistance of an extensive artesian bed increases with time as the ever-widening area of influence of the well expands. Consequently, the specific capacity of the well, which is discharge per unit drawdown, decreases both with time and with discharge.

The multiple-step drawdown test outlined in this paper permits the determination of the well loss and of the "effective radius" of the well. The trend of drawdown is observed in the pumped well and in one or more near-by observation wells as the discharge is increased in stepwise fashion. A simple graphical procedure gives the permeability and the compressibility of the bed. From these several factors it is possible to predict the pumping level at any time for any given discharge.

Notation

The letter symbols in this paper are defined where they first appear and are assembled alphabetically, for convenience of reference, in the Appendix.

Introduction

It has long been known that the discharge of an artesian well is almost, but not quite, proportional to the drawdown. In a well that is pumped the drawdown is the difference between the static water level and the pumping

Note.—Published in May, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Hydr. Engr., Water Resources Branch, U. S. Geological Survey, Washington, D. C.

water level, customarily measured after several hours of continuous operation. Usually the major part of this loss of head, or drawdown, occurs in the formation, where the energy expended in overcoming the frictional resistance of the sand against the slowly moving water is directly proportional to that rate of motion. A smaller although no less important part of the loss of head occurs as the water moves at relatively high velocities through the screen and upward inside the casing to the intake of the pump. This head loss is approximately proportional to some higher power of the velocity approaching the square of the velocity. Adding these two components of drawdown:

$$s_w = B\,Q + C\,Q^2 \quad \text{(1)}$$

—approximately. Considering the drawdown, s_w, analogous to electric potential drop and the discharge, Q, analogous to electric current, the factor B can be defined as the "resistance" of the formation. This factor represents the total hydraulic resistance of the formation, from the face of the well to some distance where the head drop is virtually zero and where the radial motion of water toward the discharging well has not yet begun. The ratio of discharge to drawdown, called "specific capacity," is seen from Eq. 1 to be

$$Q/s_w = 1/(B + C\,Q) \quad \text{(2)}$$

Clearly, then, the specific capacity must vary, however slightly, with the discharge. Also, it must vary with time because, as will be shown, the resistance B increases with time as the ever-widening area of influence of the well expands.

It is the purpose of this paper to demonstrate that the factors B and C can be determined by a procedure that is little more elaborate than the usual "drawdown test" made to determine the specific capacity and to check the performance of the pump and motor. This is accomplished simply by controlling, more closely, the stepwise variation of the discharge and by observing, more frequently and more accurately, the trend of the pumping level as it is lowered.

Distribution of Drawdown in and Near an Artesian Well

Fig. 1 shows three typical examples of artesian wells that completely penetrate extensive formations of assumedly homogeneous structure and uniform thickness. Fig. 1(*a*) is the ideal case of an uncased hole drilled through a water-bearing sandstone confined above and below by impervious shales. Virtually all the head loss occurs in the formation, since no well screen or slotted casing is present to impede the flow of water into the hole. There must inevitably be some additional friction as the water moves up the hole, and consequently the pumping water level in the hole does not coincide exactly with the head at the face of the hole just inside the formation, but rather stands somewhat lower, perhaps as indicated by the dashed line in Fig. 1(*a*).

Fig. 1(*b*) shows a common type of construction in an unconsolidated artesian sand, where a screen is necessary. For comparison, this sand is shown as having the same thickness and permeability as the sandstone of Fig. 1(*a*).

In the second case, with the same discharge there is the same drop in head within the formation; but in addition there is a "well loss" which includes the head lost through friction as the water flows upward inside the screen and casing to the pump intake as well as to the head drop across the screen. The radial distribution of head within the formation is about the same in both

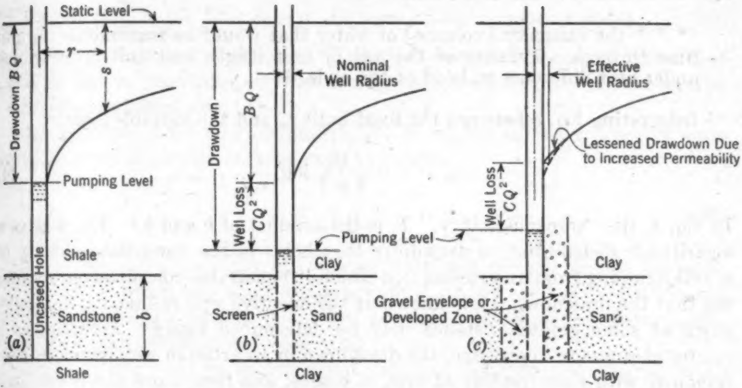

FIG. 1.—TYPICAL EXAMPLES OF ARTESIAN WELLS, SHOWING DISTRIBUTION OF DRAWDOWN

cases, which may indicate that the sand in Fig. 1(*b*) is not greatly affected by drilling or developing operations; the screen effectively retains all the sand including fines.

A common, although not always essential, item of artesian well construction in unconsolidated formations—the gravel envelope—is shown in Fig. 1(*c*). The gravel envelope is particularly effective when the water-bearing sand is fine and of uniform grading. When properly constructed, it is also useful in other situations—to prevent the fines from being drawn into the well. If the size of gravel is properly chosen, the head loss in the immediate vicinity of the screen is reduced to less than it would be if the natural undisturbed water-bearing formation which the gravel replaced were there. Developing a well to remove the fines from the material surrounding the screen has a similar effect. In some sands, developing operations alone are adequate and gravel-wall construction is not needed. In either case the increased permeability of the material surrounding the well lessens the drawdown and increases the effective radius of the well. "Effective radius" is defined as that distance, measured radially from the axis of the well, at which the theoretical drawdown based on the logarithmic head distribution (defined subsequently by Eq. 4) equals the actual drawdown just outside the screen (see Fig. 1(*c*)).

The dashed curved line in Fig. 1(*c*) represents the head distribution that would exist if the water-producing bed were left in place undisturbed, with uniform permeability. That curve duplicates the drawdown curves in Figs. 1(*a*) and 1(*b*). It is so shaped because, to maintain a steady flow of water (at the rate Q) toward the well, the hydraulic gradient must be inversely pro-

portional to the radial distance; or, actually:

$$\frac{ds}{dr} = -\frac{Q}{2\,\pi\,k\,b\,r} \quad \text{.......................(3)}$$

in which b is the thickness of the bed and k is the "permeability" or transmission constant of the sand, defined as:

> "* * * the quantity [volume] of water that would be transmitted in unit time through a cylinder of the soil of unit length and unit cross-section under unit difference in head at the ends."[2]

Integrating Eq. 3 between the fixed limit r_w and the variable limit r:

$$s_w - s = \frac{Q}{2\,\pi\,T}\log_e \frac{r}{r_w} \quad \text{.......................(4)}$$

In Eq. 4, the "transmissibility," T, is the product of k and b.[3] Eq. 4 gives a logarithmic distribution of drawdown that holds in the immediate vicinity of a well pumping from an artesian bed which it penetrates completely. Assuming that the drawdown, s_w, is known at the effective well radius, r_w, the drawdown at some greater distance may be determined easily. Actually, as a matter of common knowledge, the drawdown in an artesian well increases continuously with time (rapidly at first, of course, and then more slowly) as long as the discharge continues at a steady rate and also provided that the well is not too near the margin of the aquifer where the head may be maintained essentially constant despite the withdrawal of water. To determine the drawdown at the well and its distribution throughout an extensive aquifer at any time, it is necessary to study the flow of the confined water in response to varying heads more closely, taking into consideration the compressibility of the water and also the compressibility of the sand bed.

Theory of Nonsteady Radial Flow in an Extensive Artesian Aquifer

Consider a cylindrical shell of height b, inner radius r, and outer radius $(r + \delta r)$ concentric with the axis of the well. By the principle of continuity, the net outward flow of water from this shell must equal the time rate of decrease of the volume of water within the shell, referred to a constant (atmospheric) pressure. The total volume of water in the shell is

$$V_w = 2\,\pi\,r\,\delta r\,b\,n \quad \text{.......................(5)}$$

in which n is the porosity of the sand. The time rate of decrease of this volume is $2\,\pi\,r\,\delta r\,b\,n\,\beta\,\frac{\partial(\gamma\,s)}{\partial t}$, in which γ is the specific weight of the water and β is its compressibility. To allow for the compressibility of the water-producing bed, which is assumed to be compacted elastically as the pressure is reduced

[2] "Theoretical Investigation of the Motion of Ground Waters," by Charles S. Slichter, *Nineteenth Annual Report*, U. S. Geological Survey, 1899, Pt. II, p. 323.

[3] "The Relation Between the Lowering of the Piezometric Surface and the Rate and Duration of Discharge of a Well Using Ground-Water Storage," by Charles V. Theis, *Transactions*, Am. Geophysical Union, Pt. II, 1935, p. 520.

and as the water is allowed to expand, an apparent compressibility, β', is substituted for β. Experience[4,5] indicates β' to be several times the actual water compressibility, β. Combining several factors into a nondimensional coefficient,

$$S = \gamma \, \beta' \, b \, n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6a)$$

and $2 \pi r \, \delta r \, S \dfrac{\partial s}{\partial t}$ is the time rate of decrease of the volume of water. In Eq. 6a S is the "coefficient of storage,"[6,7] which defines the volume of water that a unit decline in head releases from storage in a vertical prism of the aquifer of unit cross-sectional area.

The apparent fluid compressibility, β', is related to the respective compressibilities of the water and the sand as follows:

$$\beta' = \beta + \frac{\alpha}{n} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6b)$$

Again β is the compressibility of the water, and n is the porosity of the sand. The symbol α represents the "compressibility" of the sand bed—that is, the relative decrease in thickness of the bed per unit increase of the vertical component of compressive stress in the sand.

The foregoing relation in somewhat different notation was derived in an earlier paper[8] by the writer in which the theory of nonsteady flow in elastic artesian aquifers was developed.

The outward flow of water from the shell through its inner cylindrical surface is equal to $- 2 \pi r T \left(\dfrac{\partial s}{\partial r} \right)$. Similarly, the outward flow through the outer cylindrical surface is $2 \pi T (r + \delta r) \left(\dfrac{\partial s}{\partial r} + \dfrac{\partial^2 s}{\partial r^2} \delta r \right)$. Assuming the upper and lower bounding planes of the aquifer to be impermeable, the sum of these two terms may be equated to the time rate of decrease of the enclosed volume of water. Expanding, eliminating differentials of higher order, simplifying, and dividing through by $(2 \pi r T \delta r)$:

$$\frac{\partial^2 s}{\partial r^2} + \frac{1}{r} \frac{\partial s}{\partial r} = \frac{S}{T} \frac{\partial s}{\partial t} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

The solution of this fundamental differential equation that is sought here must satisfy the following conditions:

$$s = 0 \quad \text{for} \quad t \leqq 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (8a)$$

$$\lim_{r \to \infty} s = 0 \quad \text{for} \quad t > 0 \ldots\ldots\ldots\ldots\ldots\ldots (8b)$$

and

$$\underset{r \to 0}{\text{Limit}} \left(r \frac{\partial s}{\partial r} \right) = - \frac{Q}{2 \pi T} \quad \text{for} \quad t > 0 \ldots\ldots\ldots\ldots \text{(8c)}$$

The answer is given in terms of an infinite series[8,9,10] as follows:

$$s = \frac{Q}{4 \pi T} \left(-0.5772 - \log_e u + u - \frac{u^2}{2 \times 2!} - \frac{u^3}{3 \times 3!} + \cdots \right) \ldots \text{(9)}$$

in which

$$u = \frac{t^*}{t} = \frac{r^2 S}{4 T t} \ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(10)}$$

In still simpler notation,

$$s = \frac{Q}{4 \pi T} W(u) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(11)}$$

Fig. 2 gives a nondimensional plotting of Eq. 9 or of Eq. 11. The well starts pumping at a steady rate Q at time zero ($t/t^* = 0$). The drawdown at a given distance from the well increases very slowly at first and reaches a

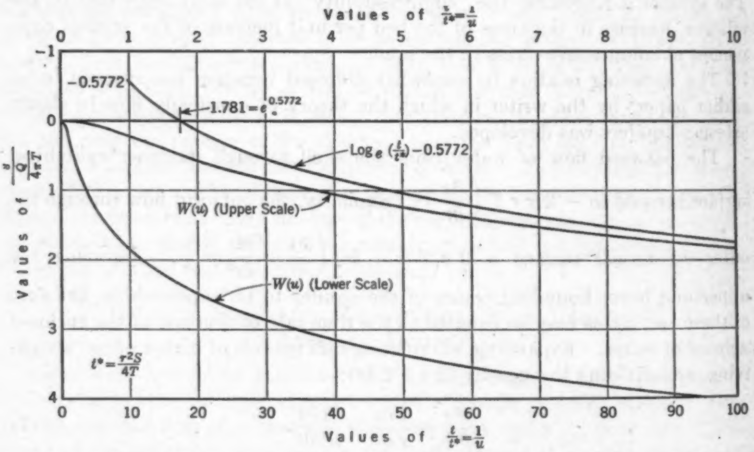

FIG. 2.—NONDIMENSIONAL TIME-DRAWDOWN CURVES, EXACT AND APPROXIMATE, FOR SINGLE WELL DISCHARGE AT A STEADY RATE, FROM AN EXTENSIVE ARTESIAN AQUIFER

maximum rate of increase at $t/t^* = 1$. As this is the point of inflection on the time-drawdown curve, t^* may be called the "inflectional time." Thereafter the rate of increase of drawdown diminishes continually but never vanishes. Theoretically, the drawdown becomes infinite at infinite time.

In Fig. 3 the same equation is plotted on semilogarithmic paper, again in nondimensional form. For sufficiently large values of t, the W-function may be approximated by a simple logarithmic expression that plots as a straight

[9] "The Relation Between the Lowering of the Piezometric Surface and the Rate and Duration of Discharge of a Well Using Ground-Water Storage," by Charles V. Theis, *Transactions*, Am. Geophysical Union, 1935, Pt. II, pp. 519–524.

[10] "The Flow of Homogeneous Fluids Through Porous Media," by M. Muskat, McGraw-Hill Book Co., Inc., New York, N. Y., 1937, p. 667.

line on that graph. Thus, the drawdown after sufficient time has elapsed is given approximately by

$$s = \frac{Q}{4\,\pi\,T}\left(\log_e \frac{t}{t^*} - 0.5772\right) \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

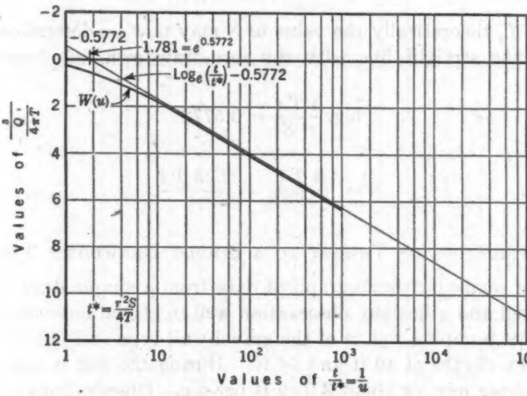

FIG. 3.—SEMILOGARITHMIC PLOTTING OF THEORETICAL TIME-DRAWDOWN CURVE AND STRAIGHT-LINE APPROXIMATION

The drawdown in a well with a negligible well loss (Fig. 1(*a*)) is then:

$$s_w = \frac{Q}{4\,\pi\,T}\left(\log_e \frac{t}{t^*_w} - 0.5772\right) \ldots\ldots\ldots\ldots\ldots\ldots (13a)$$

in which $t^*_w = r^2_w \frac{S}{4\,T}$, r_w being the effective radius of the well. When the well loss is appreciable (Figs. 1(*b*) or 1(*c*)), the drawdown in the well is

$$s_w = \frac{Q}{4\,\pi\,T}\left(\log_e \frac{t}{t^*_w} - 0.5772\right) + C\,Q^2 \ldots\ldots\ldots\ldots (13b)$$

Comparing Eq. 13*b* with Eq. 1, the resistance of the aquifer is

$$B = \frac{\log_e \frac{t}{t^*_w} - 0.5772}{4\,\pi\,T} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

According to Eq. 12 or Eq. 13*a*, S and T may be determined from a series of drawdown observations by plotting values of s against values of the logarithm of t. For sufficiently large values of t, relative to t^* or t^*_w, the points should fall on a straight line. Taking two points on that line to determine the slope,

$$T = \frac{2.30\,Q\,\log_{10}\frac{t_2}{t_1}}{4\,\pi\,(s_2 - s_1)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (15a)$$

Eq. 15*a* can be simplified further by choosing, arbitrarily, the two points one log cycle apart. Then, $\log_{10} \frac{t_2}{t_1} = 1$, and

$$T = \frac{2.30\, Q}{4\,\pi\,(s_2 - s_1)} \quad \text{(15b)}$$

Knowing T, theoretically the value of S may now be determined from the intercept of the straight line with the zero-drawdown line because at this point $(t, 0)$—

$$\log_e \frac{4\,T\,t}{r^2\,S} = 0.5772 \quad \text{(16)}$$

from which

$$S = \frac{4\,T\,t}{r^2\,e^{0.5772}} = \frac{2.25\,T\,t}{r^2} \quad \text{(17)}$$

Application of Theory to a Simple Drawdown Test

Fig. 4 is a semilogarithmic graph of data from a simple drawdown test of a pumping well and a near-by observation well in glacial outwash near Meadville, Pa. The pumping well is of the gravel-wall type and has 15 ft of 18-in. screen between depths of 49 ft and 64 ft. During the test it was pumped at $Q = 1{,}350$ gal per min, or about 3.0 cu ft per sec. Observations of drawdown were made periodically by an air line in the pumping well. An automatic gage gave a continuous record of the drawdown and subsequent recovery in an observation well 1,200 ft away from the pumping well. The data for the drawdown period are plotted as open circles. The data for the recovery period are plotted as solid circles.

The transmissibility may be determined from the slope of either straight line. In both cases the change in drawdown over one log cycle is 2.27 ft. According to Eq. 15*b*, with Q equal to 3.0 cu ft per sec, the value of T is $\frac{2.30 \times 3.0}{4\,\pi \times 2.27} = 0.24$ sq ft per sec. The storage coefficient may be determined from the intercept of the upper straight line with the zero-drawdown line by substituting $t = 693$ sec in Eq. 17. The result of this calculation is $S = \frac{2.25 \times 0.24 \times 693}{1.44 \times 10^6} = 0.00026$.

Assuming the porosity of the sand to be 35% and its effective thickness about 100 ft, the apparent water compressibility is computed as follows: By Eq. 6*a*,

$$\beta' = \frac{S}{\gamma\,n\,b} = \frac{0.00026}{62.4\ (\text{lb per cu ft}) \times 0.35 \times 100\ (\text{ft})}$$

$$= \frac{1}{8{,}400{,}000\ (\text{lb per cu ft})} = \frac{1}{58{,}000\ (\text{lb per cu in.})}$$

The bulk modulus of gas-free water at ordinary temperatures is about 300,000 lb per sq in. The apparent water compressibility (which is the reciprocal of bulk modulus) in this case is then about five times the actual compressibility of water.

Assuming that this value of S holds within the immediate vicinity of the well, the well loss and the factor C may be determined under the further provisional assumption that the effective well radius is equal to the nominal well radius (see Fig. 1(*b*)).

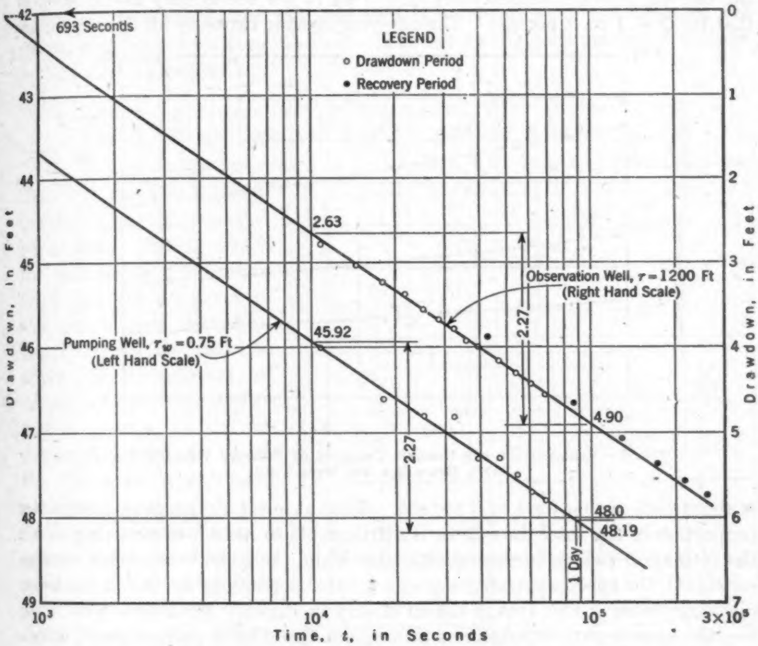

FIG. 4.—SEMILOGARITHMIC PLOTTING OF DATA FROM A SIMPLE DRAWDOWN TEST OF A PUMPING WELL AND A NEAR-BY OBSERVATION WELL TO DETERMINE TRANSMISSIBILITY, STORAGE COEFFICIENT, AND WELL LOSS

For example, to determine the drawdown for one day, with the use of Fig. 4 solve the formula:

$$s_w = \frac{Q}{4\,\pi\,T}\left(2.303\,\log_{10}\frac{4\,T\,t}{r^2{}_w\,S} - 0.5772\right) + C\,Q^2 \ldots\ldots\ldots(18)$$

The fraction $\frac{4\,T\,t}{r^2{}_w\,S} = \frac{4 \times 0.24 \times 86{,}400}{0.5625 \times 2.6 \times 10^{-4}} = 5.67 \times 10^8$; $\log_{10}\frac{4\,T\,t}{r^2{}_w\,S} = 8.753$; the value in parentheses in Eq. 18 equals $(8.753 \times 2.303) - 0.58 = 19.5$; and $s_w = \frac{3.0 \times 19.58}{4\,\pi \times 0.24} + C\,Q^2 = 19.5 + C\,Q^2 = 48.0$ ft. Finally, $C\,Q^2 = 9.0\,C = 48.0 - 19.5 = 28.5$ ft; from which $C = 3.2\left(\frac{\text{sec}^2}{\text{ft}^5}\right)$. The foregoing calculations indicate that $B\,Q$ in this case was about 19.5 ft after 24 hours of continuous pumping. The observed drawdown in the pumping well at that time was 48.0 ft,

leaving 28.5 ft for the well loss. Inasmuch as Q was about 3.0 cu ft per sec, the numerical value of C was approximately 3.2.

Fig. 5 shows how the specific capacity of the well under discussion would vary with the discharge or with time. Because of the relatively high well loss, the one-day specific capacity for $Q = 3$ cu ft per sec is only about 60% of that for $Q = 1$ cu ft per sec. The one-year specific capacity for 3 cu ft per sec

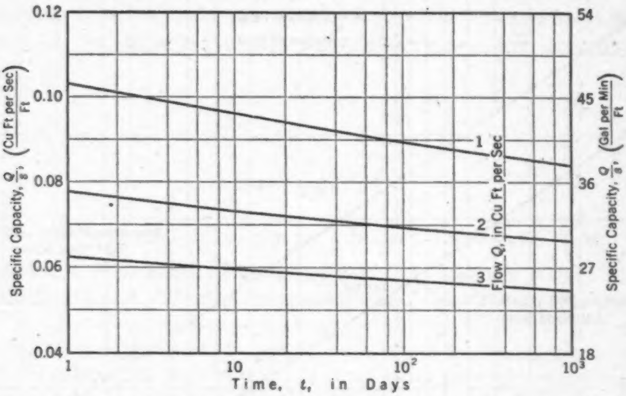

Fig. 5.—Variation of the Specific Capacity of Pumping Well of Fig. 4 with Discharge and with Time

is about 65% of that for 1 cu ft per sec. Since at lower discharge rates a greater proportion of the total drawdown is attributable to head loss occurring within the formation (which increases with time while the other component remains constant), the specific capacity shows a greater percentage decline at the lower discharge rates. This fact is shown clearly in Fig. 5. With $Q = 1$ cu ft per sec, the specific capacity declines from about 0.104 cu ft per sec per ft at one day to about 0.086 cu ft per sec per ft at one year—a drop of about 17%. On the other hand, with $Q = 3$ cu ft per sec, the specific capacity declines from about 0.063 cu ft per sec per ft at one day to about 0.056 cu ft per sec per ft at one year—a drop of about 11%.

Fig. 5 illustrates the importance of stating the length of the pumping period during which the discharge remains constant and at the end of which the reported specific capacity is to be determined. It is also important to state the discharge. Too often in the past the specific capacity has been regarded as invariable, only passing attention being given to its variation with discharge and little or nothing being noted about its variation with time. This neglect may perhaps be attributed to the fact that, most commonly, measurements of drawdown are made by an air line, with a pressure gage reading to the nearest pound per square inch or an altitude gage reading to the nearest foot—no effort being made to interpolate closer than half a scale division. Very often the discharge is allowed to vary unmethodically to obtain several points quickly on the discharge-head curve for checking the characteristics of the pump and motor.

In the example given in this section it was assumed that the gravel envelope was not particularly effective for reducing the drawdown in the vicinity of the well and that therefore the nominal radius of the well screen might be used for the effective radius of the well. Actually, a more practical line of attack is to assume that conditions are as indicated in Fig. 1(*c*) and then to devise a method of determining the well loss that is independent of the effective well radius, which is to be determined last. The theory of such a method is outlined in the following section.

Theory of Multiple-Step Drawdown Test to Determine Well Loss and Effective Well Radius

Eq. 13*b* gives the drawdown in an artesian well with an appreciable well loss. It applies to a single drawdown period preceded by a period during which the well is idle. By modifying the second term of the right-hand member, Eq. 13*b* may be made to apply to increments of drawdown occurring in successive periods, at the beginning of each of which the discharge is increased abruptly.

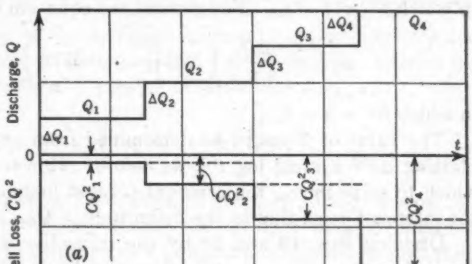

Fig. 6.—Variation of Discharge, Drawdown, and Well Loss in Multiple-Step Drawdown Test

Fig. 6 depicts the progressive lowering of head in a multiple-step drawdown test. Two sets of drawdown curves are shown: The light lines in Fig. 6(*b*) show the draw-down that would occur during the successive periods of the test if there were no well loss; and the heavy lines, to which the notations refer, include the well losses, $C\,Q^2$, values of which are indicated in Fig. 6(*a*).

At time $t = t_0$ if the well (which theretofore has been idle) is started pumping at a rate $Q_1 = \Delta Q_1$, the drawdown at any time t thereafter is given by

$$\Delta s' = \frac{\Delta Q_1}{4\,\pi\,T}\left(\log_e \frac{t'}{t^*_w} - 0.5772\right) + C\,Q^2_1 \ldots\ldots\ldots\ldots (19a)$$

in which $t' = t - t_0$. If at some later time t_1 the discharge is increased by an amount ΔQ_2 to a new rate Q_2, the second increment of drawdown obeys the relation,

$$\Delta s'' = \frac{\Delta Q_2}{4\pi T}\left(\log_e \frac{t''}{t^*_w} - 0.5772\right) + C\,(Q^2_2 - Q^2_1) \quad \text{(19b)}$$

with $t'' = t - t_1$.

Similarly, the third increment of drawdown beginning at time t_2 obeys the relation,

$$\Delta s''' = \frac{\Delta Q_3}{4\pi T}\left(\log_e \frac{t'''}{t^*_w} - 0.5772\right) + C\,(Q^2_3 - Q^2_2) \quad \text{(19c)}$$

n which $t''' = t - t_2$. The generalized equation of this progression is

$$\Delta s^{(i)} = \frac{\Delta Q_i}{4\pi T}\left(\log_e \frac{t^{(i)}}{t^*_w} - 0.5772\right) + C\,(Q^2_i - Q^2_{i-1}) \quad \text{(20)}$$

in which $t^{(i)} = t - t_{i-1}$.

The value of T might be determined from any one of these equations by plotting $\Delta s^{(i)}$ against $\log_e t^{(i)}$, as before. However, to determine $r^2_w S$, from which to solve for r_w, the constant C must first be found, as this factor shifts the intercept according to the magnitude of Q_{i-1} and Q_i.

Dividing Eqs. 19 and 20 by the respective increments of discharge, and fixing $t' = t'' = t''' \cdots = t^{(i)}$, after simplifying the differences in squares of values of discharge:

$$\left.\begin{aligned}
\frac{\Delta s'}{\Delta Q_1} &= B + C\,\Delta Q_1 \\
\frac{\Delta s''}{\Delta Q_2} &= B + C\,(2\,Q_1 + \Delta Q_2) \\
\frac{\Delta s'''}{\Delta Q_3} &= B + C\,(2\,Q_2 + \Delta Q_3) \\
&\cdots\cdots \\
\frac{\Delta s^{(i)}}{\Delta Q_i} &= B + C\,(2\,Q_{i-1} + \Delta Q_i)
\end{aligned}\right\} \quad \text{(21)}$$

Taking the differences between successive pairs of equations,

$$\left.\begin{aligned}
\frac{\Delta s''}{\Delta Q_2} - \frac{\Delta s'}{\Delta Q_1} &= C\,(\Delta Q_1 + \Delta Q_2) \\
\frac{\Delta s'''}{\Delta Q_3} - \frac{\Delta s''}{\Delta Q_2} &= C\,(\Delta Q_2 + \Delta Q_3) \\
&\cdots\cdots \\
\frac{\Delta s^{(i)}}{\Delta Q_i} - \frac{\Delta s^{(i-1)}}{\Delta Q_{i-1}} &= C\,(\Delta Q_{i-1} + \Delta Q_i)
\end{aligned}\right\} \quad \text{(22)}$$

Considering $\log t$ to be variable, Eqs. 21 are the equations of a series of parallel straight lines whose spacings are given by Eqs. 22. Just as the ratio of discharge to drawdown is termed "specific capacity," the ratio of drawdown

to discharge may be termed "specific drawdown." Similarly, the ratio of an increment of drawdown to the increment of discharge producing it may be termed "specific incremental drawdown." Eqs. 21, then, give the specific incremental drawdown as a function of time, the factor B increasing with time while the factor C remains constant.

The factor C may be determined from any one of Eqs. 22. Then, knowing C, there may be determined the difference:

$$\frac{\Delta s'}{\Delta Q_1} - \frac{\Delta s^\circ}{\Delta Q_0} = C\,(\Delta Q_0 + \Delta Q_1) \qquad (23)$$

In Eq. 23, $\frac{\Delta s^\circ}{\Delta Q_0}$ is an abbreviation for the limiting value that the specific incremental drawdown approaches as the discharge increment approaches zero and as the well loss consequently becomes negligible. Subtracting Eq. 23 from the first of Eqs. 21, recalling Eq. 14, and keeping in mind that $\Delta Q_0 \rightarrow 0$:

$$\frac{\Delta s^\circ}{\Delta Q_0} = B = \frac{1}{4\,\pi\,T}\left(\log_e \frac{t}{t^*_w} - 0.5772\right) \qquad (24)$$

If the values of specific incremental drawdown given by Eqs. 21 are plotted against $\log t$, as suggested previously a series of straight lines is obtained. Eq. 24 can be plotted on the same graph as a straight line parallel to the others and spaced with reference to the first of the other straight lines in accordance with Eq. 23. Inasmuch as the C-term is lacking in Eq. 24, that equation simply expresses the component of drawdown that occurs in the formation. From its intercept with the zero-drawdown line, then, the effective radius of the pumping well may be determined by the following modification of Eq. 17:

$$r^2_w = 2.25\,\frac{T\,t}{S} \qquad (25)$$

In Eq. 25, S can be determined from observations in a near-by observation well at a known distance r, as shown in Fig. 4.

Data from Multiple-Step Drawdown Test

Figs. 7 and 8 give data from a multiple-step drawdown test run in August, 1943, at Bethpage, Long Island, N. Y. The well that was tested was gravel packed and had 50 ft of 8-in. screen with a No. 60 slot, and with bottom at 350 ft. It was equipped with a 1,200 gal per min deep-well turbine pump. The flow was metered with a propeller-type meter in the discharge line. Water levels inside the casing were measured by an air line with a pressure-gage reading in pounds per square inch. During the first period of the test, measurements of depth to water were made with a weighted steel tape. Thereafter it was not possible to lower the tape to the water surface.

This test had four periods of approximately one hour's duration each. By timing the dial on the nonrecording flow meter with a stop watch, it was possible to secure virtually instantaneous readings of the discharge. Actually, the pumping rate declined slightly during each period of the test as the constant-

speed pump adjusted itself to the lowering water level in accordance with the head-discharge characteristic. As these variations were slight, only the average discharge for each period is shown in Fig. 7. Readings of the air-line pressure gage (converted) are indicated by ×'s. The circles plotted one hour after the beginning of each period are interpolated points that are carried over to the discharge-drawdown diagram (Fig. 7(*c*)). Curve A, drawn through these points, is the type of curve ordinarily obtained, drawdown readings being taken only at the end of each period of the test. Customarily, the specific capacity is determined from an average secant of curve A passing through the origin.

Values of drawdown increments taken from Fig. 7(*b*), divided by corresponding increments of discharge, are plotted in Fig. 8 against appropriate values of

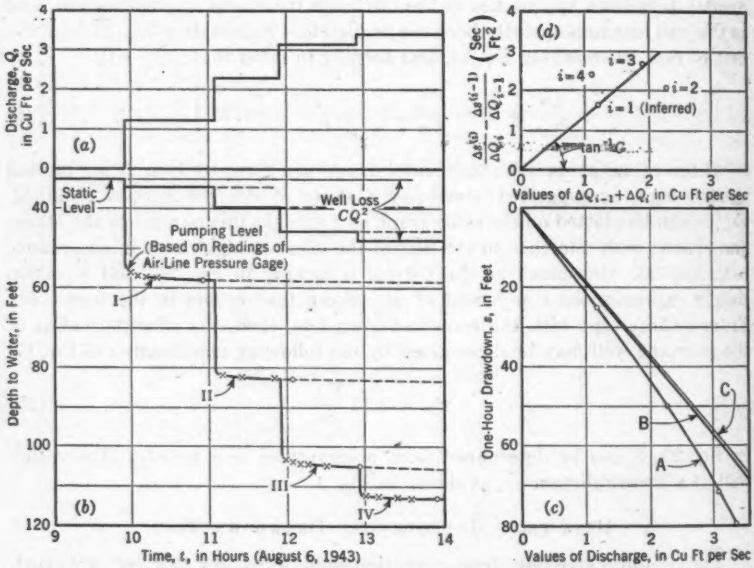

FIG. 7.—DETERMINATION OF WELL LOSS WHEN EFFECTIVE WELL RADIUS IS NOT KNOWN

time on a logarithmic scale. Using the tape readings during the first period as a guide, the slope of the several lines (which theoretically are parallel) is determined. The spacing of the lines in units of feet per cubic feet per second is given in the first column of the tabulation in Fig. 8. Also tabulated are the numbers of the periods, the discharge during each period, the increment of discharge at the beginning of each period, and the sums of neighboring increments of discharge. In accordance with Eqs. 22, data in the first and last columns of this tabulation are plotted in Fig. 7(*d*) to determine C. The three experimental points, for $i = 2$, 3, and 4, show considerable scattering, partly

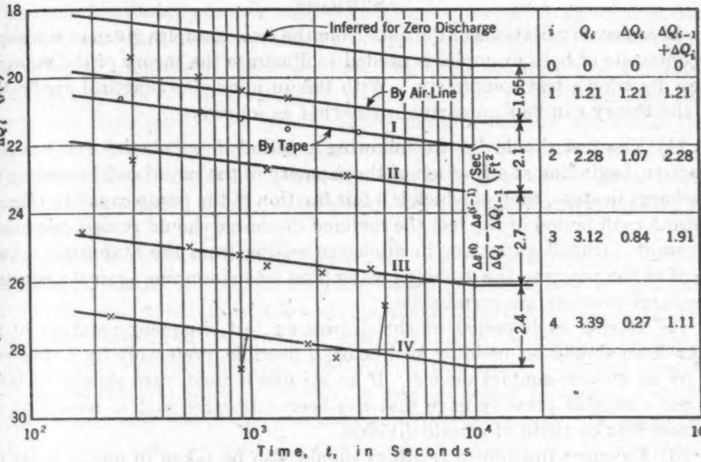

FIG. 8.—SEMILOGARITHMIC GRAPH OF DATA FROM FIG. 7(b)

perhaps because of the insufficiency of the theory but more likely because of inaccuracies of the air-line pressure-gage readings. From the slope of the straight line drawn through the center of mass of the three points, C is found to be $1.35 \left(\frac{\text{sec}^2}{\text{ft}^5}\right)$.

Knowing C, the amount of well loss during each period of the test may now be determined. For the fourth period of the test, when the discharge was 3.39 cu ft per sec (1,520 gal per min), the well loss is computed as 15.5 ft. During the earlier periods of the test, when the discharge was smaller, the well loss was correspondingly smaller, as indicated in Fig. 7(a). Subtracting the appropriate value of well loss from each point plotted in Fig. 7(c), curve B is obtained. This curve then represents the discharge-drawdown relation for zero well loss. The straight line C (Fig. 7(c)) represents the relation between discharge and drawdown that would be obtained with zero well loss if separate one-hour tests were run at each rate, starting from rest with long intermediate periods of shutdown.

Theoretically, it should be possible to determine the transmissibility of the bed from the slope of the straight lines in Fig. 8; but the situation is complicated somewhat by the lenticular structure of the material penetrated by the well. Although the sand within a few hundred feet of the well is definitely confined, at greater distances it is effectively although somewhat circuitously interconnected with overlying beds of sand. If the setup were more nearly ideal and if there were a near-by observation well from which to determine the value of S, the effective radius of the pumping well might be determined.

Summary

Because of limitations of the data from the two examples given in the paper, a composite of both examples is needed to illustrate the theory of the multiple-step drawdown test completely. With this in mind, the practical application of the theory can be summarized somewhat as follows:

(1) The test should be run following a period in which the well has been inactive, beginning at a fraction of the capacity of the pump and increasing the discharge in steps, each of which is a fair fraction of the pump capacity (Fig. 7). During each period of the test the metered discharge should remain essentially constant. (Small variations in discharge arising from the automatic adjustment of the pump to the declining water level when pumping against a constant discharge pressure are permissible.)

(2) During each period of the drawdown test, frequent readings of the drawdown should be made by air line or, if possible, preferably by a steel tape or by an electric-contact device. If an air line is used, care should be taken to use a reliable pressure gage that has been calibrated and to read it to the nearest fifth or tenth of a scale division.

(3) Frequent drawdown readings should also be taken in one or more observation wells tapping the same sand. If the screen of the pumping well does not completely penetrate the sand, the nearest observation well for this purpose should not be closer than about twice the sand thickness from the pumping well.

(4) Plot the data obtained under item (3) on a semilogarithmic graph (Fig. 4), using increments of drawdown against logarithm of time. Determine the transmissibility from the slope of the straight lines and the storage coefficient from their average intercept.

(5) Plot the data obtained under items (1) and (2) on rectangular coordinates (Figs. 7(a) and 7(b)). Extrapolate the drawdown curve for each period through the following period to determine the increments of drawdown.

(6) Plot values of specific incremental drawdown against the logarithm of time on semilogarithmic paper (Fig. 8). Draw parallel straight lines through the plotted points. (Extensions of these straight lines should check the extrapolations on the other graph. Secondary adjustments may be made to improve the extrapolations.)

(7) Plot differences of specific incremental drawdown given by neighboring lines against the sum of neighboring discharge increments (Fig. 7(d)). Determine C from the slope of the straight line through the origin and through the center of mass of the plotted data.

(8) Compute the well loss for each period of the test from $C\,Q^2$.

(9) Infer the limiting straight-line relation for zero discharge (Fig. 8) and from its intercept with the zero-drawdown line, using the value of storage coefficient determined under item (4), compute the effective radius of the well.

If the storage coefficient and transmissibility of the bed and the effective radius of the well are determined, it is possible to compute the resistance, B, at any time. Knowing the factor C, it is possible to compute the well loss. Combining the two, the total drawdown in the pumping well may be determined for any time and for any pumping rate.

In extensive artesian aquifers such predictions of drawdown are often trustworthy for periods of several months or a few years, but longer-term predictions must be based upon further consideration and closer evaluation of the outer "boundary conditions" of the aquifer. In local artesian beds this type of analysis may be required even for short-term predictions. In either case the concepts and procedures advanced in this paper should constitute useful implements, although not displacing in any way that knowledge of the geology and hydrology of an aquifer that is so necessary for a complete understanding of its performance.

The procedure itemized in this "Summary" should make possible, at any time during the life of a well, the accurate determination of both components of its specific drawdown, thus, for example, facilitating the recognition of the effects of encrustation of the screen or sand packing of the gravel wall, which too often have been ascribed to "depletion of the sand." Furthermore, it should enable the evaluation of the effectiveness of gravel packing and of the various development operations practiced in well construction. Through the accumulation of data, as wells are developed and placed in operation, this procedure should greatly aid in the selection of the proper gravel size and the appropriate screen opening so that the efficiency of wells will be increased and much needless waste of pumping energy will be prevented. Similarly, where the gravel wall is not called for, unnecessary expenditures for this type of construction may be avoided by referring to cases that have been tested under similar circumstances. Through predictions of the trend of pumping levels with time, proper selection of the pump and motor may be made that will give optimum performance throughout the life of the well, thus avoiding the wasteful practice of operating a pump with its discharge throttled to keep within the limits set by the diminishing capacity of the well.

The decline in production of oil wells is perhaps even more troublesome than that in the production of water wells. Often, it is difficult to determine whether the decline is due merely to depletion of the reservoir or whether it is due to the plugging of the perforations in the "liner," to the transportation of the fines, to the deposition of asphaltic substances, or to other causes. With some modifications the procedure outlined in this paper can be applied to oil wells as an aid in answering such questions. However, more accurate determinations of fluid level would be required than are now generally feasible while pumping steadily at different rates of production.

Acknowledgment

The writer wishes to express his appreciation of their helpfulness to O. E. Meinzer, chief of the Ground-Water Division, Water Resources Branch, United States Geological Survey, and to M. L. Brashears, Jr., district geologist, in charge of ground-water investigations in New York and New England, under whose direction he worked during the development of this paper.

APPENDIX. NOTATION

The following letter symbols conform essentially with American Standard Letter Symbols for Hydraulics (ASA—Z10.2—1942) and with ASCE *Manual of Engineering Practice No. 22* on "Soil Mechanics Nomenclature":

B = "hydraulic resistance" of formation, head loss per unit discharge;
b = thickness of confined sand bed;
C = coefficient in term $C\,Q^2$ expressing "well loss," a component of drawdown, the other term of which is $B\,Q$;
k = transmission constant, or "coefficient of permeability";
n = porosity of sand;
Q = discharge of well;
ΔQ_i = increment of discharge; $i = 1, 2, 3, \cdots$;
r = radial distance from axis of well;
r_w = "effective radius" of well;
S = "coefficient of storage" = $(b/V)(dV_w/ds)$;
s = drawdown at distance r, the difference between initial head and head at time t at that distance;
s_w = drawdown at r_w, according to theoretical logarithmic distribution;
$\Delta s^{(i)}$ = increment of drawdown produced by ΔQ_i;
$\Delta s^{(i)}/\Delta Q_i$ = "specific incremental drawdown" during i^{th} period of test;
$\Delta s^\circ/\Delta Q_0$ = limiting value of specific incremental drawdown for discharge approaching zero ($= B$);
T = "transmissibility" of sand bed = $k\,b$;
t = time;
t^* = "inflectional time" = $r^2\,S/4\,T$;
u = $r^2\,S/4\,T\,t = t^*/t$, a nondimensional variable;
V = volume;
V_w = volume of water;
$W(u)$ = "well function" of u, or the negative "exponential integral" of $-u$, for which tables are available;
α = "compressibility" of solid skeleton of sand bed, relative decrease in thickness per unit increase of vertical component of compressive stress in sand bed;
β = compressibility of water in sand bed;
β' = apparent compressibility of water = $\beta + \alpha/n$; and
γ = specific weight of water.

DISCUSSION

N. S. BOULTON,[11] ESQ.—The importance of carefully recording both the small variations in pumping level, which may occur during pumping tests at constant discharge, and the duration of the test, are appropriately stressed in this paper. From such information it is possible to predict, as the author has shown, the probable steady decline in specific capacity "for periods of several months or a few years" when the well is pumped at constant discharge. It is important to remember, however, that the accuracy of this prediction depends essentially on the assumption that the compressibility of the aquifer (which enters into the coefficient of storage) has the same value for the very small pressure releases which occur at large distances from the pumped well as for the comparatively large pressure releases near to the well. It would be appreciated if the author could present evidence in support of this assumption, based on long-period observations of declining well levels. In addition, it would be interesting to know whether the author has been able to check the values for "well loss" by direct estimates of the pipe friction loss as the water flows inside the well casing and also of the loss of head due to the screen.

For the fourth period of the test at Bethpage, Long Island, N. Y., the depth of water in the well was apparently about 238 ft. Allowing for the water entering the well uniformly along the bottom 50 ft, a reasonable estimate (from a usual formula) for the head lost in pipe friction in the 8-in.-diameter tube is about 10.5 ft, including 1.5 ft for the velocity head. The computed well loss (see heading, "Data from Multiple-Step Drawdown Test") is stated to be 15.5 ft, which leaves 5 ft for the loss due to the screen. It is easy to calculate the latter loss on the assumption of flow through a uniform permeable medium outside the screen to which Darcy's law may be applied. Thus, for long vertical slots spaced equally around the circumference of the well, it can be shown from the potential solution for the flow net that the head loss due to the restricted inlet area provided by a slotted tube is closely given by:

$$h = \frac{Q}{2\,\pi\,N\,b\,k} \log_e \left(\frac{2}{1 - \cos \nu\,\pi}\right) \qquad (26)$$

in which N is the number of vertical slots around the circumference of the tube; and ν is the slot-width ratio or width of slot divided by the distance between the centers of two adjacent slots.

According to Eq. 26, the head loss is proportional to the discharge and, for a given slot-width ratio, inversely proportional to the number of slots.

If $Q = 3.39$ cu ft per sec and $b = 50$ ft, as in the fourth period of the Bethpage test, and if $k = 0.004$ ft per sec (as deduced from Fig. 8), assuming $\nu = \frac{1}{4}$ (since the dimensions of the slotted tubing are not given in the paper), it is found on substitution in Eq. 26 that $h = 5.2/N$ ft. For one hundred slots, each 0.063 in. wide, uniformly spaced around the circumference, $h = 0.052$ ft which is negligible. On the other hand, if the slots are arranged in batteries

[11] Lecturer in Chg., Dept. of Civ. Eng., Univ. of Sheffield, Sheffield, England.

numbering, say, ten in the circumference, the batteries being 0.5 in. wide with 2 in. between them, $h = 0.52$ ft which is still small.

It should be emphasized that this calculation makes no allowance for any clogging of the slots. Such clogging may account for the discrepancy between the small calculated screen loss and the value of 5 ft deduced from the test result.

CARL ROHWER,[12] M. ASCE.—The serious depletion of ground-water supplies in many areas during World War II has focused attention on the problems of ground-water hydrology. In this connection the investigations of the engineers of the Water Resources Branch of the U. S. Geological Survey are adding important information regarding the characteristics of wells and the capacity of ground-water formations. The analysis of drawdown tests of artesian wells by the author is a valuable contribution to this subject.

The writer is in agreement with the objectives of the author's investigations but he is of the opinion that the analysis of the problem would have been simplified if some of the factors that have only a slight effect on the results had been ignored. Under most conditions met with in the field of engineering the compressibility of water can be ignored. The coefficient is approximately 4×10^{-6} per pound pressure at ordinary temperatures and pressures. A reduction in pressure of 10 lb per sq in. would increase the volume of 1 cu ft of water by only 0.00004 cu ft, a difference of 1 in 25,000. In view of the large unavoidable errors involved in other measurements it seems that this factor could well be neglected. The same may be stated of the compression of the aquifer. As indicated by the author (see heading, "Application of Theory to a Simple Drawdown Test"), the combined effect of compressibility of the water-bearing formation is only five times the actual compressibility of water. Consequently, the combination of these two factors would produce a change of only 1 in 5,000 for a drop in pressure of 10 lb (approximately 23 ft). If the change in pressure were increased to 100 ft the effect produced by the compressibility of the water and aquifer would not be significant.

In reference to the tests on a shallow well at Meadville, Pa., the author states in the sentences following Eq. 18, that:

> "The foregoing calculations indicate that $B\,Q$ in this case was about 19.5 ft after 24 hours of continuous pumping. The observed drawdown in the pumping well at that time was 48.0 ft, leaving 28.5 ft for the well loss."

Such a large well loss seems unusual for an inflow of 1,350 gal per min through 15 ft of 18-in. screen unless the screen were badly encrusted or improperly perforated. Immediate steps should be taken to improve the performance of the screen in this well.

In the solution of problems involving many variables of which only a few can be determined by direct measurement, the use of multiple equations provides a method of determining the unknowns. However, there are difficulties inherent in this method which may lead to contradictory or inconsistent results.

---

[12] Senior Irrig. Engr., Div. of Irrig., Soil Conservation Service, U. S. Dept. of Agriculture, Fort Collins, Colo.

As shown by the author in reference to the determination of C (see heading, "Data from Multiple-Step Drawdown Test"), there is considerable scattering in the values obtained for the "specific incremental drawdown," Fig. 7(d). No doubt, this is due in part to the inaccuracies in the drawdown readings. If this method were used on problems in which all readings could be made accurately, consistent results should be expected. Since this is not generally true, the multiple-equation method results in solutions in which the final answers may have errors greatly in excess of the observed data. The writer is not aware of the mathematical basis for this assumption, but he observed the same effect when attempting to use a similar method to determine the values of the factors involved in the seepage from canals. The conclusion was reached that, in the elimination of variables from the series of equations by subtraction, the variables eliminated were forced to conform exactly to the law; and, as a result, all the discrepancies accumulated and finally appeared in the solution of the unknown. A solution based on another pair of equations may, therefore, yield a result widely different from the first one.

Since the author has had the opportunity to observe how the solutions vary when he uses different equations it would be of interest to study the mathematical principles causing the variations. No doubt rules could be formulated which would make it possible to obtain more consistent results from the observed data. Such an analysis would be useful in the solution of problems in other fields of engineering.

R. M. Leggette,[13] Affiliate, ASCE—Although it covers a highly technical subject, this paper clearly demonstrates the practical importance of a number of factors of well design. It seems desirable to emphasize these practical considerations because they are often given too little attention. Frequently water works men and well-drilling contractors greatly belittle or fail to recognize the magnitude of what Mr. Jacob calls "well loss."

It is obvious, of course, that the water level in a pumping well must be lower than the water level immediately outside the well. In many wells, much of this difference in head is screen friction loss which results from the use of a poorly designed screen. This difference in head is sometimes presumed to be only a few inches, or a fraction of a foot; however, actual observations have shown that in some wells the well loss is a considerable part of the total drawdown. Thus, from the point of view of economy of operation, well loss may be an important factor.

The paper also indicates the desirability of increasing the effective radius of a "sand and gravel" well by development to remove the fine material surrounding the screen, or by artificial gravel packing. It should be noted that the advantages of development or gravel packing may be largely overcome if an inefficient well screen is used.

The process of development by surging, swabbing, and brushing is being used more and more in uncased wells (rock wells), the walls of which apparently become "mudded up" during the drilling process. This clogging of the uncased wall of the well has the same effect as an inefficient well screen in a "sand

[13] Cons. Ground-Water Geologist, New York, N. Y.

data as those presented in the paper. Whereas from a theoretical standpoint, with ideal data, the procedure outlined in the paper is sound; in practice it needs modification. Higher precision of measurement may warrant the assumption that the drawdown obeys the law $s_w = B\,Q + C\,Q^n$, introducing a third unknown, the exponent n (<2), to be determined by trial-and-error computation, or by graphical procedure together with the coefficients B and C.

An important point is raised by Mr. Leggette—that the advantages of gravel packing or developing a well may be offset by poor design or improper choice of screen. The writer feels that amassing empirical values of C and of r_w, together with pertinent data on the details of design and construction of wells, may eventually make possible the accurate appraisal of these various factors. The selection of screen type, slot opening, and gravel size—and even the determination of whether or not a gravel envelope is required—may be lifted from the realm of guesswork to a rational plane through the future study of existing and newly constructed wells and through the measurement of their characteristics of performance, due consideration being given to the transient behavior of the aquifer.

In emphasizing the magnitude of well losses, condemnation of the well driller is not intended, for much of the friction loss in and near a well is unavoidable and will never be entirely eliminated. Nevertheless, it behooves the engineer and the well-drilling contractor alike to strive for as efficient design and construction as possible to meet the stringencies of economic demands. The points summarized by Mr. Leggette thus are objectives toward which progress should be made.

Mr. Lewis suggests that similar analyses be made for unconfined flow under simple water-table conditions, and for confined flow in which recharge from the soil surface occurs through a relatively impermeable confining bed. To the writer's knowledge a satisfactory analysis of nonsteady unconfined flow has not been given. Even in the case where the storage coefficient (S, ultimately approaching "specific yield") is constant, there are insuperable difficulties. Only by analogy to confined flow, and then in cases where the maximum drawdown is but a small fraction of the initial depth of flow, has an approximate solution been obtained. It may be stated, however, that even in the absence of well losses the specific capacity of a water-table well would vary with the discharge, the curve of drawdown versus discharge at constant time being a parabola under certain approximative assumptions. Further work should be done on this problem, both in the laboratory and in the field.

A solution has been given for the nonsteady radial flow toward a steadily discharging well in a leaky confined aquifer.[16] The leakage is assumed proportional to the drawdown. Whether this is exactly the condition Mr. Lewis has in mind is not known, but in the early phase of a transient state such a system acts like an ideal elastic aquifer without leakage. Accordingly, a short multiple-step drawdown test could be analyzed under those conditions on the basis of the elastic theory, although long-term predictions would consider the leakage.

Paper No. 2322

RIGID-FRAME STRUCTURES SUBJECT TO NONUNIFORM THERMAL ACTION

By Carl C. H. Tommerup,[1] Assoc. M. ASCE

With Discussion by Messrs. I. Oesterblom, Frank R. Higley, A. L. Miller, Charles O. Boynton, William A. Conwell, and Carl C. H. Tommerup.

Synopsis

The purpose of this paper is to clarify the problem of determining stresses and strains at any point in rigid frames whose members are subject to a nonuniform temperature differential; that is, structural members in which the temperature on one face is different from that on the other face. Many engineers are unaware of the exceedingly high stresses created by this quite common loading condition. The paper develops a rational setup which is of general scope since it is applicable to any type of framework.

This paper is divided into five parts, of which Sections 2, 3, and 4 contain the complete thermal analyses of three basic types of frames.

1. Introduction

Thermal stress analysis is of considerable importance in many branches of the metal industry in connection with castings, structural frames, etc., as well as in the field of such reinforced-concrete structures as flues, flue portals in plinths of stack foundations, hot liquid flumes, foundations for boilers, oil refinery furnaces, and blast furnaces.

Although it is generally recognized that reinforced concrete is far from being an ideal material in structures that are subject to high nonuniform temperature changes, it is continually used under these circumstances with reasonable success. The main reason for this is undoubtedly the fact that no other material is so readily applied to a variety of structures. It is equally well known, however, that a reinforced-concrete structure built in the shape of a rigid frame (a closed ring, for example), and then heated to a fairly high degree from within, is certain to develop a number of noticeable fractures along all outside edges. These fractures, which are caused entirely by thermal action,

Note.—Published in June, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Chf. Structural Engr., John Graham, Archts. and Engrs., Seattle, Wash.

vary in width with the depth of the frame member; that is, a deep frame member produces a wider fracture than a shallow member produces. In some instances such fractures do not impair the efficiency of the frame and may safely be neglected; yet, in many cases, the formation of fractures is an indication that the structure in question should have been designed along entirely different lines.

As stated in the "Synopsis," this paper analyzes thermal stresses in three distinct types of frames. The frames chosen are reinforced-concrete foundations for boilers and oil refinery furnaces. The analyses, of course, are equally applicable to frames of any other shape and built of any material or combination of materials. For simplicity, the frames are symmetrical and their members are of constant cross section from joint to joint. If the cross sections of the members vary, the amount of computation is naturally increased but the basic principles remain the same. No loading other than that produced by nonuniform thermal action is treated. Because of the greater ease, member lengths, as a rule, are taken along their inside surfaces. In order to gain knowledge as

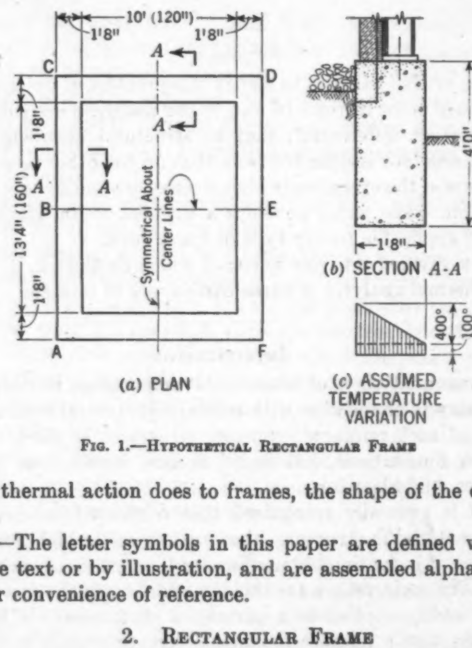

FIG. 1.—HYPOTHETICAL RECTANGULAR FRAME

to just what thermal action does to frames, the shape of the elastic curves is determined.

Notation.—The letter symbols in this paper are defined where they first appear, in the text or by illustration, and are assembled alphabetically in the Appendix, for convenience of reference.

2. RECTANGULAR FRAME

A plan view of the simple rectangular frame to be analyzed first is shown in Fig. 1. Fig. 1(*b*) is an enlarged typical cross section through any frame member, showing the lower part as a reinforced-concrete foundation wall, 4 ft high by 1.67 ft thick. Superimposed on this wall is the furnace wall proper with its columns, buckstays, steel casing, insulation, and refractory lining.

The furnace floor, which is formed by broken firebrick laid directly on the elevated soil, is at the left. The upper part of the foundation wall is protected from the intense heat, to some extent, by a cast-in-place refractory facing of high insulating value. Heat is transmitted from the furnace floor through the soil to the inside face of the foundation wall. The right-hand side of Fig. 1(*b*) is exposed to the atmosphere and indicates the outside grade level as being approximately at the midheight of the foundation wall. The assumed temperature variation is illustrated in Fig. 1(*c*). The inside wall face is at 500°, and the outside face at 100°, leaving a temperature differential of 400°.

Assume now that the frame is cut at each of its corners and that the temperature differential is subsequently applied. This will cause each of the four separate beams to bow inward since their inside faces have received an increase in length, whereas the length of their outside faces remains unchanged. The amount of bow, curvature, etc., is obtained from Fig. 2 which shows the right-hand half of wall FD. With the temperature differential of 400° and with a

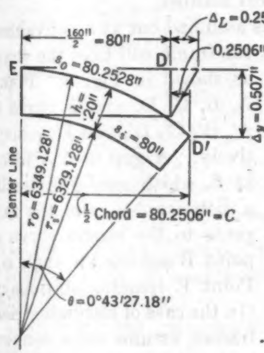

FIG. 2

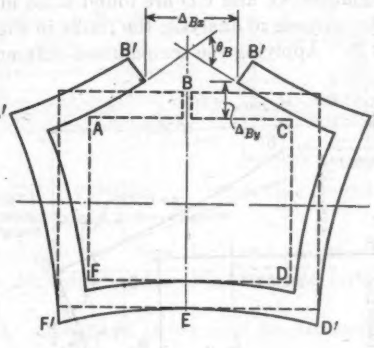

FIG. 3

coefficient of expansion equal to 0.0000079 in. per in. per degree, the wall length ED receives an increase in length of $\Delta_L = 0.0000079 \times 400° \times 80$ in. $= 0.2528$ in. and point D moves to point D′, Fig. 2.

The expressions for the lengths of arc s_o and s_i can be written:

$$s_o = \frac{\pi r_o \theta}{180} \qquad (1a)$$

and

$$s_i = \frac{\pi r_i \theta}{180} \qquad (1b)$$

The measure of the difference between the inner and outer arc lengths is Δ_L, Fig. 2, or

$$\Delta_L = s_o - s_i = \frac{\pi \theta}{180}(r_o - r_i) \qquad (2)$$

Since $r_o - r_i = h$ (Fig. 2), $\Delta_L = \frac{\pi\,\theta\,h}{180}$, or, in degrees:

$$\theta = \frac{180\,\Delta_L}{\pi\,h} \qquad (3)$$

Substituting numerical values in Eq. 3, $\theta = 0.724219° = 0°\,43'\,27.18''$. By Eq. 1a, $r_o = \frac{180\,s_o}{\pi\,\theta} = 6{,}349.128$ in. The vertical deflection Δ_y equals:

$$\Delta_y = 2\,r_o \sin^2 \tfrac{1}{2}\,\theta \qquad (4)$$

from which, by proper substitution, $\Delta_y = 0.507$ in. Similarly, half the chord length C is equal to

$$C = r_o \sin\theta \qquad (5)$$

or $C = 80.2506$ in. (see Fig. 2).

The various values found, by Eqs. 1 to 5, for the length ED also apply to lengths FE, AB, and BC, Fig. 1(a), by symmetry. The corresponding values for members AF and CD are found in an identical manner.

For purpose of analysis, the frame in Fig. 1 is assumed cut at a convenient point B. Applying the temperature differential, the frame will take the shape as shown in Fig. 3. Points A, B, C, D, and F move to A′, B′, C′, D′, and F′, respectively. A gap of Δ_{Bx} forms at B, which moves vertically a distance Δ_{By}, and the tangents to the elastic curve at point B assume an angle ϕ_B. Point E remains stationary. (In the case of unsymmetrical frames, assume some convenient point as being fixed in location and let the structure displace itself thermally in all directions from that one point. Should the temperature differential vary from joint to joint, displacement must be modified accordingly. If a member or a part of a member has no temperature differential, its elastic line in a displacement diagram remains unaltered.) The numerical values of all displacements are given in Fig. 4. The rotational displacement at point B is $\phi_B = 2(2\,\theta + \beta) = 5°\,04'\,10.28'' = 0.0884$ radian. The computations for the vertical and horizontal displacements are, respectively (see Fig. 4): $\Delta_{By} = (0.507 + 2.535 + 120.3482) - (0.507 + 120.0000) = 2.8832$; and $\Delta_{Bx} = 2\,(80.0000 + 0.2506 + 1.5220$

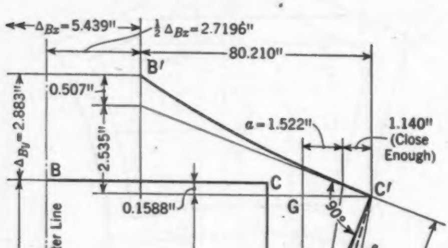

FIG. 4.—NUMERICAL VALUE OF DISPLACEMENTS

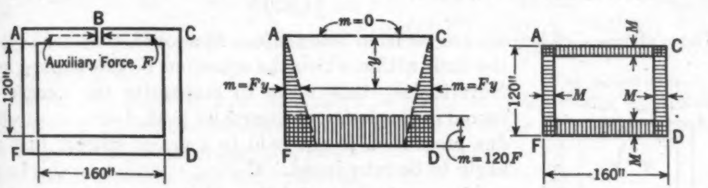
+ 1.1400 − 80.2100) = 5.4052. Various slight approximations have been made in computing these displacements.

The unknown thermal moments are solved for by the elastic energy theory[2] because of its universal application and the ease with which it lends itself to this type of problem. The effect of axial forces in frame members are neglected in the following computations unless otherwise noted. All four corner moments must be equal because both the frame and its loading are symmetrical about the same center lines. Since no external forces are acting between joints, the moment curve becomes a straight line from joint to joint. It follows, therefore, that neither shears nor axial forces are present. Any point of the frame is affected only by a moment that is of uniform magnitude all around. Each wall is reinforced by eight 1-in. round rods in the outside face, and four ½-in. rounds in the inside face. The moment of inertia of the wall, I, transformed into terms of concrete, is 14,230 in.^{4}; the corresponding area, A, is 1,060 sq in.; the modulus of elasticity E is assumed equal to 2,000,000 lb per sq in. (E



(a) AUXILIARY LOADING (b) AUXILIARY MOMENTS (c) ACTUAL MOMENTS

FIG. 5.—MOMENT CURVES, LINEAR DISPLACEMENTS

and I are constant throughout); and $n = 15$. Figs. 5(*a*) and 5(*b*) show the auxiliary loading, F, and moments M, respectively. Fig. 5(*c*) sets forth the actual, or M, moments.

Computing the unknown thermal moment M in terms of longitudinal displacement Δ_{Bx}:

$$F\,\Delta_{Bx} = \int_{B}^{B} \frac{m\,M\,ds}{E\,I} \quad\text{.....................}(6a)$$

or

$$E\,I\,\Delta_{Bx} = \int_{B}^{B} \frac{m\,M\,ds}{F} \quad\text{.....................}(6b)$$

Furthermore, $E\,I\,\Delta_{Bx} = \int_{A}^{F} \frac{F\,y\,M\,dy}{F} + \int_{C}^{D} \frac{F\,y\,M\,dy}{F} + \int_{A}^{C} \frac{0\,M\,dx}{F}$

$+ \int_{D}^{F} \frac{120\,F\,M\,dx}{F} = \int_{A}^{F} M\,dy \times \bar{y} + \int_{C}^{D} M\,dy \times \bar{y} + 120 \int_{D}^{F} M\,dx$; or

$$E\,I\,\Delta_{Bx} = (\text{area}) \times \bar{y}\,\Big]_{A}^{F} + (\text{area}) \times \bar{y}\,\Big]_{C}^{D} + 120 \times (\text{area})\,\Big]_{D}^{F} \quad\text{....}(7)$$

Substituting the numerical values: 2,000,000 × 14,230 × 5.439 = 2 × 120 M × 60 + 120 × 160 M; and M = 4,600,000 in.-lb (tension outside).

[2] "Elastic Energy Theory," by J. A. Van den Broek, 2d Ed., John Wiley & Sons, Inc., New York, N. Y., 1942.

That the moment produces tension in the outside face of the members is evident by reasoning as follows: If members were cut loose at corners, A, C, D, and F, the beams would, upon being heated along their inner faces, bow inwardly as shown in Figs. 2, 3, and 4, and their ends would form acute angles at the joints. However, the ends are compelled to remain at angles of 90° apart because of the rigidity of the system. This can be accomplished only by "negative" joint moments; that is, resisting moments that cause tension in the concave or outer faces.

The thermal moment of 4,600,000 in.-lb produces the following stresses:

Material	Computation	Stress (Lb Per Sq In.)
Tensile steel................	$\dfrac{4{,}600{,}000 \times 10.6 \text{ in.}}{14{,}230} \times 15$	51,300
Compressive steel..........	$\dfrac{4{,}600{,}000 \times 3.4 \text{ in.}}{14{,}230} \times 15$	16,500
Concrete.................	$\dfrac{4{,}600{,}000 \times 6.4 \text{ in.}}{14{,}230}$	2,070

These stresses, of course, are far from being safe. Moreover, they are beyond the limit within which the equations of this paper apply. Nevertheless, they serve to emphasize the danger incurred in the design of unequally heated structures when due precaution is not paid to thermal stresses that are likely to be introduced. Calling attention to this fact is the foremost purpose of the paper.

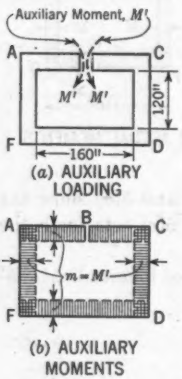


FIG. 6.—MOMENT CURVES, ANGULAR ROTATION

It is interesting to note that even if the temperature differential is as little as 200° F instead of 400° F the resulting moment (one half M) would still be of enormous magnitude considering the fact that stresses produced by it are in reality secondary stresses.

In case one is not interested in obtaining a complete picture of the linear displacements, the moment M may be more promptly arrived at through application of the angular rotation θ_B which is readily computed by Eq. 3. For this setup, Fig. 6 shows the auxiliary loading and moment diagrams, respectively. The actual or M-diagram is the same as previously indicated in Fig. 5(c).

With $\theta_B = 0.0884$ radian:

$$M' \, \theta_B = \int_B^B \frac{m \, M \, ds}{E \, I} \quad \text{.....................(8a)}$$

or

$$\theta_B = \frac{1}{E \, I} \int_B^B \frac{M' \, M \, ds}{M'} \quad \text{.....................(8b)}$$

and

$$E \, I \, \theta_B = \int_B^B M \, ds = (\text{area}) \Big]_B^B \quad \text{..................(9)}$$

Substituting the numerical values in Eq. 9: $2{,}000{,}000 \times 14{,}230 \times 0.0884 = M \, (2 \times 160 + 2 \times 120)$; which yields, $M = 4{,}500{,}000$ in.-lb. The small

discrepancy between this value and that of 4,600,000 in.-lb previously found is caused by the slight approximations made in computing displacements.

If the problem at hand concerns merely that of a simple frame, and assuming that the designer is desirous of ascertaining neither linear nor rotational displacements, the thermal moment may be determined quickly on the basis of the arch theory,[3] by the formula,

$$\text{Moment } M_t = \frac{\alpha\, \Delta t\, E \sum \frac{ds}{h}}{\sum \frac{ds}{I}} \quad \text{(10)}$$

in which: α = coefficient of thermal expansion; Δt = temperature differential; and ds = element of length along the arc of a member, measured along the gravity axis. Since the frame is symmetrical about both center lines, the elastic center coincides with the geometrical center of the structure and their results: $\sum \frac{ds}{h} = \frac{160}{20} \times 2 + \frac{120}{20} \times 2 = 28$; and $\sum \frac{ds}{I} = \frac{160}{14{,}230} \times 2 + \frac{120}{14{,}230} \times 2 = 0.0394$. The moment is: $M_t = \frac{0.0000079 \times 400 \times 2{,}000{,}000 \times 28}{0.0394} = 4{,}500{,}000$ in.-lb.

Having obtained the stresses created in the rectangular frame by a 400° temperature differential between inside and outside faces of frame members, the shape of the elastic curve, as it exists when frame comes to rest after thermal loading is applied, can be established.

Considering the four frame members as simple beams (cut at corners) and applying the temperature differential, they would deform as indicated in Fig. 7(*a*). The deflection Δ_{ml} at midpoint of long beams is $\frac{M\, l^2}{8\, E\, I} = \frac{4{,}500{,}000 \times 160^2}{8 \times 2{,}000{,}000 \times 14{,}230} = 0.507$ in. (see Fig. 2). The deflection Δ_{ms} at the midpoint of short beams is $\frac{4{,}500{,}000 \times 120^2}{8 \times 2{,}000{,}000 \times 14{,}230} = 0.285$. The deflections at the center of beams caused solely by the uniform restraining moments are shown in Fig. 7(*b*).

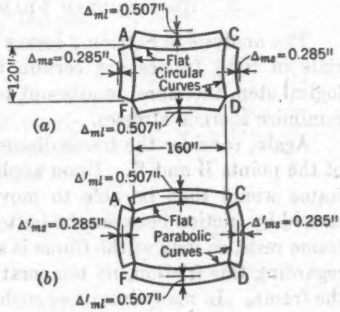

FIG. 7

The foregoing values of Δ_m reveal the interesting fact that when the members of a simple closed frame, of any shape, are subjected to a nonuniform temperature change through their "depth" (h) they undergo no deformation. As long as temperature change, depth, and moment of inertia remain constant for all members, the elastic curve remains a straight line throughout (in cases where frame members were originally straight) despite the fact that bending moments of enormous magnitude are created.

Various other facts of interest may be observed from Figs. 5(*c*) and 6. For example:

[3] "Reinforced Concrete and Masonry Structures," by George A. Hool and W. S. Kinne, McGraw-Hill Book Co., Inc., New York, N.Y., 1924, p. 477, Eq. 115.

(1) If frame members were doubled in length, the linear expansions Δ_L and Δ_s and angles θ, β, and ϕ_B would double in magnitude. Hence, the left-hand term of Eq. 9 would double; but so would the right-hand term since the moment area now has twice its former value. The result is that the moment of 4,500,000 in.-lb remains constant regardless of lengths of members so long as the ratio of lengths, temperatures, and depth of members are not changed. The foregoing facts might also have been deduced by considering Fig. 5. With the member lengths doubled, linear displacements Δ_{Bx} and Δ_{By} would become four times as great as shown. However, the right-hand side of Eq. 7 would also be increased to four times its former value, since both moment areas and their arms are doubled in magnitude.

(2) Assuming that instead of doubling member lengths, the thickness h is doubled. Eq. 3 shows that in this case angles θ, β, and ϕ_B would be halved. However, the moments of inertia of the members are now increased to eight times their original value (assuming that the proper percentage of steel reinforcement is added to the new section). Therefore, the net result is that the left-hand term of Eq. 9 becomes four $(= \frac{1}{2} \times 8)$ times as great as before. Since moment areas have not changed in size, the right-hand side of Eq. 9 remains unchanged. Consequently, doubling the wall thickness quadruples the moment.

If, as in the foregoing example, the walls are of equal cross section, the "ratio of lengths" mentioned in Section 1 is of no significance.

3. Rectangular Frame with Tie Rod and Hinges

The analysis in Section 2 serves to indicate that high temperature differentials in rigid frames are certain to create troublesome problems. It is a logical step, therefore, to attempt to make the frames less rigid in an effort to minimize thermal stresses.

Again, consider the frame discussed in Section 2 and place a hinge at each of the points B and E. Upon application of the temperature differential, the frame would then be able to move without any restraint other than that caused by friction between the bottom of the walls and the soil upon which the frame rests, so long as the frame is symmetrical about both center lines. Disregarding this friction, no temperature stresses whatever would be created in the frame. In many instances such hinges would serve well as an inexpensive expedient. In other cases the considerable increase of distance between points B and E, as well as the comparatively abrupt change in curvature at these points, would have a most unfavorable effect on the superimposed equipment such as structural framing and refractory walls. For this reason it is generally advantageous to introduce a fairly heavy, yet slender, tie member between points B and E, Fig. 1, as illustrated for point B in Fig. 8.

The setup for the frame shown in Fig. 1(a), with the addition of links at points B and E and a tie rod between these points, then becomes as shown in Fig. 9. It is assumed that the tie rod BE receives a temperature increase of 300° F through the soil. This causes the tie rod to elongate an amount 120 in. $\times$ 300° $\times$ 0.0000067 = 0.242 in.; and 80.2293 in. $\times \tan\frac{\beta}{2} = 80.2293 \times \tan$ (0° 32′ 35.39″) = 0.761 in.

Fig. 9 shows the deformation of one half of the frame without the restraining action of a tie rod. The change of span length between points B and E, that causes stress in the members, then is 122.914 − 120.242 = 2.672 in.; but

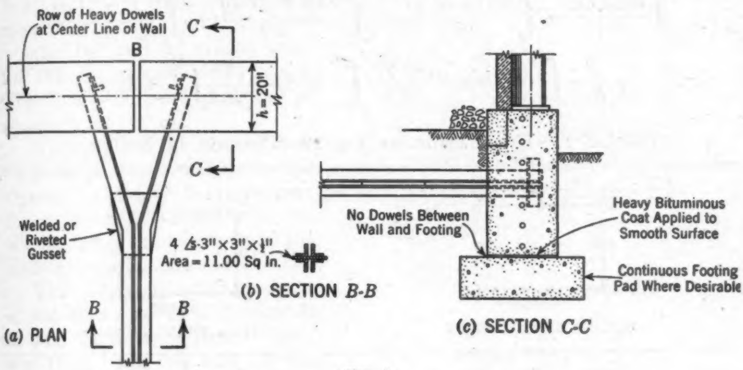

FIG. 8

the tie rod also elongates, due to its stress, an amount equal to $\frac{T_{BE}\,L}{A\,E}$, in which: T = the force sustained by the rod; and L = length of member. Hence, the displacement becomes $2.672 - \frac{T_{BE} \times 120}{5.50 \times 30{,}000{,}000}$.

For a slender tie rod, stored-up elastic energy of both axial forces and moments must be included in the elastic energy equation, which for one half of the complete frame reads:

$$\sum \frac{F\,T\,L}{A\,E} + \int \frac{m\,M\,ds}{E\,I}$$

$$= 2.672 - \frac{T_{BE} \times 120}{5.50 \times 30{,}000{,}000} \quad \ldots\ldots(11)$$

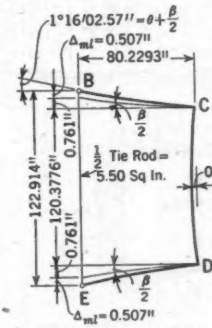

FIG. 9

The force in the tie rod is the only redundant. Once this force is known, the frame is statically determinate. Since one equation is all that is necessary for its solution, the solution of tie-rod force T_{BE} can be based upon the displacement, $2.672 - \frac{T_{BE} \times 120}{5.50 \times 30{,}000{,}000}$, of point E relative to point B.

The auxiliary and actual stress diagrams, respectively, for axial forces in the frame members are included in Table 1 which is used to evaluate the term,

$$\sum \frac{F\,T\,L}{A\,E} = +\,0.000000784 \times T' \times T_{BE} \ldots\ldots\ldots\ldots(12)$$

in which T' is an auxiliary tie-rod force. In order to evaluate the term

(1) If frame members were doubled in length, the linear expansions Δ_L and Δ_s and angles θ, β, and ϕ_B would double in magnitude. Hence, the left-hand term of Eq. 9 would double; but so would the right-hand term since the moment area now has twice its former value. The result is that the moment of 4,500,000 in.-lb remains constant regardless of lengths of members so long as the ratio of lengths, temperatures, and depth of members are not changed. The foregoing facts might also have been deduced by considering Fig. 5. With the member lengths doubled, linear displacements Δ_{B_x} and Δ_{B_y} would become four times as great as shown. However, the right-hand side of Eq. 7 would also be increased to four times its former value, since both moment areas and their arms are doubled in magnitude.

(2) Assuming that instead of doubling member lengths, the thickness h is doubled. Eq. 3 shows that in this case angles θ, β, and ϕ_B would be halved. However, the moments of inertia of the members are now increased to eight times their original value (assuming that the proper percentage of steel reinforcement is added to the new section). Therefore, the net result is that the left-hand term of Eq. 9 becomes four ($= \frac{1}{2} \times 8$) times as great as before. Since moment areas have not changed in size, the right-hand side of Eq. 9 remains unchanged. Consequently, doubling the wall thickness quadruples the moment.

If, as in the foregoing example, the walls are of equal cross section, the "ratio of lengths" mentioned in Section 1 is of no significance.

3. Rectangular Frame with Tie Rod and Hinges

The analysis in Section 2 serves to indicate that high temperature differentials in rigid frames are certain to create troublesome problems. It is a logical step, therefore, to attempt to make the frames less rigid in an effort to minimize thermal stresses.

Again, consider the frame discussed in Section 2 and place a hinge at each of the points B and E. Upon application of the temperature differential, the frame would then be able to move without any restraint other than that caused by friction between the bottom of the walls and the soil upon which the frame rests, so long as the frame is symmetrical about both center lines. Disregarding this friction, no temperature stresses whatever would be created in the frame. In many instances such hinges would serve well as an inexpensive expedient. In other cases the considerable increase of distance between points B and E, as well as the comparatively abrupt change in curvature at these points, would have a most unfavorable effect on the superimposed equipment such as structural framing and refractory walls. For this reason it is generally advantageous to introduce a fairly heavy, yet slender, tie member between points B and E, Fig. 1, as illustrated for point B in Fig. 8.

The setup for the frame shown in Fig. 1(*a*), with the addition of links at points B and E and a tie rod between these points, then becomes as shown in Fig. 9. It is assumed that the tie rod BE receives a temperature increase of 300° F through the soil. This causes the tie rod to elongate an amount 120 in. $\times$ 300° $\times$ 0.0000067 = 0.242 in.; and 80.2293 in. $\times \tan\frac{\beta}{2}$ = 80.2293 $\times$ tan (0° 32′ 35.39″) = 0.761 in.

Fig. 9 shows the deformation of one half of the frame without the restraining action of a tie rod. The change of span length between points B and E, that causes stress in the members, then is $122.914 - 120.242 = 2.672$ in.; but

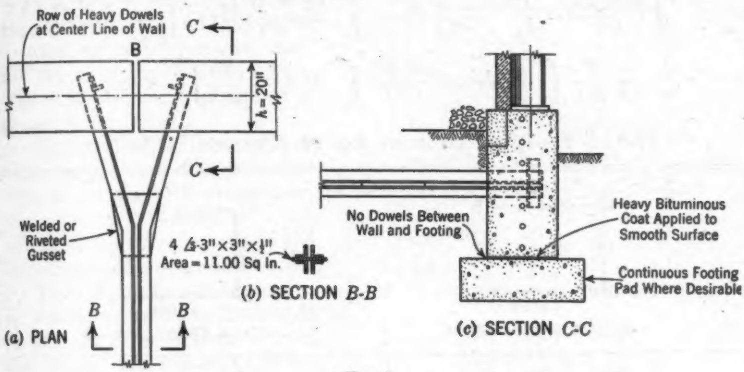

FIG. 8

the tie rod also elongates, due to its stress, an amount equal to $\frac{T_{BE}\,L}{A\,E}$, in which: T = the force sustained by the rod; and L = length of member. Hence, the displacement becomes $2.672 - \frac{T_{BE} \times 120}{5.50 \times 30{,}000{,}000}$.

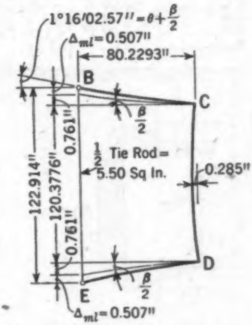

FIG. 9

For a slender tie rod, stored-up elastic energy of both axial forces and moments must be included in the elastic energy equation, which for one half of the complete frame reads:

$$\sum \frac{F\,T\,L}{A\,E} + \int \frac{m\,M\,ds}{E\,I} = 2.672 - \frac{T_{BE} \times 120}{5.50 \times 30{,}000{,}000} \quad \ldots\ldots (11)$$

The force in the tie rod is the only redundant. Once this force is known, the frame is statically determinate. Since one equation is all that is necessary for its solution, the solution of tie-rod force T_{BE} can be based upon the displacement, $2.672 - \frac{T_{BE} \times 120}{5.50 \times 30{,}000{,}000}$, of point E relative to point B.

The auxiliary and actual stress diagrams, respectively, for axial forces in the frame members are included in Table 1 which is used to evaluate the term,

$$\sum \frac{F\,T\,L}{A\,E} = +\,0.000000784 \times T' \times T_{BE} \ldots\ldots\ldots\ldots (12)$$

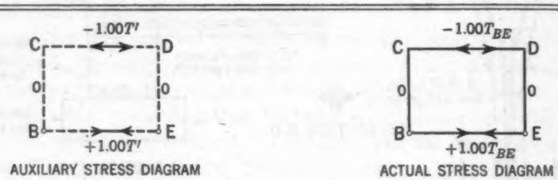
in which T' is an auxiliary tie-rod force. In order to evaluate the term

$\int \frac{m\,M\,ds}{E\,I}$, in Eq. 11, refer to the auxiliary and actual moment diagrams in Figs. 10(*a*) and 10(*b*), respectively:

$$\int \frac{m\,M\,ds}{E\,I} = \int_B^C \frac{T'\,x\,M\,dx}{E\,I} + \int_C^D \frac{80\,T'\,M\,dy}{E\,I} + \int_E^D \frac{T'\,x\,M\,dx}{E\,I}$$

$$= \frac{T'}{E\,I}\int_B^C M\,dx\,x + \frac{80\,T'}{E\,I}\int_C^D M\,dy + \frac{T'}{E\,I}\int_E^D M\,dx\,x,$$

TABLE 1.—Evaluation of Eq. 12 (Tension Is Positive)



Member	Force F (lb)	Force T (lb)	L (in.)	Area A (in.²)	E (lb per sq in.)	$\frac{FTL}{AE}$
BC.......	0	0	80	1,060	2,000,000	0
CD.......	$-1.00\,T'$	$-1.00\,T_{BE}$	120	1,060	2,000,000	$+0.0000000566\,T'\,T_{BE}$
DE.......	0	0	80	1,060	2,000,000	0
BE.......	$+1.00\,T'$	$+1.00\,T_{BE}$	120	5.50	30,000,000	$+0.0000007272\,T'\,T_{BE}$
Σ.......	....	....	....	....	....	$+0.000000784\,T'\,T_{BE}$

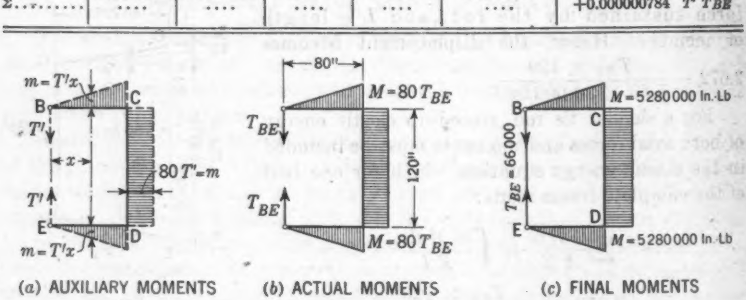


Fig. 10.—Moment Curves as Affected by a Tie Rod

that is,

$$\int \frac{m\,M\,ds}{E\,I} = \frac{T'}{E\,I}\Big[\,(\text{area}) \times x\,\Big]_B^C$$

$$+ \frac{80\,T'}{E\,I}\Big[\,(\text{area})\Big]_C^D + \frac{T'}{E\,I}\Big[\,(\text{area}) \times x\,\Big]_E^D \ldots\ldots\ldots(13)$$

Substituting the known values in Eq. 13, $\int \frac{m\,M\,ds}{E\,I} = \frac{T'}{2{,}000{,}000 \times 14{,}230}$ $(80\,T_{BE} \times 40 \times 53.3 + 80 \times 80\,T_{BE} \times 120 + 80\,T_{BE} \times 40 \times 53.3) = 0.000039\,T'\,T_{BE}$.

With the two terms evaluated, Eq. 11 yields:

$$0.000000784\,T'\,T_{BE} + 0.000039\,T'\,T_{BE} = 2.672 - 0.000000727\,T_{BE} \ldots (14)$$

The auxiliary force T' might have been assumed as unity at the outset since it cancels; hence, $0.000040511 \times T_{BE} = 2.672$; and $T_{BE} = \dfrac{2.672}{0.000040511}$

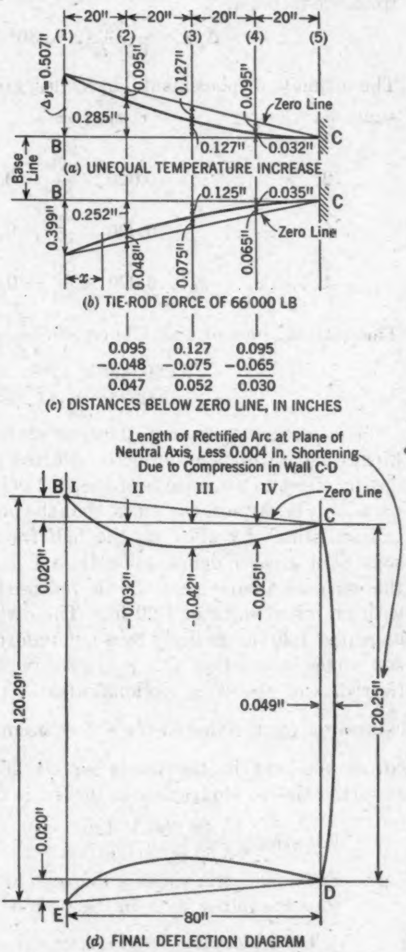

FIG. 11.—CONSTRUCTION OF DEFLECTION DIAGRAM IN RELATION TO THE ZERO LINE

= 66,000 lb. The maximum moment now is $66{,}000 \times 80 = 5{,}280{,}000$ in-lb, or greater than for the hinge-and-tieless frame. The final moment diagram is shown in Fig. 10(*c*).

With respect to the end wall CD, its moment has been increased by 15%. Nevertheless, the moments are eased over the middle part of the side walls by the introduction of hinges and a tie rod.

The extremely strange shape of the elastic curve is illustrated in Fig. 11(*d*) as compiled from Fig. 11(*c*). For end wall CD the tie-rod pull of 66,000 lb (Fig. 11(*b*)) is sufficient to overcome the inward bow caused by the temperature differential (Fig. 11(*a*)), since tie-rod pull forces the end wall to bow outward. Regarding wall pieces BC and ED, Fig. 11(*d*), the inward temperature bow remains predominant in spite of tie-rod pull. The outside faces of these two wall pieces are in tension, even though the elastic curve apparently indicates that the opposite is true.

The exact deflections at various points of the frame are determined as follows: The length that wall CD shortens as the result of compression, $\dfrac{T_{BE}\,L}{A\,E}$, is equal to $\dfrac{66{,}000 \times 120}{1{,}060 \times 2{,}000{,}000}$ or 0.004 in. In other words, the length of the rectified arc at the plane of the neutral axis (see Fig. 11(*d*)), less a shortening of 0.004 in. as the result of compression in wall CD, is 120.25 in. The tie-rod elongation, in inches, is—

For stress, $\dfrac{66{,}000 \times 120}{5.50 \times 30{,}000{,}000}$ 0.048

For a 300° temperature increase, Δt, through the soil...... 0.242

Total increased length.......................... 0.290

Deflections as given in Fig. 11(*d*) are established in part by means of the setup in Fig. 11(*c*) as being the difference between deflection caused by thermal bow (see Fig. 2) and deflection produced in opposite direction by tie-rod pull, from the formula,

$$\Delta_{BB} = \frac{T_{BB}}{6\,E\,I}\,(2 \times 80^3 - 3 \times 80^2 x + x^3) \qquad (15)$$

The ultimate displacements, in inches, are obtained as follows:

Section (see Fig. 11)	Computation	Δ	Fig. No.
1	....	−0.020	11(*d*)
2	$0.020 \times \frac{60}{80} - 0.047$	−0.032	11(*c*)
3	$0.020 \times \frac{40}{80} - 0.052$	−0.042	11(*c*)
4	$0.020 \times \frac{20}{80} - 0.030$	−0.025	11(*c*)

The outward bow of wall CD equals $\frac{M\,l^2}{8\,E\,I} - 0.285$ (see Fig. 7(*a*))

$$= \frac{5{,}280{,}000 \times 120^2}{8 \times 2{,}000{,}000 \times 14{,}230} - 0.285 = 0.049 \text{ in.}$$

The foregoing computations serve to indicate that the introduction of hinges and tie rods at properly selected points of the frame may bring a relieving effect to some parts of the structure, but an aggravating effect to other parts. It is natural, therefore, that the next step should be to investigate what can be gained by allowing the half frame BCDE, Fig. 11(*d*), to acquire a somewhat greater deformation than a fixed-length the tie rod permits. For this purpose assume that the tie rod used in the preceding example is placed with an initial slack of 1.20 in. The distance between hinges, then, must be increased 1.20 in. (entirely by a nonuniform heating of the walls) before the tie rod comes into action as a load-carrying member of the system. If the new tie rod is of the same sectional area as the four angles previously used, the expression for the tie-rod force T_{BB} becomes $\frac{2.672 - 1.20}{0.000040511} = 36{,}300$ lb. The corner moment in the frame equals $36{,}300 \times 80 = 2{,}900{,}000$ in.-lb. The corrected tie-rod elongation, in inches, is now determined as before—

For stress, $\frac{36{,}300 \times 120}{5.50 \times 30{,}000{,}000}$	0.026
For a 300° temperature increase Δt through the soil	0.242
Plus the initial slack in the tie rod	1.200
Total increased length	1.468

The center deflection of wall CD, in inches, will be—

Thermal curvature inward (see Fig. 7(*a*))	+0.285
Restraining corner moments (outward) $\frac{M\,l^2}{8\,E\,I} = \frac{2{,}900{,}000 \times 120^2}{8 \times 2{,}000{,}000 \times 14{,}230}$	−0 184
Ultimate deflection (inward)	+0.101

Fig. 12 shows the final moment and deformation diagrams, respectively. It is interesting to note by comparing Figs. 10(c) and 12(a) that the initial tie-rod slack has reduced the frame moment by almost one half. The increase in distance between points B and E is only half that which would have been produced in the frame with hinges at points B and E—but without any tie rod. This also holds true for the abruptness of the change in curvature at points B and E.

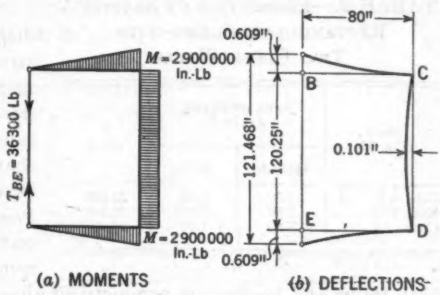

Fig. 12.—Moments and Deflections, Rectangular Frame with Tie Rod and Hinges

Comparison between Figs. 11(d) and 12(b) reveals that the elastic curve of end wall CD in one case is outside, and in the other case inside, its original position.

The analysis demonstrates that the introduction of a tie rod with an initial slack, in many instances, should constitute an economical means by which to bring thermal stresses within a reasonable range. The greater the permissible slack, the less will be resulting thermal stresses. The proper amount of slack is governed by the magnitude of abrupt displacement which the equipment (refractory wall, steel structure, etc.) will safely withstand, and should be subject to close scrutiny by the designer in each individual case.

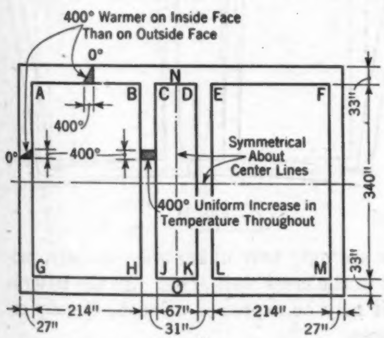

Fig. 13.—Rectangular Frame with Two Cross Walls

4. Rectangular Frame with Two Cross Walls

The last type of frame to be analyzed is a foundation consisting of six monolithic walls. A simplified plan of the structure is essentially as shown in Fig. 13. It differs from the frames described in Section 3 in that it is much larger and contains members of different cross section. Side walls AF and GM, Fig. 13, are identical. Cross walls BH and EL are also identical but of a somewhat lighter section. End walls AG and FM are of a lighter section than any of the others. A cross section through the exterior walls is substantially as shown in Fig. 1(b).

The exterior walls are subject to the same temperature differential (400° F) as the frames previously analyzed. The two cross walls, however, receive a uniform temperature increase of 400° F throughout since they are exposed to similar heat from both sides.

Axial forces are neglected in the following computations. Moments of inertia, transformed into terms of concrete of the three different walls, are computed for a "slice" of wall, 1 ft thick. The properties of the sections are as listed in Table 2.

TABLE 2.—PROPERTIES OF SECTIONS, RECTANGULAR FRAME WITH TWO CROSS WALLS

Wall (Fig. 15)	Area of Steel, A_s (In.²)		I (in.⁴)
	Outside	Inside	
Side, AF......	3.00	0.50	22,020
End, FM......	2.30	0.50	10,940
Cross, EL......	1.30	1.30	10,260

To obtain a picture of thermal displacements that occur when the structure is heated, cut the frame at points A, N, and F. This makes the frame statically determinate and causes it to deviate from its cold shape, as shown in dotted lines, to that shown in full lines in Fig. 14. Point O is the only spot that remains stationary. All displacements are symmetrical about line ON. Since both frame and loading are symmetrical about both center lines of the frame, the moment diagram will likewise be symmetrical about the center lines.

Fig. 15 is the complete geometrical displacement diagram for the right-hand side of the structure. The linear displacements (both horizontally and vertically), as well as the rotational displacements at points N and F, are: $\Delta_{Nx} = 2 \times 1.601 = 3.202$ in.; $\Delta_{Ny} = 0.955 + 0.231 + 0.115 = 1.301$ in.; $\phi_N = 2 \times 2\gamma = 4\gamma = 1° 4' 30.72'' = 0.01876$ radian; $\Delta_{Fx} = 278.500 + 0.847 + 9.087 + 6.786 - (230.211) + 49.150 + 1.601) = 14.258$ in.; $\Delta_{Fy} = 3.050 + 0.955 + 1.450 = 5.455$ in.; and $\phi_F = \theta + \beta + \theta - 2\gamma = 2\theta + \beta - 2\gamma = 4° 47' 53.16'' = 0.08369$ radian.

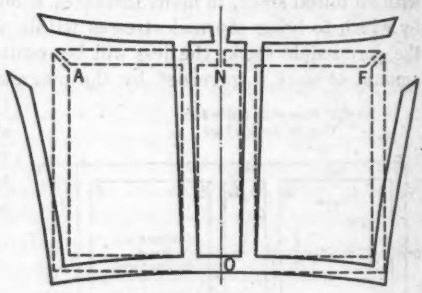

FIG. 14

It follows from Fig. 13 that there are only four unknowns—namely, moments M_D, M_E, M_F, and the moment in the cross wall M_{DK}. As the latter is the difference between M_D and M_E, it may be expressed as such, thereby reducing the number of unknowns to three.

Proceeding along the same lines as in the example Section 3, it is possible to write three elastic energy equations based on the vertical, horizontal, and rotational displacements at each of the points N and F. Examination reveals, however, that due to symmetry the equation (Eq. 4) based on vertical deflection Δ_{Ny} is unusable, still leaving an abundant number of equations. Choosing to utilize the three elastic energy equations that are based on Δ_{Nx}, Δ_{Fy}, and ϕ_F, the auxiliary loading diagrams and auxiliary moment diagrams shown in Figs. 16(*a*), 16(*b*), and 16(*c*), respectively, are constructed. The moment areas as sketched in these illustrations are drawn on that side of the members where auxiliary force produces compression.

Fig. 17(*a*) is the assumed actual, or *M*-moment diagram. The moment areas are shown on that side of the member where compression will presumably occur. It will also be noted that, for simplicity, the suffixes for moments in the upper right quadrant are repeated in the three other quadrants. The modulus of elasticity E is constant throughout and, as in the other examples of this paper, is assumed to be 2,000,000 lb per sq in. As before, $n = 15$.

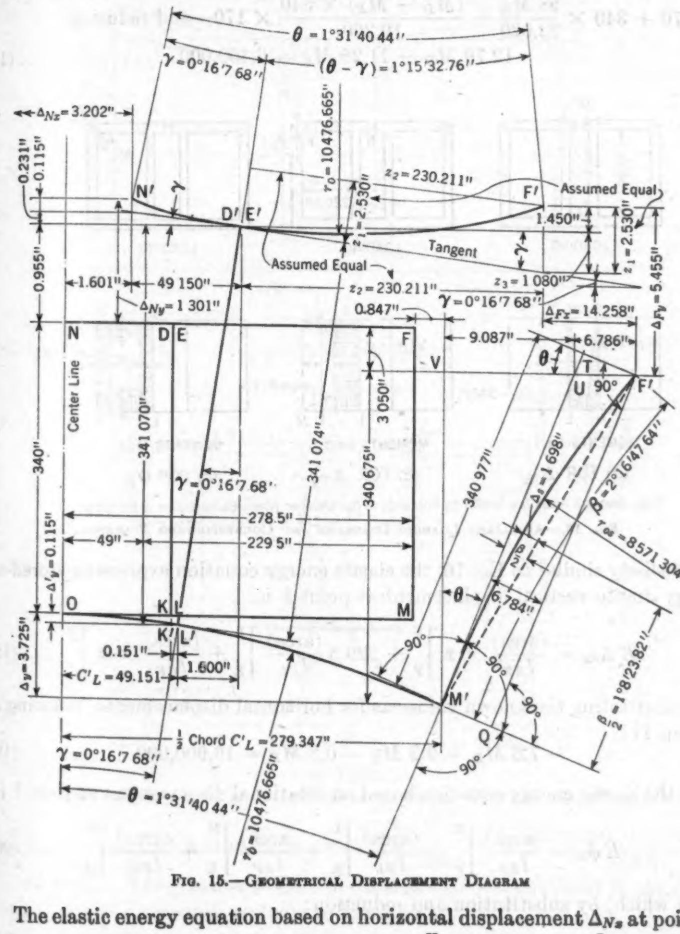

FIG. 15.—GEOMETRICAL DISPLACEMENT DIAGRAM

The elastic energy equation based on horizontal displacement Δ_{Nx} at point N (compare Eqs. 6 and 7) is written as: $E\,\Delta_{Nx} = \int_B^H \frac{F_1\, y\, M\, dy}{F_1\, I_{EL}} + \int_H^L \frac{340\, F_1\, M\, dx}{F_1\, I_{BF}}$

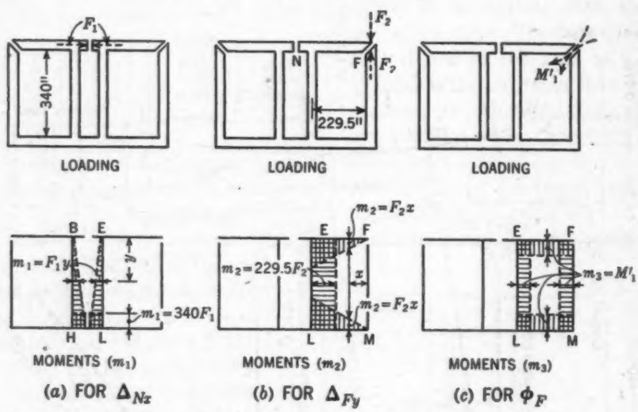
$$+ \int_L^E \frac{F_1\, y\, M\, dy}{F_1\, I_{EL}} + \int_E^B \frac{0\, M\, dx}{F_1\, I_{BF}} = \int_B^H \frac{M\, dy}{I_{EL}} \times y + 340 \int_H^L \frac{M\, dx}{I_{BF}} + \int_L^E \frac{M\, dy}{I_{EL}}$$

$\times\ \bar{y} + 0$. Similar to Eq. 7:

$$E\,\Delta_{N_x} = \frac{(\text{area})}{I_{EL}} \times \bar{y}\,\Big]_{\mathrm{B}}^{\mathrm{H}} + 340 \times \frac{(\text{area})}{I_{EF}}\,\Big]_{\mathrm{H}}^{\mathrm{L}} + \frac{(\text{area})}{I_{EL}} \times \bar{y}\,\Big]_{\mathrm{L}}^{\mathrm{E}} \ldots (16)$$

Substituting the known values—$2{,}000{,}000 \times 3.202 = \dfrac{(M_D - M_E) \times 340}{10{,}260}$ $\times\ 170 + 340 \times \dfrac{98\ M_D}{22{,}020} + \dfrac{(M_D - M_E) \times 340}{10{,}260} \times 170$—and reducing:

$$12.79\ M_D - 11.28\ M_E = 6{,}400{,}000 \ldots\ldots\ldots\ldots\ldots (17)$$



Note: Moment Areas Are Shown on That Side of the Member Where Compression is Produced

FIG. 16.—AUXILIARY LOADING DIAGRAMS AND CORRESPONDING MOMENTS

Precisely similar to Eq. 16, the elastic energy equation expressing stored-up energy due to vertical displacement at point F is:

$$E\,\Delta_{F_y} = \frac{(\text{area})}{I_{EF}} \times \bar{x}\,\Big]_{\mathrm{F}}^{\mathrm{E}} + 229.5\,\frac{(\text{area})}{I_{EL}}\,\Big]_{\mathrm{E}}^{\mathrm{L}} + \frac{(\text{area})}{I_{EF}} \times \bar{x}\,\Big]_{\mathrm{L}}^{\mathrm{M}} \ldots\ldots (18)$$

and substituting the known values as for horizontal displacements, reducing as for Eq. 17:

$$-\,7.6\ M_D + 9.2\ M_E - 0.8\ M_F = 10{,}900{,}000 \ldots\ldots\ldots\ldots (19)$$

Also, the elastic energy equation based on rotational displacement at joint F is:

$$E\,\phi_F = \frac{(\text{area})}{I_{EF}}\,\Big]_{\mathrm{F}}^{\mathrm{E}} + \frac{(\text{area})}{I_{EL}}\,\Big]_{\mathrm{E}}^{\mathrm{L}} + \frac{(\text{area})}{I_{EF}}\,\Big]_{\mathrm{L}}^{\mathrm{M}} + \frac{(\text{area})}{I_{FM}}\,\Big]_{\mathrm{M}}^{\mathrm{F}} \ldots\ldots (20)$$

From which, by substitution and reduction:

$$-\,0.0332\ M_D + 0.0436\ M_E - 0.0415\ M_F = 167{,}300 \ldots\ldots\ldots (21)$$

Solution of the three simultaneous Eqs. 17, 19, and 21 yields, in inch-pounds: $M_D = +\ 4{,}920{,}000$; $M_E = +\ 5{,}000{,}000$; $M_F = -\ 2{,}700{,}000$; and $M_D - M_E = 4{,}920{,}000 - 5{,}000{,}000 = -\ 80{,}000$.

In accordance with the sign convention used, the moments that proved to be positive were assumed correctly; those that became negative are opposite to what was assumed at the beginning (see Fig. 17(a)). The final moment diagram is as indicated in Fig. 17(b).

Side walls AF and GM are not subject to axial load. Cross walls and end walls, however, do carry an axial force (compression in cross walls and tension in

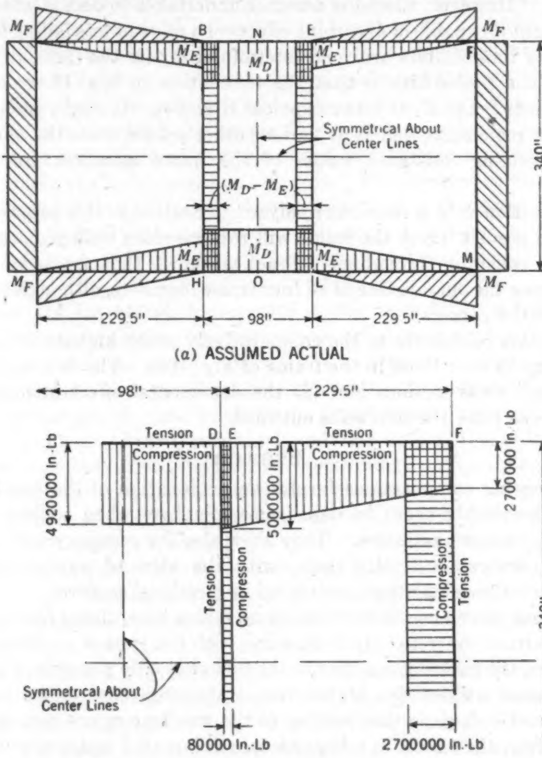


FIG. 17.—MOMENTS, M, IN A RECTANGULAR FRAME WITH TWO CROSS WALLS

end walls), the numerical value of which is $\dfrac{M_E - M_F}{229.5} = \dfrac{5{,}000{,}000 - 2{,}700{,}000}{229.5}$ $= 10{,}000$ lb. The greatest stresses in the side wall occur at point E, the magnitude of which (in pounds per square inch) is:

Material	Computation	Stress
concrete, f_c	$\dfrac{5{,}000{,}000 \times 11.4}{22{,}020}$	2,590
tensile steel, f_s	$\dfrac{5{,}000{,}000 \times (30 - 11.4)}{22{,}020} \times 15$	63,300

These stresses also are far beyond the limits within which the equations of Section 4 hold.

In view of the aforementioned stresses, the foundation would be unusable in its present rigid form, except possibly in cases where its superimposed load is quite uniformly distributed. Even in such cases, the superimposed equipment must be of a nature that will withstand the effects of a somewhat cracked-up foundation. However, when the designer undertakes to decide whether or not the equipment is capable of absorbing effects of a more or less failing foundation, the difficulty immediately arises of determining where the foundation is likely to yield. The probability is that the foundation in Fig. 13 would fracture between points B and E, or between points H and L. It might crack anywhere in these two regions, as well as at various other points, since the moments and the corresponding resistance values of the frame members are fairly proportionate.

In connection with a frame as analyzed in Section 2, it is impossible, theoretically, to predict where the frame will rupture since both moment and wall section are constant throughout. Practice shows that fractures appear at intervals along the outside face of all four frame members, although they appear mostly near the corners.

Two factors contribute to the comparatively much higher moments in the frame of Fig. 13 over those in the frame of Fig. 1(*a*). The two factors are (1) the "thicker" cross sections and (2) the detrimental effect introduced when the cross walls push the side walls outward.

5. Summary

The foregoing computations furnish an explanation of the numerous fractures that inevitably occur in rigid-frame members when subject to a nonuniform temperature variation. They show also the certainty with which it is possible to analyze such structures, with the view of minimizing thermal stresses, when the calculations are set up in a rational manner.

The actual occurrence of 500° F is by no means exceptional for the temperature of structural concrete. In connection with the type of problem discussed in this paper, the entire danger lies in the fact that only one side of each of the frame members attains the higher temperature increase. The analyses of Sections 2 and 4 disclose that neither of the two frames are capable of withstanding safely, the effects of a temperature differential materially in excess of 100° F, since the frames are already stressed to some extent by vertical loading.

For all frames analyzed in this paper, it has been assumed that the concrete maintained its elasticity even at the very high stresses encountered. This is not the case, as the stresses were computed to be way into the plastic range of concrete. For this reason it is logical to assume that once the computed stresses reach the plasticity range of the concrete they increase only slightly with further increase in displacements. This fact is most likely one of the reasons that concrete stands up as well as it does even under quite unfavorable nonuniform thermal conditions.

The degree of accuracy with which this type of analysis should be executed depends not only on the structure in question, but also on various individual

circumstances. Displacements must be computed by logarithms, whereas the slide rule offers abundant accuracy for all other numerical values.

Since the average designer has little interest in ascertaining linear displacements and deflections, considerable time may be saved by computing the frame moment entirely from rotational displacements as shown in Section 2.

One factor of uncertainty entering into thermal problems is the determination of the exact temperature on each side of the frame members. This is evidently a field in which much research should, and could, be done in order to enable the engineer to begin with reasonably correct temperature values instead of "makeshift" values that are largely a matter of guesswork. A question which (to the best of the writer's knowledge) is shrouded in total obscurity is that of how to determine intelligently the "average gradient" in a wall of limited extent whose temperature gradient varies from one edge to the other. A typical example of this is shown in Fig. 1(*b*). The thermal condition at the top of the foundation wall is quite different from that at the lower part of the wall; the upper part of wall is exposed to the cooling influence of the atmosphere; and the lower part of wall is affected by the insulating action of the surrounding soil.

In general, the investigations reported herein apparently sound a strong warning against continuity in structures whose members are subject to a fairly high nonuniform thermal action, unless it is ascertained beforehand, by an analysis, that stresses thus produced are within the allowable range.

In some instances, thermal fractures in a rigid frame are of little consequence. A good example of this is the foundation in Fig. 1(*a*). In this type of structure the superimposed load is distributed fairly uniformly so that little vertical beam action is required of the frame members.

When the frame in question forms a foundation, it is at times advisable to eliminate its continuity by cutting its members at well-chosen points, thus leaving the various parts free to assume their natural thermal deformations without restraint. However, this uncontrolled expedient usually results in a complicated and expensive foundation structure in order to maintain linear and rotational displacements within the permissible limits.

Again considering the frame of Fig. 1(*a*) assume that it has been decided to eliminate continuity altogether. Assuming also that no relative vertical settlement between the various foundation elements is permissible, the logical step would be to sever each of the two side walls AC and FD completely by a 1-in. thick rock-wool block expansion joint at a point about 2.5 ft from the inside face of each end wall AF and CD. Each end wall would be severed by the same type of joint at its center. This would create a foundation "ring" composed of six loose parts—two straight pieces of wall and four unequal angle-shaped parts. To avoid relative vertical settlement between any of these pieces, it would become necessary to place the wall parts on a footing pad with a smooth top and bituminous joint as shown in section CC of Fig. 8. The footing pad should be made discontinuous by a 1-in. thick rock-wool joint at corners A, C, F, and D. To prevent a lateral shifting of wall parts relative to footing pads, each wall part, at its extreme fourth or fifth points, must be doweled, to footing pads at two places. The dowels should be large-diameter,

round, smooth bars heavily coated in mastic. Any unequal vertical bending, which before was supported by the walls, now must be supported entirely by the footing pads.

Some degree of controlled continuity may easily be established along the lines suggested in Section 3 (see Fig. 8). Whether or not an initially slacked tie rod is used at a strategic location, this foundation might be further improved (at added cost) by thinning the wall between buckstays. To avoid exceeding the allowable soil-bearing pressure, it probably would be necessary to place the walls on a continuous footing pad as shown in section CC which, in turn, would require a smooth bearing surface and a bituminous joint, as indicated, in order to facilitate sliding. Resistance against sliding should be checked; and if of considerable magnitude it should be taken into account as a more or less uniform load acting toward the inside of the frame. It increases corner moments but decreases the moments between joints.

Offhand, it would seem that the two cross walls BH and EL, Fig. 13, should be designed as beams (to carry their vertical load) and should be supported on movable end bearings at points B, E, H, and L. In practice, however, it will generally be found that the large end reactions create frictional forces at these points considerably in excess of the thrust of 10,000 lb existing in the cross wall.

In many instances it is possible to improve, materially, the design of a nonuniformly hot foundation by substituting comparatively slender steel members for some of the bulky concrete members. Such structural steel should be encased in a suitable type of concrete of a mix that yields high insulating value but low compressive strength. In order to ascertain that this protective concrete remains in place, even though badly fractured, it should be reinforced by continuous wire mesh or welded fabric placed fairly close to the surface.

In the case of a traditional, rectangular, concrete flue, an improved design is usually achieved by eliminating dowels between base slab and walls—at the same time providing a smooth steel-troweled surface on top of the base slab. This procedure enables flue walls (as they are heated from within) to bow and displace themselves outward without any restraint other than that caused by a slight friction between walls and base slab. If the flue is underground, the thermal displacement will become less due to the lowered temperature differential. In cases where the floor of the flue is below water table, the procedure just mentioned should be reversed in order to prevent water from entering the flue; that is, flue walls should be "fixed" at floor by through dowels, and flue roof then must rest loosely on walls without any continuity.

In connection with a time-honored type of foundation—namely, that of an octagonal mat with a centrally located plinth such as is used for stacks and blast furnaces—it is the writer's belief that ring stresses of enormous magnitude exist in the outer part of the mat. The central area (under the plinth) becomes very hot; whereas the ring part undoubtedly remains at a considerably lower temperature. It appears that the most satisfactory solution is to provide eight, or at least four, 1-in. thick rock-wool joints radially from the edge of the mat to within a couple of feet of the face of the plinth. These joints,

of course, must extend through the full thickness of the mat. When placing eight radial slots in the mat it is obvious that the less economical four-way type of reinforcing must be adopted. If only four slots are used, it is still possible to utilize two-way reinforcement.

The analyses in Sections 2, 3, and 4 would seem to argue against the use of hard-grade reinforcing bars in unequally heated concrete structures. Intermediate or structural grade bars should be used because of their greater ductility. Bars rolled from the milder grades of steel offer some degree of security against the possibility that an overstressed structure will partly collapse, suddenly, due to their capacity for plastic deformation without fracture. Herein lies, undoubtedly, one of the reasons why a number of thermally overstressed concrete structures are today giving very satisfactory service despite development of numerous large fractures.

Much could be accomplished toward the exclusion of thermal stresses in concrete foundations by designing the equipment in such a manner as to prevent the heat from being transmitted to the load-carrying members. The hot equipment should be kept from coming in contact with the concrete, either by a sufficient amount of effective insulating material, or, by circulating air currents that are induced by stack action.

When at all feasible, the use of an overhead steel breeching is much more preferable than the old style of concrete flue.

Numerous troublesome problems could probably be eliminated, or at least simplified, by suspending a large proportion of the hot superstructure from carefully chosen key points. The transfer of heat from the superstructure to the foundation would then be restricted to the isolated key points where it may be dealt with more conveniently.

APPENDIX. NOTATION

The following letter symbols conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials (ASA—Z10a—1932) and for Heat and Thermodynamics (ASA—Z10.4—1943), prepared by a Committee of the American Standards Association, with Society representation.

A = area of cross section, subscripts s and c denoting "steel" and "concrete," respectively;
C = one half the length of a chord;
E = modulus of elasticity;
F = force;
f = unit force or unit stress;
h = thickness of a wall or depth of a frame member;
I = rectangular moment of inertia;
L = axial length of a member;

M = moment:

M' = auxiliary moment;

M_t = moment produced by differential temperature, Δt;

m = moment of a unit force;

n = ratio of elastic moduli, E_s/E_c;

r = radius; subscripts o and i denoting outside and inside of a curved member, respectively; r_{os} = outer radius of the side member;

s = length of arc measured along the neutral axis of a curved member; ds = elemental part of length s;

T = tie-rod force;

t = temperature (thermometric); Δt = difference in temperature between two faces of a wall:

x = horizontal ordinate distance;

y = vertical ordinate distance;

z = distances, with appropriate numerical subscripts, in Fig. 15;

α = coefficient of thermal expansion;

γ = angle of curvature of a beam (Fig. 15) see also θ and ϕ;

Δ = change in length, or the displacement of a point as the result of a differential temperature Δt:

Δ_{Bx} = horizontal component of the displacement of;

Δ_L = increase in total span length;

Δ_m = displacement of the midpoint of a member, with subscripts s and l to denote "short beam" and "long beam," respectively;

Δ_v = vertical displacement at the end of a beam (Fig. 2);

θ = angle of curvature of a beam; a construction angle (see Fig. 15); and

ϕ = angle of curvature of a beam.

DISCUSSION

I. Oesterblom,[4] M. ASCE.—It is a sign of wakening to important but neglected facts that thermal action in structures has been more frequently discussed recently. There is again a sample of this trend in the publication of the paper by Mr. Tommerup. The author has succeeded in presenting a method that is quite applicable to simple frames. This commentator agrees wholeheartedly and thankfully with the logic of the method, but believes that the details must be modified to make the method truly useful.

There seem to be two basic points that require more thought and possibly correction—and some minor points, also. One of the basic points—if the author should agree—would materially lower the stresses; the effect of the other is the reverse. Presumably, the author has neglected the second point with the very good intention of simplifying his method; but, in doing it, he may lead novices astray unless he issues at least a warning. One may well question if the omission can be made fairly, when it is connected so intimately with the designer's problem that a separate superimposed solution for the omission is not permissible.

The two items may be presented, as follows:

(1) When heat is added on one side there is not only elongation and compression on that side, but also tension on the opposite side; and

(2) The direct longitudinal forces cannot be ignored, for they are very large and also set up bending moments by acting over a curved and deflected element.

Contrary to the conclusion of Mr. Tommerup, a correction for tension on the opposite side (item (1)) yields a deflection. Item (1) is predicated on the necessity of having a tensile reaction to the compressive stresses on any small section dx exactly in that element, and that condition sets up a neutral axis in the center line. Otherwise, where could the reactions be? They must be included somewhere, and analysis of the element dx would indicate that they must be there, regardless of the fact that the accumulation appears as a moment at the corner. This also sets up a longitudinal shear, which the author—quite correctly from his point of view—has omitted.

Figs. 2, 3, and 4 are correspondingly subject to criticism, and need correction. Fig. 2 should show center lines of the elements; the deflection should apply to these lines. The gap and the deflection in Fig. 3 should be similarly adjusted, and so should the displacements in Fig. 4. It follows then that the stresses would be different—roughly, about one half of the values shown.

There is also doubt as to the value of E assumed for the rationalized concrete that is made today. With the aggregates properly selected, graded, and proportioned, and with the quantity of water under control, E is more likely to be nearer to 3.5×10^6 than the 2×10^6 as assumed[5]—thus a reduction of the

[4] Engr., Carbide & Carbon Chemicals Corp., South Charleston, W. Va.

[5] "Johnson's Materials of Construction," by J. B. Johnson, rewritten and revised by M. O. Withey and J. Ashton, John Wiley & Sons ,Inc. ,New York ,N. Y .,8th Ed., 1939, p. 479.

concrete stress approximately to $\left(\frac{1}{2} \times \frac{2}{3.5} = \right)$ 29% of what is shown. The revised value of 600 lb does not seem so devastating as the 2,070 lb computed by Mr. Tommerup; yet, the revised value must be increased considerably due to the direct normal strains and stresses.

To compute these corrections the designer must know the initial construction temperature in addition to the 100° assumed at the time of the thermal addition of 400°. If the frame were built in cold weather with the temperature at 40° a rise of (60° + 200° =) 260° would be required to reach the average of the frame at that time. With the corners fixed against translation the stress is $\delta = E\,\Delta t\,\alpha = 3.5 \times 260 \times 7.9 = 7{,}200$ lb per sq in., which is to be added to the previous concrete figures, algebraically. As a result there is compression on the heated side equal to (7,200 + 600 =) 7,800 lb and compression, also, on the cool side equal to (7,200 − 600 =) 6,600 lb. In addition, there are the bending stresses caused by the thrust being applied to an independently created eccentricity.

To compute this bending is a very laborious task. Almost the only way to combine the two problems is by the aid of Castigliano's second law, which presents such difficulties as to make the simple method proposed by Mr. Tommerup very attractive. For this reason the writer sincerely hopes that his argument concerning the deflection can be proved erroneous.

There is a saving feature which bears directly and heavily on the high stresses—in actual construction it is difficult to establish complete fixation against translation. Thus, if the elements in question could be completely freed from external restraint there would be no direct thermal stress; and, depending on how much restraint there is, the stresses would vary between 0 lb and 7,200 lb.

This brings to the fore a point that Mr. Tommerup has demonstrated so well and so fairly: Investigators concerned with thermal forces must know how they act, and then must design the details so that these forces are nil, if possible, or at least very small. It is only by proper details that a structure can be prevented from cracking or crumbling or even complete disaster. This is an extremely important point to which very few designers give proper emphasis.

Gratitude is due Mr. Tommerup; structural engineers are fortunate that he has presented this phase of a complex subject so well. He has advanced it in the right direction; but he has still left much work to be done to amplify his method. As presented, it does not seem to be complete enough for safety. When it is finished no one should be able to charge a thermal failure in a simple frame to "the act of God" or "force majeure," as is so often done today by the formula fraternity inside the profession.

FRANK R. HIGLEY,[6] Esq.—A sheet metal unit developed in 1944 for a mechanical cycling operation responsive to nonuniform thermal action serves to demonstrate the possible danger from thermal stresses in unequally heated

[6] Cleveland, Ohio.

structures. The unit (see Fig. 18) comprises a single piece of steel, 0.040 in. thick and 5 in. long which, secured at one end, deflects its opposite end laterally 0.20 in. in 60 sec against a 1-lb load responsive to a minimum size gas pilot flame, substantially independent of ambient temperatures up to 1,000° (these data being approximate).

With one objective in mind, it is often enlightening to study efforts leading toward the opposite objective. Of course, the purpose of designing such a thermal unit was opposite to that of designing the structures so ably analyzed in the paper. The sheet metal thermal unit is provided with a single slot and is simply bent along the line of the slot to provide a pair of members disposed in a parallel, slightly spaced, relation, with an integral interconnection adjacent to their ends along one edge of the resultant unit.

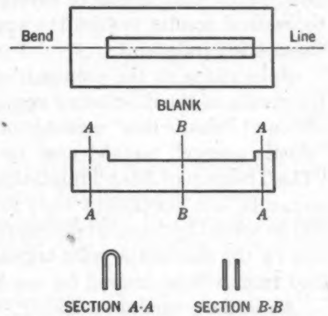

FIG. 18.—THERMALLY RESPONSIVE UNIT.

The principal features of the unit are: (*a*) Heat transfer between the members is inhibited to the greatest extent possible so that the thermal differential may be as great as possible; (*b*) the members have positive rigid interconnection at their ends to make best use of the relative expansive forces set up in the heated leg; and (*c*) while remaining rigid in the direction of generated force, the members are arranged to permit flexure in the resultant force direction desired.

Application of the same considerations to the type of structure described by the author indicates that (1) the wall should first be made laminate in so far as possible, to provide stratification between high-temperature and low-temperature faces; and (2) adjacent extremities of the laminas should be free from each other in the direction of their relative expansion. The author has at least implied the former of these two considerations under the heading, "2.—Rectangular Frame"; and has, in effect, quite thoroughly analyzed the second.

Inherently, from both the paper and the foregoing discussion, it appears that a plane of lamination, which in section determines what may be considered as a neutral thermal axis, should as nearly as possible be located to coincide with the common neutral axis of gyration between the same members at that section. Thus, as far as possible the members may have free relative expansion under the superimposed temperature differential, with relative expansion only on one side and relative contraction only on the other side of the axis.

A. L. MILLER,[7] M. ASCE.—A distinct service has been rendered by the author in directing attention to problems arising from differential temperature change, and by presenting a feasible interpretation and theoretical evaluation. Necessarily, theory is abstract. Limited by hypothesis and assumption, it produces results which must be interpreted with due regard for these limitations. In addition to the generally recognized stipulations of the theory of flexure and continuity, the materials are presumed to possess their usual prop-

[7] Prof. of Mechanics and Structures, Dept. of Civ. Eng., Univ. of Washington, Seattle, Wash.

erties and behavior above the ordinary range of temperature. Also, it will be observed that the dimensional changes of the convex face of a member are assigned to its centroidal axis. Both premises are justifiable and undoubtedly give results that are more severe than the real effects. In other words, the theoretical results predict the upper limit of effects within which to exercise engineering judgment.

Subscribing to the proposals of the paper, this discussion aims to validate the results of the illustrative examples and to indicate procedures for the application of "elastic line" methods of calculation for those who prefer them to the "elastic energy" method used by the author. "Moment Distribution"[8] and "The Theorem of Joint Translation"[9] (an extended form of the theorem of three moments) are convenient tools for this purpose. The examples of the paper will be solved by moment distribution, a most useful elastic line method. Solution by the theorem of joint translation will not be illustrated but the essential load term will be derived for use by those who are familiar with the theorem.

An initially straight member, when subjected to differential thermal action throughout its length, tends to assume a circular arc unless resistance is afforded by its attachments or supports. Since the curvature is relatively small, the theory applicable to straight members applies with negligible error. The extent to which the member is prevented from assuming the span-end slopes of the circular arc determines the span-end moments induced by the action and the consequent stresses and deflections throughout a rigid frame.

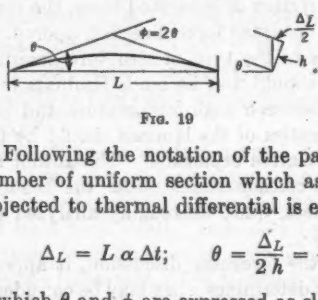

Fig. 19

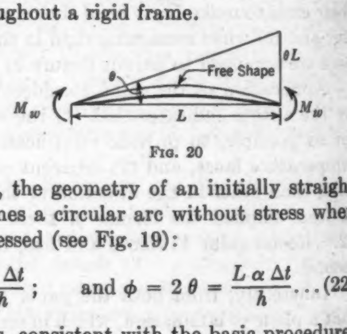

Fig. 20

Following the notation of the paper, the geometry of an initially straight member of uniform section which assumes a circular arc without stress when subjected to thermal differential is expressed (see Fig. 19):

$$\Delta_L = L\,\alpha\,\Delta t; \qquad \theta = \frac{\Delta_L}{2\,h} = \frac{L\,\alpha\,\Delta t}{2\,h}; \qquad \text{and } \phi = 2\,\theta = \frac{L\,\alpha\,\Delta t}{h} \ldots (22)$$

in which θ and ϕ are expressed as slopes, consistent with the basic procedures of the theory of flexure. Accordingly, the fixed-beam moment $M_{F,N}$ caused by the thermal differential, for use in the moment-distribution method, is as follows (Fig. 20): By the moment-area principle,

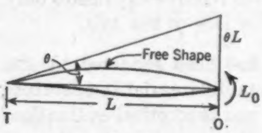

Fig. 21

$$\theta\,L = \frac{M_w}{E\,I}\,\frac{L^2}{2}; \qquad \text{and } M_w = \frac{2\,E\,I\,\theta}{L} \ldots . (23a)$$

Therefore—

$$M_w = \frac{E\,I\,\alpha\,\Delta t}{h} \ldots\ldots\ldots (23b)$$

—with rotational signs determined by inspection. Eq. 23b demonstrates that

[8] "Moment Distribution," *Bulletin No. 64*, Eng. Experiment Station, Univ. of Washington, Seattle.

[9] "The Theorem of Joint Translation," *Bulletin No. 89*, Eng. Experiment Station, Univ. of Washington Seattle.

the fixed-beam moment M_w caused by the thermal differential is no function of the span length.

The load term, L_o, for use with the theorems of two moments, three moments, and joint translation is derived as follows (Fig. 21): By the moment-area principle,

$$\theta L = \frac{L_o}{E I}\left(\frac{L}{2}\right)\frac{L}{3}; \qquad \text{and } L_o = \frac{6 E I \theta}{L} \ldots\ldots\ldots\ldots (24a)$$

Therefore—

$$L_o = \frac{3 E I \alpha \Delta t}{h} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24b)$$

The differential temperature Δt that causes upward deflection is positive. The rectangular frame of Fig. 1 is solved by moment distribution as follows:

The joint coefficients of the span ends are computed in the conventional manner, being 0.429 and 0.571 for the 160-in. and 120-in. members, respectively.

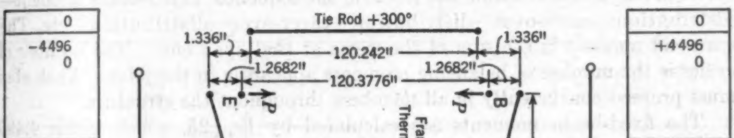

Fig. 22

The carry-over factors are 0.5 throughout. The fixed-beam moments are found by the equation,

$$M_w = \frac{E I \Delta t}{h} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

Thus, $M_w = \dfrac{2{,}000 \times 14{,}230 \times 0.0000079 \times 400}{20} = 4{,}496.68$ kip-in. for all members since each is subjected to the same thermal differential and possesses

the same values of E, I, and h. Since no balancing moment appears in the first operation, subsequent distributions and carry-overs are zero, giving 4,496.68 kip-in. as the precise result at each span end. When arithmetical and geometrical approximations are eliminated, the solutions presented in the paper produce this result.

The rectangular frame with tie rod and hinges (Fig. 9) is analyzed by moment distribution as follows:

The joint coefficients of each span end are computed in the usual manner with due regard for the pins at points B and E. Carry-over factors are all 0.5 except those to the pins, B and E. The form of tabular procedure shown in Fig. 22 is convenient for any rigid frame and is self-explanatory to one familiar with the method of moment distribution. The boxes representing the joints provide a space in which to record the balancing moments; the joint coefficients appear on the span ends adjacent to the joints; and the steps in the successive cycles proceed outward from the joints in the sequence: Fixed-beam moment—distribution—carry-over—distribution—carry-over—distribution—etc. The span-end moment is the sum of the items at that span end. The number of cycles is the number of balancing moments appearing in the joint. Each step must proceed concurrently in all members throughout the structure.

The fixed-beam moments are calculated by Eq. 25, which yields 4,496 kip-in. for members BC and ED and 5,204 kip-in. in member CD. Rotational signs are determined by inspection. The computation is completed as follows:

Item	Description	
1	The load P (in kips), necessary to cause a displacement Δ of 1.2682 in., is $\frac{5{,}204}{80.2293}$, or........................	65.00
	Displacement Indexes, in Inches per Kip—	
2	Bending throughout the frame is $\frac{1.2682}{65.0}$, or..........	0.0195
3	Compression in member CB is $\frac{P\,L}{2\,A\,E} = \frac{1 \times 60.189}{1{,}060 \times 2{,}000}$, or	0.000028
4	Bending and compression combined..................	0.019528
5	Elongation of tie rod is $\frac{P\,L}{2\,A\,E} = \frac{1 \times 60.121}{5.5 \times 30{,}000}$, or.....	0.000364
6	Total index (items 4 and 5)........................	0.019892
7	The displacement Δ (in inches) of the frame plus the tie rod is $T_{BE} \times 0.019892$, or...........................	1.336
8	The tie-rod force T_{BE} (in kips) is $\frac{1.336}{0.019892}$, or.........	67.0
9	The bending moment M, in kip-inches, is...............	5,360
10	If the tie rod is lengthened 1.20 in., item 5 becomes $\frac{1 \times 60.721}{5.5 \times 30{,}000}$, or..............................	0.000368
11	The tie-rod force (item 8) becomes $\frac{1.336 - 0.60}{0.019896}$, or.....	37.0
12	The corresponding bending moment is.................	2,960

The rectangular frame with two cross walls in Fig. 13 must be analyzed in two separate solutions. The span-end moments due to curvature, computed in Fig. 23(a), are superimposed on the moments due to the differential expan-

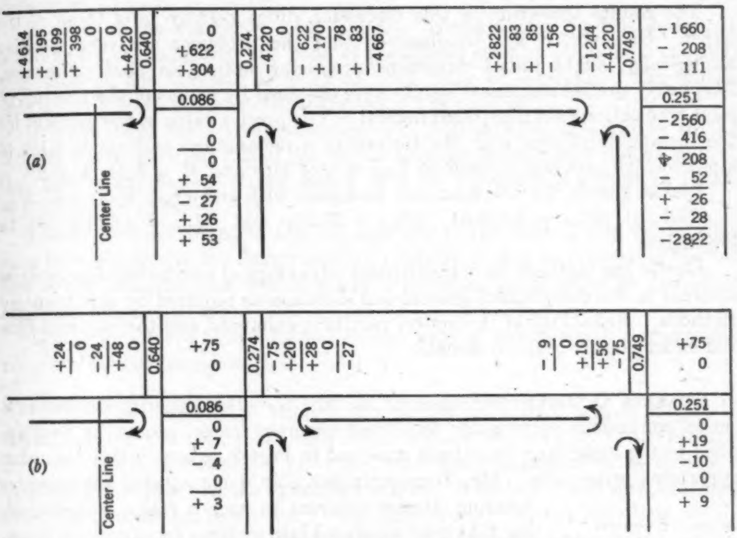

FIG. 23.—RECTANGULAR FRAME WITH TWO CROSS WALLS; CHECK SOLUTION

sion between the cross walls and end walls in Fig. 23(b) to produce the final results in Fig. 24. The magnitude of differential displacement between the ends of the 229.5-in. members is 0.015 in., based on the dimensions shown in Fig. 15. Because the frame is biaxially symmetrical, only one quarter, as shown in Fig. 17(b), will be needed for the solutions since a carry-over can be regarded as reflected back from an axis of symmetry with reversal of sign.

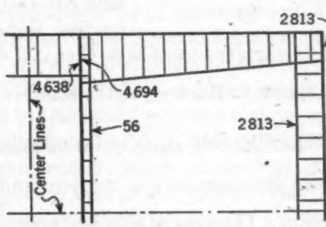

FIG. 24.—FINAL MOMENTS IN KIP-INCHES

The joint coefficients are found in the usual manner and all carry-over factors are 0.5. Fixed-beam moments due to curvature are found by Eq. 25 for each member, and three cycles of operation follow.

The coefficients of the frame having been found, the fixed-beam moments due to end translation are computed by:

$$M_d = \frac{6\,E\,I\,\Delta}{L^2} \qquad (26)$$

and found to be 75 kip-in. for each of the 229.5-in. members when = 0.015 in. Δ

The term is zero for all other members. Two cycles produce precise results.

Combining the results of Figs. 23(*a*) and 23(*b*) and expressing them in accordance with the general sign convention for comparison with Fig. 17(*b*) produces the moments shown in Fig. 24.

The results appearing in this discussion differ slightly from those of the paper. However, it will be observed that the problems are very sensitive numerically, slight initial variations producing noticeable final differences. Absolutely precise numerical results were obtained by means of the theorem of joint translation (not illustrated herein). The precise value of the moment for the rectangular frame with the tie rod in a rectangular position is 5,188.48 kip-in. which produces a value of T_{BE} = 66.8 kips and M = 5,344 kip-in.

Precise results for the span-end moments with two cross walls are: M_{BA} = 4,687.12; M_{AB} = 2,810.64; M_{BH} = 57.61; and M_{BE} = 4,636.6—all in kip-inches.

Elastic line methods have the distinct advantage of eliminating inaccuracies inherent in the complicated geometrical calculations required by elastic energy methods. Reliability of theoretical results is enhanced and the required time and effort greatly reduced thereby.

Charles O. Boynton,[10] Assoc. M. ASCE.—The bending stresses in a closed continuous rectangular reinforced concrete frame, caused by heat applied to the inner face, have been analyzed in Part 2, to which this discussion appertains principally. Mr. Tommerup has ably demonstrated the excessive bending stresses inherent in such a frame, recommending that it be separated into sections by expansion joints.

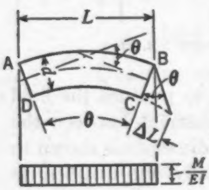

Fig. 25

It should be emphasized that the full magnitude of the uniform bending moment obtains in any part of the beam, however short, when restrained from bending. This condition may be illustrated by reference to Fig. 25, in which ABCD represents any very short part of the beam of length L and depth d, free from restraint. Side AB has been heated t° F hotter than side CD, with relative elongation ΔL. If the temperature coefficient of linear expansion is α, then $\Delta L = \alpha\, t\, L$ and the central angle formed by the tangents to the ends of the elastic curve, $\theta = \frac{\Delta L}{d} = \frac{\alpha\, t\, L}{d}$ (θ being very small).

Let the conjugate beam be loaded with the $\frac{M}{E\,I}$-diagram, M being constant since the curvature is uniform and just sufficient to "straighten" the curved beam. The area of this diagram, $\frac{M\,L}{E\,I}$ by the moment area method equals the angle θ, or $\frac{M\,L}{E\,I} = \frac{\alpha\, t\, L}{d}$ and $M = \frac{\alpha\, t\, E\, I}{d}$. Substituting the author's values, $M = \frac{0.0000079 \times 400 \times 2{,}000{,}000 \times 14{,}230}{20}$ = 4,500,000 in.-lb. This bend-

[10] Engr., Structural Design, Blanchard & Maher-Frederic R. Harris, Inc.-Keller & Gannon, San Francisco, Calif.

ing moment agrees with the author's determination and is about twice the safe resisting moment of the beam. However, had the more common grade of concrete been employed, with E equal to about 3,000,000 lb per sq in., the resulting stresses would be 50% greater.

In view of the extremely large uniform bending stress in this design, it would be logical to destroy the bond of the tensile steel by applying a coating, thus allowing the concrete to crack at very frequent intervals. The tensile bars would help to prevent disintegration of the concrete.

If the ends of the frame are restrained, there will be, in addition to the bending stress, an axial thrust due to an average temperature rise of 200° F, the unit compressive stress being $E \alpha t = 2{,}000{,}000 \times 0.0000079 \times 200 = 3{,}160$ lb per sq in.

The stresses developed in this example are so far beyond safe values that some basic changes in the design would be indicated, such as protecting the hot face of the concrete with firebrick and ventilation, in addition to providing expansion joints.

This paper affords good information on a type of design which is frequently not given careful consideration.

William A. Conwell,[11] M. ASCE.—In analyzing rigid frames subject to thermal action, the author has fully demonstrated the severity of the stresses involved. It is unfortunate, however, that the demonstration is largely a qualitative one rather than a quantitative one. With few exceptions, as stated in the paragraphs following Eq. 7, the stresses are "beyond the limit within which the equations of this paper apply." The stresses encountered are beyond the elastic range, but the methods of analysis are based on elastic behavior and real solution lies only in drastic revision of the type of structure.

The author's method of computing deformations due to thermal action, as demonstrated in Fig. 2 and the subsequent detailed applications to frames, is unique in that it sets aside the usual approximations made in small-angle geometry and treats the problem as a precise surveying layout. This action has forced the author out of the usually accepted method of slide-rule computation and has led him to the statement (in Section 5) that "Displacements must be computed by logarithms, whereas the slide rule offers abundant accuracy for all other numerical values." With a view to determining whether the comparatively large deflections involved in this study required such means of computation, the writer computed the deflections by 10-in. slide rule in the usual manner, as shown in Table 3. The comparison with the author's results (shown in Col. 8, Table 3) would seem to indicate that properly read slide-rule computations can be expected to give reasonably accurate results.

Although it is often desirable and sometimes necessary to know the deflections of a frame under various hypothetical conditions of cutting, support, etc., it is believed that the importance of such deflections has been emphasized unduly in this paper. The designer is first interested in bending moments, shear and axial forces, and then stresses. If these can be obtained without consideration of hypothetical deflection conditions he is usually happy to obtain

[11] Gen. Engr., Structural Eng. and Design Dept., Duquesne Light Co., Pittsburgh, Pa.

them in that manner. *Having obtained these elements of design he may later elect, or be required, to compute the actual deflections, and these furnish real information as to the ultimate action of the structure.

TABLE 3.—COMPARISON OF COMPUTATIONS FOR DEFLECTIONS, SLIDE RULE VERSUS LOGARITHMS, IN THE FRAME OF FIG. 4

Deflections	POINT D IN RELATION TO POINT E		POINT C FROM POINT D		POINT B FROM POINT C		TOTAL, POINT B FROM POINT E	
	Computations	Inches or radians	Computations	Inches or radians	Computations	Inches or radians	Slide rule	Logarithms
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
Δx	0.00316×80	0.2528	$0.000158 \times 120^2 \times \frac{1}{2}$ 0.01264×120	1.137 1.518 2.655	$0.00316 \times (-80)$	−0.2528	2.655	2.720
Δy	$-0.000158 \times 80^2 \times \frac{1}{2}$	−0.506	0.00316×120	0.379	$0.000158 \times 80^2 \times \frac{1}{2}$ 0.0316×80	0.506 2.528 3.034	2.907	2.883
θ	0.000158×80	0.01264	0.000158×120	0.01896	0.000158×80	0.01264	0.04424	0.0442

Section 2 furnishes an example of the emphasis on deflections. In the sixth paragraph of Section 2, prior to the application of the elastic energy equations, the author logically concludes, without reference to deflections, that "Any point of the frame is affected only by a moment that is of uniform magnitude all around." At this point the entire problem may be solved by considering the 1-in. element of the frame shown in Fig. 26. Under thermal action this element tends to assume a wedge shape with its inside fiber $0.0000079 \times 400 \times 1 = 0.00316$ in. longer than the unheated outside fiber. The bending moment induced by this tendency is sufficient to maintain the faces of the element parallel, and is equal to that necessary to turn the face of the element through an angle $d\phi = 0.00316 \times 1/20 = 0.000158$. Such bending moment is quickly determined by substituting known quantities in the expression $d\phi = \frac{M\,ds}{E\,I}$, whence $M = 0.000158 \times 2{,}000{,}000 \times 14{,}230 = 4{,}500{,}000$ in.-lb.

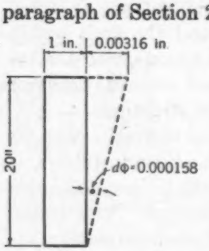

FIG. 26.—DEFORMATION OF THE FRAME ELEMENT

If there is justification for an elaborate computation of thermal deformations, such nicety should be extended to other phases of the calculations. Experience shows that the best results in the solution of statically indeterminate structures are obtained when the same basis is used for each part of the computations. For instance, the use of precise methods in certain steps of a calculation, and not in others, does not necessarily improve the ultimate result over a balanced calculation, on a lower level of accuracy, in which the same factors have been disregarded throughout. The author uses precise methods of calcu-

lation for thermal deformations; but he uses them in connection with the less accurate equations of elastic energy, the derivation of which disregards all quantities resulting from the multiplication of two or more differentials. It is this lack of balance which contributes to the discrepancy between the bending moments of 4,500,000 in.-lb and 4,600,000 in.-lb in Section 2 rather than "the slight approximations made in computing displacements," the reason assigned by the author. In support of this contention is the writer's calculation of the preceding paragraph which checks that made by the author on the basis of angular rotation. In further corroboration of this point of view is the fact that, if the writer's value for Δx (taken from Col. 7, Table 3, as $2 \times 2.655 = 5.310$ in.) is substituted with other known quantities in Eq. 7, a value of 4,500,000 in.-lb, consistent with other balanced calculations, is obtained for M. It is not claimed that these checks, which are the product of consistency, indicate a more accurate value of M; but they certainly enhance the confidence of the designer in his calculations. A more accurate value may be obtained only by conducting a completely balanced calculation on a higher plane, not by improving only one step in the process.

In Section 1 the author states: "Because of the greater ease, member lengths, as a rule, are taken along their inside surfaces." No difficulty is attached to the use of inside surfaces as a basis for calculating thermal deformations except the fact that the comparatively small effect of the corners is thus neglected. Some allowance for corners could have been made by taking member lengths along a plane midway between their outside and inside surfaces, although this in itself is a matter of small moment. Since the bending moment in the frame of Section 2 is dependent only on angular deformations of the frame and not on change in length of the members, the place of measurement of member lengths is immaterial. The same, however, may not be stated of the structures studied in Section 3 and Section 4.

An examination of Fig. 12 reveals that not only have the lengths of the members been taken along their inside faces, but the neutral planes have likewise been taken in that position. The neutral plane of member CD is actually some 90 in. from the line of action of T_{BE} if it is assumed to be about midway between the inner and outer surfaces of the member. This is not a bad assumption. The bending moment actually developed in member CD because $T_{BE} = 36{,}300$ lb would be $36{,}300 \times 90$ or 3,267,000 in.-lb. Although specifications would permit the use of a face-of-support bending moment of 2,900,000 in.-lb in the design of member BC, they would normally require the higher value for member CD; but, more deeply, T_{BE} has been determined on the basis of a bending moment of 2,900,000 in.-lb in member CD and its value would change were the moment other than this value. There is thus some question as to the conformance of the frame analyzed by the author and that which it was intended to investigate. The properties of, and the conditions affecting, the frame analyzed by the author are, upon study and inspection, as follows:

1. Tie member BE is treated substantially as required by the actual design data;
2. Members BC and DE have lengths of 80 in. each and have their neutral planes initially at a distance of 120 in. from each other;

3. Member CD has a length of 120 in. and has its neutral plane 80 in. from the line of action of member BE;
4. Members BC, CD, and DE are subject to the angular deformation resulting from a temperature differential of 400° between their outside and inside faces; and
5. Members BC, CD, and DE are subject to linear expansion resulting from a uniform temperature increase of a full 400° throughout their length.

There is some question as to whether this frame sufficiently conforms to the one being investigated. In the latter, members BC and DE have effective lengths of about 90 in. and member CD, a length of about 140 in. The linear expansion to which each of these members is subject is that resulting from an average increase in temperature of only 200° throughout its length.

A similar situation obtains as regards the frame of Section 4. A study reveals the following with respect to the frame analyzed by the author:

(1) Members AF and GM have lengths of 557 in. each and have their neutral planes initially at a distance of 340 in. from each other;
(2) Members AG and FM have lengths of 340 in. each and have their neutral planes initially at a distance of 557 in. from each other;
(3) Members BH and EL have lengths of 340 in. each and have their neutral planes initially at a distance of 98 in. from each other;
(4) Members AF, GM, AG, and FM are subject to the angular deformations resulting from a temperature differential of 400° between their inside and outside faces; and
(5) All members, not only BH and EL, are subject to linear expansion resulting from a uniform temperature increase of a full 400° throughout their length.

Again there is question as to whether this frame meets the design conditions outlined in Fig. 13; particularly with regard to the fact that spans BH and EL are the only members of the given frame that undergo the full 400° rise in temperature, whereas all other members are subjected to an average increase of only 200°. That this condition is a fact is further borne out by Fig. 15 in which member FM is shown as elongating an amount about equal to that of EL.

With a view to checking the statement of the foregoing paragraph (and, incidentally, demonstrating how well the method of moment distribution lends itself to these problems) a solution was developed for a frame having the foregoing characteristics and represented as the frame actually solved by the author in Section 4. This solution is shown in Fig. 27. The fixed-end moments for each member were determined by the method outlined by the writer in Fig. 26 and the fourth paragraph of this discussion. Moments were distributed in the usual manner. The values are seen to differ somewhat from those of the author but this difference is again the result of the unbalance of elaborate deformation calculations used in conjunction with the ordinary equations of elastic energy. As a means of further checking this point, the writer, in the manner previously demonstrated in Table 3, calculated Δx at point N, Δy at point F, and θ at point F, obtaining 3.19 in., 5.04 in., and 0.08375 radians, re-

spectively. Substitution of these values in Eqs. 16, 18, and 20, and simultaneous solution, yielded the following data which check those obtained by moment distribution: M_D, 4,595,000 in.-lb; M_E, 4,645,000 in.-lb; and M_F, 2,836,000 in.-lb. By methods similar to those used in the treatment of sidesway, any difference in linear expansion between exterior and interior members of this frame may also be easily handled by moment distribution.

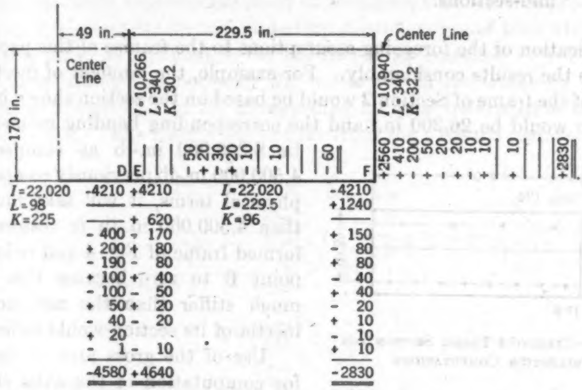

Fig. 27.—Solution, by Moment Distribution, of the Frame Analyzed in Section 4

In the solution of reinforced-concrete structures subject to elastic deformation only, it is not important that the absolute moment of inertia of the section of each member be determined. It is usually sufficient to establish relative values with respect to some base, the most important item being that the same procedure be used in determining the moment of inertia of each member. An example of such procedure is the often-used assumption that each member is adequately reinforced, and, accordingly, that the moments of inertia are proportional to the cubes of the depths of the members.

When other than elastic deformations are involved, as in the present study, determination of the absolute moment of inertia for the purpose of computing deflections is essential. This paper uses the same moment of inertia for calculating deformations as for determining stresses, a procedure which is open to question.[12] After delineating the differences in action between reinforced concrete and homogeneous beams but arriving at the conclusion that it would be desirable to employ the same methods for calculating deflections, F. E. Turneaure, Hon. M. ASCE, and E. R. Maurer specify the following procedure to bring calculated deflections within the range of observed test deflections:[12]

> "For the reasons stated above, the deflection formulas for homogeneous beams will be used for reinforced-concrete beams, but modified in accordance with the following assumptions:
>
> "1. That the representative or mean section has a depth equal to the distance from the top of the beam to the center of the steel;

[12] "Principles of Reinforced Concrete Construction," by F. E. Turneaure and E. R. Maurer, John Wiley & Sons, Inc., New York, N. Y., 3d Ed., 1919, Chapter VI.

"2. That it sustains tension as well as compression, both following the linear law;

"3. That the proper mean modulus of elasticity of the concrete equals the average or secant modulus up to the working compressive stress; and

"4. That the allowance for steel in computing the moment of inertia of the mean section should be based on the amount of steel in the mid-sections."

Application of the foregoing assumptions to the frames of this paper would influence the results considerably. For example, the moment of inertia of the section of the frame of Section 2 would be based on the section shown in Fig. 28. Its value would be 26,200 in.[4] and the corresponding bending moment would be 8,250,000 in.-lb as compared with 4,500,000 in.-lb previously computed. In physical terms, it will take much more than 4,500,000 in.-lb to restore the deformed frame of Fig. 4 and reduce Δx at point B to zero because this frame is much stiffer than the net moment of inertia of its section would indicate.

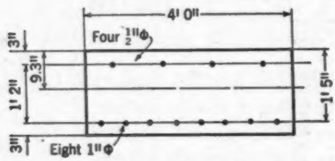

FIG. 28.—EFFECTIVE FRAME SECTION FOR DEFLECTION COMPUTATIONS

Use of the gross area of the section for computation of the axial elastic deformations as employed in this paper is scarcely consistent with the use of net moment of inertia but would fit well into the use of the total section outlined by Messrs. Turneaure and Maurer. (The upper 17 in. of concrete in Fig. 28 is considered effective in both tension and compression, in the computation of deflections.)

As to notation, x and y are defined as horizontal and vertical ordinate distances, while actually all values of x and y lie in a horizontal plane. The symbol m is defined as the moment of a unit force, whereas throughout the paper it is used as the bending moment caused by the various auxiliary forces and moments. Letter symbols $\bar{x}$ and $\bar{y}$ are not defined, although investigation of their use usually discovers their meaning. It is suggested that some definite and compact form of notation be adopted for the undefined quantity "area" which has not the same value for each member of a frame although it seems to have, as it appears in the various equations and formulas, devoid of subscripts or other means of identification.

In paragraph 15 of Section 2 the statement that "when the members of a simple closed frame, of any shape, are subjected to a nonuniform temperature change through their 'depth' (h) they undergo no deformation" should be modified by the words "except axial elongation."

The author states Eq. 14 as four terms, only two of which contain the quantity T'. He then follows with the statement that "The auxiliary force T' might have been assumed as unity at the outset since it cancels * * *." It is not clear how T' can be canceled from an equation when it appears in only two of the four terms. Since the value of the auxiliary force is at the choice of the computer there is no reason why it should not have originally been taken as

unity. In any event it should have been assumed as unity or disposed of by cancellation before it had an opportunity to appear in Eq. 14, which is satisfied only when $T' = 1$.

Another observation which may be made of Eq. 14 is the smallness of the terms expressing axial deformations as compared with that concerned with angular deformations. Although the author normally disregards axial deformations, he has made a particular point of including them in this problem by stating that "For a slender tie rod, stored-up elastic energy of both axial forces and moments must be included in the elastic energy equation * * *." With a view to ascertaining this necessity the writer solved the frame by moment distribution as shown in Fig. 29, disregarding all axial deformation including that of the tie rod. The results are not far from the author's results.

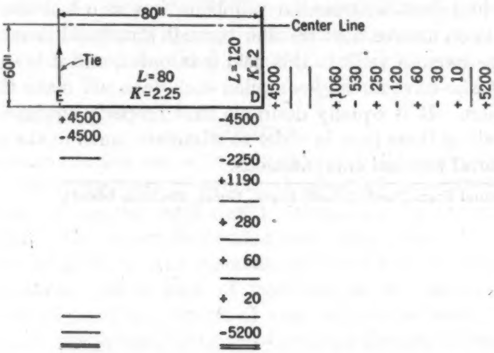

FIG. 29.—SOLUTION BY MOMENT DISTRIBUTION, NEGLECTING ALL AXIAL DEFORMATION; FRAME ANALYZED IN SECTION 3 (I = 14,230 THROUGHOUT; MOMENTS ARE IN INCH-KIPS)

A study of this paper would have been made more facile by inclusion of such basic data as the location of reinforcing rods, the positions of which had to be ascertained in each instance by working back from dimensions which the author substituted in formulas; by including a statement that the values of A, and I given in Table 2 are per-foot height of wall (or that the walls are only 12 in. high); and by avoidance of generalities in the statement of problems such as that in the first paragraph of Section 4: "A cross section through the exterior walls is substantially as shown in Fig. 1(*b*)."

The computations of Section 4 would have been much simplified by making use of both axes of symmetry, taking the midpoint of member EL as a base, cutting the frame at point N and at the midpoint of member FM, and so confining all treatment to the upper right-hand quadrant.

Much of the "Summary" is devoted to a discussion of construction details which were not previously treated and which, accordingly, could well have been placed in a section of their own.

CARL C. H. TOMMERUP,[13] M. ASCE.—Many new ideas, twists, and short cuts have been advanced in the interesting discussions, for which the writer wishes to express his gratitude.

Some of the discussers criticize the fact that the computations in the paper are not sufficiently accurate and that various approximations are made. Be that as it may. A far greater number of engineers have criticized the paper on the ground that the computations were needlessly exact.

Enlightening as the discussions are, the writer is greatly disappointed that the discussers submit so little actual field data on similar problems. By actual data are meant observations, tests, and unusual design features. It seems reasonable to assume that many engineers have in the past been confronted with the same type of problem in one form or another.

The paper was submitted in the hope of extracting replies from engineers who not only had dealt with similar problems, but who had also collected experimental data on uneven heat transfer through structural members. A large amount of experimental work in this field is in order, and it is sincerely hoped that engineers who have already compiled such data will make them available to the profession. It is equally desirable that properly equipped institutions conduct tests along these lines in order to eliminate much of the present guesswork in structural thermal computations.

MATRIX ANALYSIS OF CONTINUOUS BEAMS

By Stanley U. Benscoter,[1] Assoc. M. ASCE

With Discussion by Messrs. I. Oesterblom, Harris Solman, Rufus Oldenburger, Horace A. Johnson, Lloyd T. Cheney, Paul W. Norton, A. Floris, Sven Olof Asplund, and Stanley U. Benscoter.

Synopsis

An introduction to the use of matrix algebra in the development and explanation of various methods of structural analysis is presented in this paper. The possibilities of making rapid design calculations by matrix methods are also illustrated. The paper is divided into four parts: In the first part an explanation is given of the elementary operations of addition, subtraction, multiplication, and division of matrices; in the second part a general formula is derived for the solution of any continuous beam (on unyielding supports) in matrix notation; in the third part the moment distribution process is developed by matrix algebra; and in the fourth part two successive correction methods of computation which may be regarded as variations of the method of moment distribution are illustrated and discussed.

PART I. ELEMENTARY OPERATIONS

Introduction

Matrix algebra may be regarded as a "shorthand" technique for representing a system of linear equations by a single equation and then solving that single equation. The rules of matrix algebra provide a computational procedure which is often more rapid than the numerical processes in common usage. Since all indeterminate structures are governed by systems of linear equations, the possibility of useful application of matrix methods by the structural engineer is suggested. The ability of the reader to understand, appreciate, and evaluate the matrix methods presented in this paper will be dependent, in a large measure, on his willingness to familiarize himself with the elementary operations. These mechanical procedures can be learned only by practice on

Note.—Published in October, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Aeronautical Engr., Bureau of Aeronautics, Washington, D. C.

numerical examples, just as the mechanical procedure of moment distribution must be learned.

Evaluation of Determinants

It is essential that the reader recall the process of evaluating a determinant. The determinant of A is a square array of numbers which is written in the following form:

$$|A| = \begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix} \qquad (1)$$

In order that the reader may check his ability to evaluate determinants, the following examples are given of second-order and third-order determinants:

$$\begin{vmatrix} 3 & 1 \\ 2 & 4 \end{vmatrix} = 12 - 2 = 10 \qquad (2a)$$

and

$$\begin{vmatrix} 5 & 1 & 2 \\ 0 & 3 & 1 \\ 1 & 2 & 4 \end{vmatrix} = 5 \times 10 - 1 \times (-1) + 2 \times (-3) = 45 \qquad (2b)$$

Addition and Subtraction of Matrices

A matrix is also an array of numbers, but it may be either square or rectangular. A matrix will be indicated by a bracket and written in the following form:

$$[A] = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix} \qquad (3)$$

The subscripts of the elements of the matrix or determinant are chosen so that the first subscript corresponds to the row containing the element and the second subscript corresponds to the column. To make use of matrices it is necessary to know the rules for addition, subtraction, multiplication, and division of matrices. These rules will be stated as simply as possible and should be learned by application to numerical cases.

Consider the matrix $[A]$ in Eq. 3 and the matrix $[B]$ given in the following form:

$$[B] = \begin{bmatrix} b_{11} & b_{12} & b_{13} \\ b_{21} & b_{22} & b_{23} \\ b_{31} & b_{32} & b_{33} \end{bmatrix} \qquad (4)$$

If the matrices $[A]$ and $[B]$ are added, a matrix $[C]$ is obtained and $[C]$ is also a 3×3 array of numbers:

$$[A] + [B] = [B] + [A] = [C] \qquad (5)$$

in which

$$[C] = \begin{bmatrix} c_{11} & c_{12} & c_{13} \\ c_{21} & c_{22} & c_{23} \\ c_{31} & c_{32} & c_{33} \end{bmatrix} \qquad (6)$$

Each element of $[C]$ is obtained by adding the corresponding elements of $[A]$

and [B]. Thus, the elements of [C] are computed as follows:

$$c_{11} = a_{11} + b_{11} \quad \text{(7a)}$$

$$c_{12} = a_{12} + b_{12} \quad \text{(7b)}$$

$$c_{13} = a_{13} + b_{13} \quad \text{(7c)}$$

etc. Matrices are subtracted in the same manner.

The following examples illustrate the processes of addition and subtraction; let

$$[M] = \begin{bmatrix} 2 & 1 \\ 1 & 3 \end{bmatrix}; \text{ and } [N] = \begin{bmatrix} 1 & 0 \\ 2 & 4 \end{bmatrix} \quad \text{(8)}$$

then

$$[S] = [M] + [N] = \begin{bmatrix} 3 & 1 \\ 3 & 7 \end{bmatrix} \quad \text{(9)}$$

and

$$[T] = [M] - [N] = \begin{bmatrix} 1 & 1 \\ -1 & -1 \end{bmatrix} \quad \text{(10)}$$

Multiplication of Matrices

If the matrices [A] and [B] are multiplied, a matrix [D] is obtained which is also a 3×3 array of numbers:

$$[A][B] = [D] \quad \text{(11)}$$

in which

$$[D] = \begin{bmatrix} d_{11} & d_{12} & d_{13} \\ d_{21} & d_{22} & d_{23} \\ d_{31} & d_{32} & d_{33} \end{bmatrix} \quad \text{(12)}$$

The elements of [D] are computed from the elements of [A] and [B] by using the "row by column" rule. The rows of [A] are multiplied by the columns of [B]. The row of [A] to be used corresponds to the row of the element of [D] being computed and the column of [B] to be used corresponds to the column of the element of [D]. Thus, d_{11} is computed by multiplying the first row of [A] by the first column of [B]. This multiplication may be indicated by

$$d_{11} = [a_{11}\ a_{12}\ a_{13}] \begin{bmatrix} b_{11} \\ b_{21} \\ b_{31} \end{bmatrix} \quad \text{(13)}$$

These quantities are multiplied by adding the products of corresponding elements:

$$d_{11} = a_{11}\,b_{11} + a_{12}\,b_{21} + a_{13}\,b_{31} \quad \text{(14)}$$

A curious but important property of matrices is that they are noncommutative in multiplication. Thus, in general, the product [A][B] does not equal the product [B][A]. This property of matrices deserves emphasis since the structural engineer is not accustomed to dealing with noncommutative numbers.

The following example illustrates the process of multiplication; let

$$[A] = \begin{bmatrix} 2 & 0 \\ 1 & 4 \end{bmatrix}; \text{ and } [B] = \begin{bmatrix} 1 & 2 \\ 3 & 1 \end{bmatrix} \qquad (15)$$

then

$$[A][B] = \begin{bmatrix} 2 & 0 \\ 1 & 4 \end{bmatrix}\begin{bmatrix} 1 & 2 \\ 3 & 1 \end{bmatrix} = \begin{bmatrix} 2 & 4 \\ 13 & 6 \end{bmatrix} \qquad (16a)$$

and

$$[B][A] = \begin{bmatrix} 1 & 2 \\ 3 & 1 \end{bmatrix}\begin{bmatrix} 2 & 0 \\ 1 & 4 \end{bmatrix} = \begin{bmatrix} 4 & 8 \\ 7 & 4 \end{bmatrix} \qquad (16b)$$

Eqs. 16 show how the reversal of the order of multiplication gives a different answer. Two more examples will illustrate the multiplication of rectangular matrices:

$$\begin{bmatrix} 3 & 2 & 4 \\ 2 & 0 & 1 \end{bmatrix}\begin{bmatrix} 1 & 2 \\ 0 & 1 \\ 1 & 3 \end{bmatrix} = \begin{bmatrix} 7 & 20 \\ 3 & 7 \end{bmatrix} \qquad (17)$$

$$\begin{bmatrix} 2 & 1 & 0 \\ 1 & 3 & 2 \end{bmatrix}\begin{bmatrix} 2 \\ 1 \\ 4 \end{bmatrix} = \begin{bmatrix} 5 \\ 13 \end{bmatrix} \qquad (18)$$

In Eq. 17 a 3×2 matrix is multiplied by a 2×3 matrix and the result is a square 2×2 matrix. In Eq. 18, a 3×2 matrix is multiplied by a column matrix, commonly called a column vector. The result is a column vector of two elements. The elements of a column vector are frequently called the components of the vector. The reader should attempt to multiply the matrices in Eqs. 17 and 18 in reverse order. In the first case the multiplication is possible whereas in the second case it is impossible. The first matrix in a multiplication must have the same number of columns as there are rows in the second matrix.

If a matrix is to be multiplied by a constant, each element of the matrix must be multiplied by the constant. Thus,

$$2\begin{bmatrix} 2 & 1 \\ 0 & 3 \end{bmatrix} = \begin{bmatrix} 4 & 2 \\ 0 & 6 \end{bmatrix} \qquad (19)$$

Division of Matrices

To explain the process of dividing matrices, it is necessary to introduce the following definitions which are applicable only to square matrices:

1. The "principal diagonal" of a matrix is the set of elements extending from the upper left-hand corner to the lower right-hand corner.

2. The "transpose" of $[A]$ is obtained by rotating $[A]$ about its principal diagonal. The rows and colums thus become interchanged. A transpose is indicated by a prime. Thus,

$$[A] = \begin{bmatrix} 2 & 7 \\ 3 & 1 \end{bmatrix}; \text{ and } [A]' = \begin{bmatrix} 2 & 3 \\ 7 & 1 \end{bmatrix} \qquad (20)$$

3. A matrix is "symmetrical" if the matrix is equal to its transpose. Thus,

$$[A] = \begin{bmatrix} 2 & 3 \\ 3 & 6 \end{bmatrix}; \text{ and } [A] = [A]' \quad \text{.......... (21)}$$

4. Corresponding to each element of a matrix (or determinant) there is a "minor" which is obtained by striking out the row and column of the matrix (or determinant) containing the element. The minor corresponding to an element of a matrix (or determinant) is a determinant that can be evaluated to obtain an ordinary number. Considering the determinant of Eq. 1 or the matrix of Eq. 3, the following minors illustrate the definition:

$$\text{Minor corresponding to } a_{11} = \begin{vmatrix} a_{22} & a_{23} \\ a_{32} & a_{33} \end{vmatrix} \quad \text{.......... (22a)}$$

and

$$\text{Minor corresponding to } a_{12} = \begin{vmatrix} a_{21} & a_{23} \\ a_{31} & a_{33} \end{vmatrix} \quad \text{.......... (22b)}$$

5. The "cofactor" of an element of a matrix (or determinant) is the signed minor corresponding to that element. A "signed minor" is a minor with the appropriate sign, either plus or minus, prefixed. The proper sign for the cofactor of the first element a_{11} is positive. The signs for the cofactors of the other elements alternate according to their position relative to a_{11}. Thus, the cofactor of a_{12} is negative, that of a_{13} is positive, that of a_{21} is negative, etc. It is convenient to use a corresponding capital letter to indicate a cofactor. Thus,

$$\text{Cofactor of } a_{11} = A_{11} = + \begin{vmatrix} a_{22} & a_{23} \\ a_{32} & a_{33} \end{vmatrix} \quad \text{.......... (23a)}$$

and

$$\text{Cofactor of } a_{12} = A_{12} = - \begin{vmatrix} a_{21} & a_{23} \\ a_{31} & a_{33} \end{vmatrix} \quad \text{.......... (23b)}$$

6. The "adjoint" of a matrix $[A]$ is the matrix obtained by replacing each element of $[A]$ by its cofactor and then transposing the matrix. Thus,

$$\text{Adjoint of } [A] = \begin{bmatrix} A_{11} & A_{21} & A_{31} \\ A_{12} & A_{22} & A_{32} \\ A_{13} & A_{23} & A_{33} \end{bmatrix} \quad \text{.......... (24)}$$

The following numerical example is an illustration:

$$[A] = \begin{bmatrix} 2 & 3 & 0 \\ 1 & 2 & 1 \\ 2 & 4 & 3 \end{bmatrix} \quad \text{.......... (25)}$$

$$\text{Adjoint of } [A] = \begin{bmatrix} 2 & -9 & 3 \\ -1 & 6 & -2 \\ 0 & -2 & 1 \end{bmatrix} \quad \text{.......... (26)}$$

7. The "unit matrix" is a matrix in which the elements on the principal diagonal are 1's whereas the remaining elements are 0's. It is indicated by

[I]; thus,

$$[I] = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \ldots\ldots\ldots\ldots\ldots\ldots (27)$$

This matrix is also called the identity matrix. It plays a part in the algebraic manipulation of matrices which is similar to the part played by unity in the algebra of ordinary numbers. With ordinary numbers:

$$1 \times a = a \times 1 = a \ldots\ldots\ldots\ldots\ldots\ldots (28)$$

With matrices:

$$[I][A] = [A][I] = [A] \ldots\ldots\ldots\ldots\ldots\ldots (29)$$

The verity of Eq. 29 can be easily demonstrated by applying the "row by column" rule to a numerical example.

8. The "reciprocal" (or "inverse") of [A] is a matrix which, when multiplied by [A], produces the unit matrix. Thus,

$$[A][A]^{-1} = [A]^{-1}[A] = [I] \ldots\ldots\ldots\ldots\ldots\ldots (30)$$

The following example can be checked by the "row by column" rule for multiplication:

$$[A] = \begin{bmatrix} 2 & 1 \\ 5 & 4 \end{bmatrix}; \text{ and } [A]^{-1} = \begin{bmatrix} 4/3 & -1/3 \\ -5/3 & 2/3 \end{bmatrix} \ldots\ldots\ldots (31)$$

Multiplying [A] by [A]$^{-1}$ gives:

$$[A][A]^{-1} = \begin{bmatrix} 2 & 1 \\ 5 & 4 \end{bmatrix} \begin{bmatrix} 4/3 & -1/3 \\ -5/3 & 2/3 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \ldots\ldots\ldots (32)$$

The foregoing definition of a reciprocal gives no clue as to how it can be obtained. The formula for computing the reciprocal of a matrix is as follows:

$$[A]^{-1} = \frac{\text{Adjoint of } [A]}{|A|} \ldots\ldots\ldots\ldots\ldots\ldots (33)$$

The reciprocal is equal to the adjoint divided by the determinant. Considering the example of Eq. 31,

$$\text{Adjoint of } [A] = \begin{bmatrix} 4 & -1 \\ -5 & 2 \end{bmatrix} \ldots\ldots\ldots\ldots\ldots\ldots (34)$$

and

$$|A| = 2 \times 4 - 1 \times 5 = 3 \ldots\ldots\ldots\ldots\ldots\ldots (35)$$

Substituting into Eq. 33, the reciprocal is obtained as given in Eq. 31.

The process of division can now be explained. If [B] is to be divided by [A], the result may be obtained by multiplying [B] by [A]$^{-1}$. This multiplication can be performed in two ways: [B] can be premultiplied by [A]$^{-1}$ as indicated by [A]$^{-1}$[B], or it can be postmultiplied by [A]$^{-1}$ to obtain [B][A]$^{-1}$. In general, these two methods of multiplication will give two different results. Consequently, it should be apparent that a representation of

division by writing a fraction, such as $\frac{[B]}{[A]}$, would be ambiguous and hence not permissible. Whenever a matrix equation is to be divided by $[A]$, either every term in the equation must be premultiplied by $[A]^{-1}$, or every term in the equation must be postmultiplied by $[A]^{-1}$.

Solution of Simultaneous Equations

The usefulness of matrix algebra in solving simultaneous equations can now be explained. Consider the following system of three equations in three unknowns:

$$3x_1 + x_2 - 2x_3 = 2 \qquad (36a)$$

$$x_1 + 2x_2 + 3x_3 = 1 \qquad (36b)$$

$$2x_1 - x_2 + 4x_3 = 3 \qquad (36c)$$

Eqs. 36 can be expressed, by using matrices, in the following manner:

$$\begin{bmatrix} 3 & 1 & -2 \\ 1 & 2 & 3 \\ 2 & -1 & 4 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 2 \\ 1 \\ 3 \end{bmatrix} \qquad (37)$$

If the matrices are multiplied, and corresponding elements on each side of the matrix equation are then equated, the original Eqs. 36 will be reproduced.

Introduce the following definition:

$$[A] = \begin{bmatrix} 3 & 1 & -2 \\ 1 & 2 & 3 \\ 2 & -1 & 4 \end{bmatrix} \qquad (38a)$$

with

$$[x] = \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix}; \text{ and } [k] = \begin{bmatrix} 2 \\ 1 \\ 3 \end{bmatrix} \qquad (38b)$$

Eq. 37 becomes

$$[A][x] = [k] \qquad (39)$$

The original system of linear algebraic equations has now been reduced to a single linear matrix equation. Eq. 39 is solved by multiplying through by $[A]^{-1}$. Thus,

$$[A]^{-1}[A][x] = [A]^{-1}[k] \qquad (40a)$$

or

$$[I][x] = [A]^{-1}[k] \qquad (40b)$$

or

$$[x] = [A]^{-1}[k] \qquad (40c)$$

Eq. 40c gives the values of the components of the column vector $[x]$ by a simple multiplication of matrices, provided $[A]^{-1}$ can be determined. Following the rules and definitions previously given, $[A]^{-1}$ can be computed as

$$[A]^{-1} = \frac{1}{45} \begin{bmatrix} 11 & -2 & 7 \\ 2 & 16 & -11 \\ -5 & 5 & 5 \end{bmatrix} \qquad (41)$$

Eq. 40c becomes

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \frac{1}{45}\begin{bmatrix} 11 & -2 & 7 \\ 2 & 16 & -11 \\ -5 & 5 & 5 \end{bmatrix}\begin{bmatrix} 2 \\ 1 \\ 3 \end{bmatrix} \ldots\ldots\ldots\ldots(42)$$

By performing the multiplication indicated on the right, the following values of x_1, x_2, and x_3 can be obtained:

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 41/45 \\ -13/45 \\ -2/9 \end{bmatrix} \ldots\ldots\ldots\ldots(43a)$$

or

$$x_1 = \frac{41}{45}\ ;\ x_2 = \frac{-13}{45}\ ;\ \text{and } x_3 = \frac{2}{9} \ldots\ldots\ldots\ldots(43b)$$

Since continuous structures are governed by linear algebraic equations, it should be apparent that matrix algebra may provide a useful technique for dealing with certain types of structures.

PART II. GENERAL MATRIX FORMULAS FOR CONTINUOUS BEAMS

Introduction

An analysis of a continuous beam will be developed in matrix notation on the assumption that the supports do not deflect. If the reactions of a continuous beam can be determined, the values of bending moments and shears at various sections can be calculated by statics; or, if the bending moment over each support can be determined, the moments and shears at various sections can likewise be determined. Many methods of analysis of continuous beams have been developed. In each method certain fundamental quantities appear which must be determined for each span individually. These fundamental quantities are dependent on the physical properties of the beam and on the loads in the spans. Consequently, it is necessary first to consider an individual span. The algebraic relationships between the fundamental quantities that appear in various methods of continuous beam analysis have been shown by Fang-Yin Tsai.[2]

Column Analogy

A development of the properties of a single span may begin by considering either a simply-supported beam or a fixed-end beam. The latter case will be used. Any complete group of characteristics of a fixed-end beam can be expressed in terms of five fundamental properties. Three of these properties are functions of the physical shape of the beam and two of them are dependent on both the beam shape and the loading. The column analogy method,[3] which was introduced by Hardy Cross, M. ASCE, offers a very convenient notation for stating these beam properties in a general case. Fig. 1 shows a nonpris-

[2] *Transactions*, ASCE, Vol. 102, 1937, p. 44.

[3] "The Column Analogy," by Hardy Cross, *Bulletin No. 215*, Eng. Experiment Station, Univ. of Illinois, Urbana, 1932.

matic beam with its load, the corresponding statical moment diagram, the analogous column section, and the indeterminate moment diagram. The diagrams of m_s and m_i have thicknesses normal to the paper equal to the thickness of the analogous column at a corresponding point.

The center of gravity of the analogous column section is indicated in Fig. 1(*c*). This point is considered as the origin of coordinates with x measured positive to the right. The distances to the extreme fibers are shown as c_a and c_b, the former being a negative number. The five fundamental properties are: (*a*) The load P_o on the analogous column, (*b*) its first moment about some reference axis, (*c*) the area of the analogous column A_o, (*d*) its first moment, and (*e*) its second moment.

Corresponding to the fiber distances c_a and c_b, two section moduli S_a and S_b can be defined by

$$S_a = \frac{I_o}{c_a}\text{, and } S_b = \frac{I_o}{c_b}. \quad (44)$$

in which I_o is the moment of inertia of the column section.

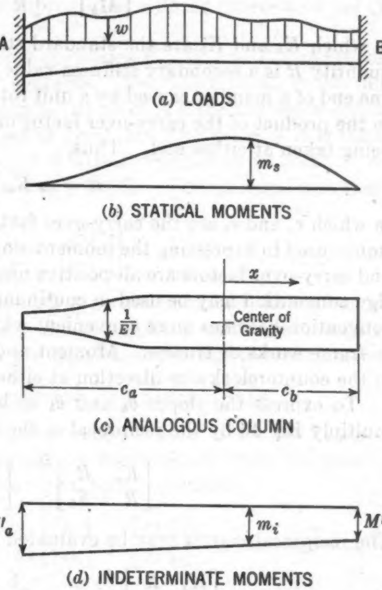

FIG. 1.—COLUMN ANALOGY FOR A SINGLE-SPAN BEAM

The modulus S_a is a negative number since I_o is always positive.

The end moments may be expressed in matrix notation as follows:

$$\begin{bmatrix} M'_a \\ M'_b \end{bmatrix} = \begin{bmatrix} A^{-1}_o & S^{-1}_a \\ A^{-1}_o & S^{-1}_b \end{bmatrix} \begin{bmatrix} P_o \\ M_o \end{bmatrix} \quad \text{.................. (45)}$$

in which M_o is the moment acting on the analogous column, or the moment of P_o about the origin. The column analogy method uses a bending-moment sign convention which defines positive moment as that producing compressive stress in the top fiber. The prime on a moment (M') indicates the fixed-end value of the moment.

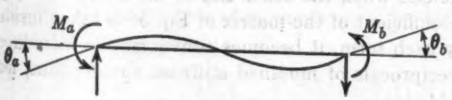

FIG. 2.—ELASTIC CURVE OF AN UNLOADED SPAN

END ROTATION EFFECT

Next it is necessary to consider the relationship between end moments and end slopes for a single span. Fig. 2 shows an unloaded span with applied end moments. The end moments and end slopes are linearly related. Each end

moment may be expressed as a linear function of the two end slopes, or each end slope may be expressed as a linear function of the two end moments. The former relationship may be written in matrix notation as

$$\begin{bmatrix} M_a \\ M_b \end{bmatrix} = \begin{bmatrix} K_a & R \\ R & K_b \end{bmatrix} \begin{bmatrix} \theta_a \\ \theta_b \end{bmatrix} \dots\dots\dots\dots\dots\dots (46)$$

in which K_a and K_b are the standard stiffness values for the member and the quantity R is a secondary stiffness value which gives the change in moment at one end of a member caused by a unit rotation at the opposite end. It is equal to the product of the carry-over factor multiplied by the stiffness, these values being taken at either end. Thus,

$$R = r_a K_a = r_b K_b \dots\dots\dots\dots\dots\dots (47)$$

in which r_a and r_b are the carry-over factors. A statical moment sign convention is used in expressing the moment-slope relationship. (The stiffness values and carry-over factors are all positive numbers.) Although a bending moment sign convention may be used in continuous beam analysis, the statical moment convention becomes more convenient when the method of analysis is extended to frame works or trusses. Moment and slope are both chosen to be positive in the counterclockwise direction at either end of the member.

To express the slopes θ_a and θ_b as linear functions of the end moments, multiply Eq. 46 by the reciprocal of the coefficient matrix; thus,

$$\begin{bmatrix} K_a & R \\ R & K_b \end{bmatrix}^{-1} \begin{bmatrix} M_a \\ M_b \end{bmatrix} = \begin{bmatrix} \theta_a \\ \theta_b \end{bmatrix} \dots\dots\dots\dots\dots\dots (48)$$

The reciprocal matrix may be evaluated to give

$$\begin{bmatrix} K_a & R \\ R & K_b \end{bmatrix}^{-1} = \frac{1}{K_a K_b - R^2} \begin{bmatrix} K_b & -R \\ -R & K_a \end{bmatrix} \dots\dots\dots\dots (49)$$

That is,

$$\begin{bmatrix} K_a & R \\ R & K_b \end{bmatrix}^{-1} = \frac{1}{D K_a K_b} \begin{bmatrix} K_b & -R \\ -R & K_a \end{bmatrix} \dots\dots\dots\dots (50)$$

in which D is the end rotation constant[4] (commonly indicated by $1/C$) for the beam corresponding to simply-supported end conditions and is given by the formula:

$$D = 1 - r_a r_b \dots\dots\dots\dots\dots\dots (51)$$

The product of the end rotation constant D and the standard stiffness value of a beam gives a modified stiffness value which is the moment required to produce a unit rotation at one end when the other end of the beam is simply supported. When the scalar coefficient of the matrix of Eq. 50 is taken inside the bracket and multiplied by each term, it becomes convenient to introduce new letters to represent the reciprocals of modified stiffness values; thus, let

$$\phi_a = \frac{1}{D K_a} ; \phi_b = \frac{1}{D K_b} ; \text{and } \gamma = \frac{R}{D K_a K_b} \dots\dots\dots\dots (52)$$

[4] "Continuous Frames of Reinforced Concrete," by Hardy Cross and N. D. Morgan, John Wiley & Sons, Inc., New York, N. Y., 1932, p. 119.

Eq. 48 now becomes

$$\begin{bmatrix} \theta_a \\ \theta_b \end{bmatrix} = \begin{bmatrix} \phi_a & -\gamma \\ -\gamma & \phi_b \end{bmatrix} \begin{bmatrix} M_a \\ M_b \end{bmatrix} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (53)$$

By Eq. 46, each end moment is expressed as a linear function of the two end slopes. By Eq. 53, each end slope is expressed as a linear function of the two end moments.

The numerical values of the stiffness quantities K_a, K_b, and R may be computed by using the column analogy concepts. The value of K_a is the indeterminant moment that would be computed at point A if the analogous column is loaded with a unit concentrated load at point A. The value of R is the indeterminant moment computed at point B with the unit load at point A, and K_b is determined by placing the unit load at point B. Thus, the stiffness values are given by

$$\begin{bmatrix} K_a & R \\ R & K_b \end{bmatrix} = \begin{bmatrix} A^{-1}{}_a & S^{-1}{}_a \\ A^{-1}{}_a & S^{-1}{}_b \end{bmatrix} \begin{bmatrix} 1 & 1 \\ c_a & c_b \end{bmatrix} \ldots\ldots\ldots\ldots\ldots (54)$$

Since the quantities on the right side of Eq. 54 are in accord with a bending moment sign convention, the quantity R as computed will have a negative sign. This sign should be ignored in a statical moment sign convention.

Slope-Deflection Equations for Single Span

The next step in the analysis requires consideration of a loaded span as shown in Fig. 3. The end moments may be expressed as linear functions of the end slopes as before, but a constant term must be added:

$$\begin{bmatrix} M_a \\ M_b \end{bmatrix} = \begin{bmatrix} K_a & R \\ R & K_b \end{bmatrix} \begin{bmatrix} \theta_a \\ \theta_b \end{bmatrix} + \begin{bmatrix} M'_a \\ M'_b \end{bmatrix} \ldots\ldots\ldots\ldots\ldots (55)$$

The elements M'_a and M'_b of the column vector that has been added to Eq. 46 to obtain Eq. 55 represent the values of M_a and M_b when both θ_a and θ_b are zero. Thus, M'_a and M'_b are the fixed-end moments for the given loading and are calculated as shown by Eq. 45. (The values of M'_a and M'_b in Eq. 45 have their signs in accord with a bending moment sign convention and must be changed to a statical moment convention.) Eq. 55 is a special case of the general slope-deflection equations which include an additional term for the effect of relative end, or joint, translation.

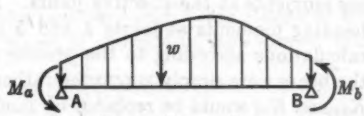

Fig. 3.—Loaded Span

It is also possible to use Eq. 53 rather than Eq. 46 to obtain an expression for end slopes in terms of moments for a loaded beam. As before, a constant term is added to obtain

$$\begin{bmatrix} \theta_a \\ \theta_b \end{bmatrix} = \begin{bmatrix} \phi_a & -\gamma \\ -\gamma & \phi_b \end{bmatrix} \begin{bmatrix} M_a \\ M_b \end{bmatrix} + \begin{bmatrix} \theta'_a \\ \theta'_b \end{bmatrix} \ldots\ldots\ldots\ldots\ldots (56)$$

The elements θ'_a and θ'_b of the column vector that has been added to Eq. 53 to obtain Eq. 56 represent the values of θ_a and θ_b when both M_a and M_b are

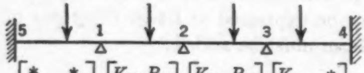
zero. Thus, θ'_a and θ'_b are the simple beam end slopes for the given loading. To evaluate θ'_a and θ'_b, the fixed-end beam is first considered with end moments M'_a and M'_b. If it is now assumed that a moment $-M'_a$ is applied at end A and a moment $-M'_b$ is applied at end B, then the fixed-end beam becomes a simply-supported beam with zero end moments. The angles through which each end rotates, such as $-M'_a$ and $-M'_b$ are applied, will be the angles θ'_a and θ'_b. Therefore, the angles θ'_a and θ'_b are linear functions of $-M'_a$ and $-M'_b$. This relationship is expressed by Eq. 53 as follows:

$$\begin{bmatrix} \theta'_a \\ \theta'_b \end{bmatrix} = -\begin{bmatrix} \phi_a & -\gamma \\ -\gamma & \phi_b \end{bmatrix} \begin{bmatrix} M'_a \\ M'_b \end{bmatrix} \dots\dots\dots\dots\dots (57)$$

This linear relationship between simple beam end slopes and fixed-end moments, for a given loading, has some usefulness in practical design work. It provides a convenient procedure for computing end slopes that are not well known to the designer from stiffness values and fixed-end moments which are well known, either by formula for prismatic beams or by graphical representations for nonprismatic beams.

Slope-Deflection Equations for Entire Beam

A four-span continuous beam is now to be considered as shown in Fig. 4. Beneath each span is shown a 2×2 matrix of stiffness values for the span corresponding to the coefficient matrix of Eq. 46. Since the ends of the beam are fixed, the rotation of joints 4 and 5 is known to be zero. Thus, there are only three effective joints. Only one of the two slope-deflection equations for the end spans and one of the stiffness values for the end spans are needed in determining the bending moments at the effective joints. As a secondary part of the solution, the bending moments at joints 4 and 5 can be computed by proper carry-over calculations according to the process of moment distribution. If the ends of the beam were simply supported rather than fixed, the standard stiffness values K_{15} and K_{34} would be replaced by modified stiffness values using the appropriate end rotation constant. The joints have been numbered by beginning with the first effective joint and continuing consecutively.



$$\begin{bmatrix} * & * \\ * & K_{15} \end{bmatrix} \begin{bmatrix} K_{12} & R_{12} \\ R_{21} & K_{21} \end{bmatrix} \begin{bmatrix} K_{23} & R_{23} \\ R_{32} & K_{32} \end{bmatrix} \begin{bmatrix} K_{34} & * \\ * & * \end{bmatrix}$$

Fig 4.—Four-Span Beam, with Stiffness Values

It should be noted that, in dealing with the continuous beam, the necessity arises for using double subscripts on the stiffness values. The first subscript corresponds to the joint, or support, and the second subscript indicates the member. The 2×2 matrices shown in Fig. 4 are symmetrical; and, hence,

$$R_{23} = R_{32}; \text{ and } R_{34} = R_{43} \dots\dots\dots\dots\dots (58)$$

Bending moments will also require double subscripts whereas joint rotations will require only a single subscript.

It is now necessary to define several column vectors. Consider first that the fixed-end moments at the left end of each member form a column vector

$[M'_a]$ and the fixed-end moments at the right end of each member form a column vector $[M'_b]$. Thus,

$$[M'_a] = \begin{bmatrix} M'_{12} \\ M'_{23} \\ M'_{34} \end{bmatrix}; \text{ and } [M'_b] = \begin{bmatrix} M'_{15} \\ M'_{21} \\ M'_{32} \end{bmatrix} \quad (59)$$

Define similar vectors of the actual moments by

$$[M_a] = \begin{bmatrix} M_{12} \\ M_{23} \\ M_{34} \end{bmatrix}; \text{ and } [M_b] = \begin{bmatrix} M_{15} \\ M_{21} \\ M_{32} \end{bmatrix} \quad (60)$$

Also define a column vector of joint rotations by

$$[\theta] = \begin{bmatrix} \theta_1 \\ \theta_2 \\ \theta_3 \end{bmatrix} \quad (61)$$

Only the effective joints are included. The vectors $[M_a]$ and $[M_b]$ can be shown to be linear matrix functions of the vector $[\theta]$. Hence,

$$[M_a] = [K_a][\theta] + [M'_a] \quad (62a)$$

and

$$[M_b] = [K_b][\theta] + [M'_b] \quad (62b)$$

The similarity in form between Eqs. 62 and Eq. 55 for a single span should be noted. The vector $[M'_a]$ is the value of the vector $[M_a]$ when all elements, or components, of the vector $[\theta]$ are zero. The coefficient matrices $[K_a]$ and $[K_b]$ have been introduced and must be defined. Each is a 3×3 matrix composed of stiffness values properly chosen from Fig. 4. The matrix $[K_a]$ is formed in the following manner: Take the first row of elements of each 2×2 matrix in Fig. 4 and write them one below another—each being staggered one place to the right. Fill the remaining places of the matrix thus formed with zeros. The result is

$$[K_a] = \begin{bmatrix} K_{12} & R_{12} & 0 \\ 0 & K_{23} & R_{23} \\ 0 & 0 & K_{34} \end{bmatrix} \quad (63a)$$

Using the second row of elements of each 2×2 matrix of Fig. 4, the vector $[K_b]$ is formed as

$$[K_b] = \begin{bmatrix} K_{15} & 0 & 0 \\ R_{21} & K_{21} & 0 \\ 0 & R_{32} & K_{32} \end{bmatrix} \quad (63b)$$

To demonstrate that Eqs. 62 are true they will be written out in full; thus,

$$\begin{bmatrix} M_{12} \\ M_{23} \\ M_{34} \end{bmatrix} = \begin{bmatrix} K_{12} & R_{12} & 0 \\ 0 & K_{23} & R_{23} \\ 0 & 0 & K_{34} \end{bmatrix} \begin{bmatrix} \theta_1 \\ \theta_2 \\ \theta_3 \end{bmatrix} + \begin{bmatrix} M'_{12} \\ M'_{23} \\ M'_{34} \end{bmatrix} \quad (64a)$$

and

$$\begin{bmatrix} M_{15} \\ M_{21} \\ M_{32} \end{bmatrix} = \begin{bmatrix} K_{15} & 0 & 0 \\ R_{21} & K_{21} & 0 \\ 0 & R_{32} & K_{32} \end{bmatrix} \begin{bmatrix} \theta_1 \\ \theta_2 \\ \theta_3 \end{bmatrix} + \begin{bmatrix} M'_{15} \\ M'_{21} \\ M'_{32} \end{bmatrix} \qquad (64b)$$

Each of these two matrix equations corresponds to three algebraic equations. If the multiplication indicated on the right side of the equations is done, a column vector of three components will exist on each side of each equation. Equating corresponding elements of these column vectors will give the two families of three algebraic equations each. Consider the first algebraic equation of the first family as follows:

$$M_{12} = K_{12}\theta_1 + R_{12}\theta_2 + M'_{12} \qquad (65)$$

Eq. 65 is one of the slope-deflection equations for the second span and corresponds exactly to the first of the two algebraic equations represented by Eq. 55. Similarly all the six algebraic equations corresponding to Eqs. 64 can be shown to be slope-deflection equations for the various spans. Hence, Eqs. 62 are valid.

Eqs. 62 represent a complete statement in matrix notation of the slope-deflection equations for any continuous beam with supports that are fixed against translation. If there are ten effective joints, the column vectors will have ten components and the coefficient matrices will be 10×10 square matrices.

Any numerical values for the components of $[\theta]$—that is, the joint rotations—may be assumed and substituted into Eqs. 62. The resulting moments will correspond to a continuous elastic curve for the beam. The moment on the left side of each joint is not equal in magnitude to the moment on the right side of the joint. From a physical standpoint this state of deflections and moments could exist only if artificial moments of sufficient magnitude to maintain the joint rotations at the assumed values were introduced at the joints. These artificial moments might be introduced by considering that torques are applied to axles which are fixed to the beam at the joints and are normal to the plane of the page.

Actually, the foregoing solution is not correct for moments resulting from the applied loads. There is one, and only one, correct set of values of the components of $[\theta]$. With this correct set of values the moment on the left side of each support is equal to the moment on the right side of the same support, but of opposite sign. In other words, each joint must be in equilibrium so that no artificial torques are required. Thus, the correct solution must satisfy both the continuity of the elastic curve and the equilibrium of the joints. Eqs. 62 guarantee continuity but do not guarantee equilibrium. Hence, the equilibrium conditions must also be imposed on the solution.

If each joint is in equilibrium, the elements of the vector $[M_a]$ must be equal and opposite in sign to the elements of $[M_b]$. Thus, the equilibrium condition is expressed by

$$[M_a] + [M_b] = 0 \qquad (66)$$

Eqs. 62 and 66 define the solution completely. The vector $[\theta]$ can be elim-

inated from these three matrix equations to give convenient formulas for design practice.

Theorem of Three Slopes

If Eqs. 62 are substituted into Eq. 66,

$$[K][\theta] + [u] = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (67)$$

in which

$$[K] = [K_a] + [K_b] = \begin{bmatrix} \Sigma_1 K & R_{12} & 0 \\ R_{21} & \Sigma_2 K & R_{23} \\ 0 & R_{32} & \Sigma_3 K \end{bmatrix} \ldots\ldots\ldots\ldots (68)$$

and

$$[u] = [M'_a] + [M'_b] = \begin{bmatrix} M'_{12} + M'_{15} \\ M'_{23} + M'_{21} \\ M'_{34} + M'_{32} \end{bmatrix} \ldots\ldots\ldots\ldots (69)$$

The elements of the stiffness matrix $[K]$ should be considered. The first element of the principal diagonal is the sum of stiffness values at joint 1. The second element of the principal diagonal is the sum of stiffness values at joint 2, etc. The matrix contains one diagonal row of elements above and one below the principal diagonal, and is symmetrical. These properties are true for the stiffness matrix of all continuous beams regardless of the number of effective joints. The diagonal row above the principal diagonal is called the "superdiagonal" and the diagonal row below the principal diagonal is called the "subdiagonal." A matrix that has a principal diagonal, subdiagonal, and superdiagonal, with all other elements equal to zero, is called a "continuant matrix."[5] (The mathematical reason for this name has been stated by A. C. Aitken.) The stiffness matrix $[K]$ is a continuant matrix. This will only be true if the effective joints are numbered in consecutive order. The subdiagonal and superdiagonal are composed of secondary stiffness values, or R-values. In any given row the diagonal element corresponds to a particular joint. The R-values in this row correspond to the members adjacent to the joint.

The vector $[u]$ is composed of components that may be recognized as the "unbalanced" moments of the moment distribution process of analysis. The unbalanced moment at a joint is the sum of the fixed-end moments at the joint. The vector $[u]$ may be written

$$[u] = \begin{bmatrix} \Sigma_1 M' \\ \Sigma_2 M' \\ \Sigma_3 M' \end{bmatrix} = \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} \ldots\ldots\ldots\ldots\ldots\ldots (70)$$

For example, from Eq. 69, $u_2 = M'_{23} + M'_{21}$.

Each of the algebraic equations represented by the matrix Eq. 67 contains three slopes, or joint rotations, irrespective of the number of spans of the continuous beam. Hence, Eq. 67 may be called the theorem of three slopes (or "angles," which is a term used by W. L. Schwalbe[6]). This equation can be

[5] "Determinants and Matrices," by A. C. Aitken, Interscience Publishers, Inc., New York, N. Y., 1939, p. 126.

[6] "Simultaneous Equations in Mechanics Solved by Iteration," by W. L. Schwalbe, *Transactions* ASCE, Vol. 102, 1937, p. 941.

solved for $[\theta]$ by multiplying the equation by $[K]^{-1}$:

$$[\theta] = -[K]^{-1}[u] \qquad (71)$$

Eq. 71 states that the joint rotations created by a given loading are linear functions of the unbalanced moments. Substituting Eq. 71 in Eqs. 62 gives

$$[M_a] = [M'_a] - [K_a][K]^{-1}[u] \qquad (72a)$$

and

$$[M_b] = [M'_b] - [K_b][K]^{-1}[u] \qquad (72b)$$

The second term on the right-hand side of Eqs. 72 may be considered a correction or modification to be added, with its negative sign, to the fixed-end moment. The final moment at a joint may be considered to be composed of a preliminary estimate, or fundamental value—the fixed-end moment plus a correction that is a linear function of the unbalanced moments of all the joints.

It is convenient to introduce the following matrices:

$$[C_a] = -[K_a][K]^{-1} \qquad (73a)$$

and

$$[C_b] = -[K_b][K]^{-1} \qquad (73b)$$

Eqs. 72 become

$$[M_a] = [M'_a] + [C_a][u] \qquad (74a)$$

and

$$[M_b] = [M'_b] + [C_b][u] \qquad (74b)$$

The numerical values of joint moments may be computed by using either Eq. 74*a* or Eq. 74*b*. However, it is advisable to use both and to compare the values as this procedure checks the computation of the elements of $[C_a]$ and $[C_b]$. Eqs. 74 give a complete statement in matrix notation of the solution of any continuous beam of any number of spans. The column vectors $[M'_a]$, $[M'_b]$, and $[u]$ are dependent on the loading and physical characteristics of the individual spans. The coefficient matrices $[C_a]$ and $[C_b]$ are dependent only on the physical properties of the structure. They can be computed for a given structure before the loading is known and need to be computed only once. The information necessary for this computation is shown in Fig. 4.

The matrix $[C_a]$ is computed in two steps: First, $[K]^{-1}$ is computed; and then this value is premultiplied by $[K_a]$. A matrix multiplication can be performed in a few minutes, particularly on modern calculators which retain and add products of numbers. Large matrices can be multiplied faster by using a calculating machine than by using a slide rule since the result of each individual multiplication does not have to be written down but is retained in the machine. The principal labor involved is in the computation of $[K]^{-1}$. The time required for computating the reciprocal of a matrix increases very rapidly with the size of the matrix. For example, the calculation of the reciprocal of a 6×6 matrix would require the evaluation of thirty-six 5×5 determinants—a very lengthy process.

It is convenient, for discussion, to introduce the correction vectors [a] and [b] by the definitions:

$$[a] = [C_a][u]; \text{ and } [b] = [C_b][u] \quad \text{.............. (75)}$$

Eqs. 74 become

$$[M_a] = [M'_a] + [a] \quad \text{.................... (76a)}$$

and

$$[M_b] = [M'_b] + [b] \quad \text{.................... (76b)}$$

The design computations for a given loading can be written in a manner similar to moment distribution after the elements of the coefficient matrices [C_a] and [C_b] have been computed. The fixed-end moments may be written, as usual, and directly below them the components of the correction vectors [a] and [b] are written. Direct addition at each joint gives the final answer. Because of the length of time required to compute the reciprocal of the stiffness matrix [K], and thus to obtain [C_a] and [C_b], a given beam can be analyzed faster for one loading condition by moment distribution than by using matrices. The advantage of using matrices would become apparent if a beam were to be analyzed for many loading conditions, since the reciprocal of [K] would need to be computed only once—suggesting that matrix methods should prove to be useful in developing influence lines.

Theorem of Three Moments

The theorem of three moments is better known to structural engineers than the theorem of three slopes. In developing the theorem of three moments, it is necessary to begin with the moment-slope relationship of Eq. 56. The end slopes are considered linear functions of the end moments. Proceeding in a manner similar to the development of the theorem of three slopes, a complete set of moment-slope relationships for the entire continuous beam can be written. This set of equations will guarantee equilibrium rather than continuity. The condition of continuity at each joint must be introduced and the theorem of three moments is then obtained. It expresses the joint moments as functions of the simple beam end slopes and can be solved directly for the moments. Eq. 57 has been given for obtaining simple beam end slopes from fixed-end moments.

To develop the theorem of three moments, it is necessary to shift to a bending moment sign convention. It is also necessary to differentiate between the slopes (rather than the moments) on the right-hand side and left-hand side of a support. Thus, slopes must have double subscripts whereas joint moments need have only single subscripts. Since these changes are very confusing, the development has been omitted, the outline merely being given to indicate a possibility for those who may wish to pursue the study further.

Numerical Example

In Fig. 5, a continuous beam is shown with parabolic haunches and simple supports. A row of standard stiffness values for each span is shown as deter-

mined from graphs published by the Portland Cement Association.[7] Since these graphs give the carry-over factors, the secondary stiffness values must be computed. Just below the stiffness values are the stiffness matrices for each span, showing a modified stiffness for the end spans caused by the simple

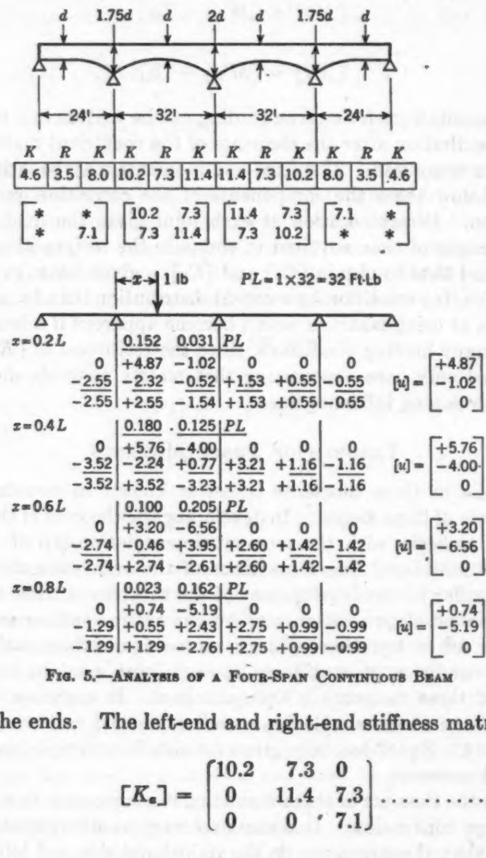


FIG. 5.—ANALYSIS OF A FOUR-SPAN CONTINUOUS BEAM

supports at the ends. The left-end and right-end stiffness matrices $[K_a]$ and $[K_b]$ are

$$[K_a] = \begin{bmatrix} 10.2 & 7.3 & 0 \\ 0 & 11.4 & 7.3 \\ 0 & 0 & 7.1 \end{bmatrix} \qquad (77a)$$

and

$$[K_b] = \begin{bmatrix} 7.1 & 0 & 0 \\ 7.3 & 11.4 & 0 \\ 0 & 7.3 & 10.2 \end{bmatrix} \qquad (77b)$$

By adding Eqs. 77*a* and 77*b*, the stiffness matrix $[K]$ is obtained

$$[K] = \begin{bmatrix} 17.3 & 7.3 & 0 \\ 7.3 & 22.8 & 7.3 \\ 0 & 7.3 & 17.3 \end{bmatrix} \qquad (78)$$

[7] "Continuous Concrete Bridges," Portland Cement Assn., Chicago, Ill., 1939.

The reciprocal is given by

$$[K]^{-1}=\frac{1}{4{,}980}\begin{bmatrix} 341 & -126 & 53.3 \\ -126 & 299 & -126 \\ 53.3 & -126 & 341 \end{bmatrix}=\begin{bmatrix} 0.0685 & -0.0253 & 0.0107 \\ -0.0253 & 0.0600 & -0.0253 \\ 0.0107 & -0.0253 & 0.0685 \end{bmatrix} \qquad (79)$$

The matrices $[K]$ and $[K]^{-1}$ are symmetrical about the principal diagonal and also about the diagonal running from the upper right-hand corner downward (the secondary diagonal). This second symmetry occurs because the beam is itself symmetrical about its center support.

The matrices $[C_a]$ and $[C_b]$ are computed to be

$$[C_a] = -[K_a][K]^{-1} = \begin{bmatrix} -0.514 & -0.180 & +0.076 \\ +0.210 & -0.499 & -0.212 \\ -0.076 & +0.180 & -0.486 \end{bmatrix} \qquad (80a)$$

and

$$[C_b] = -[K_b][K]^{-1} = \begin{bmatrix} -0.486 & +0.180 & -0.076 \\ -0.212 & -0.499 & +0.210 \\ +0.076 & -0.180 & -0.514 \end{bmatrix} \qquad (80b)$$

It should be noted that $[C_b]$ can be obtained from $[C_a]$ by two rotations of the matrix—one about the principal diagonal and one about the secondary diagonal. This condition is caused by symmetry of the beam about its center support.

The correction vectors $[a]$ and $[b]$ can now be written as

$$[a] = \begin{bmatrix} -0.514 & -0.180 & +0.076 \\ +0.210 & -0.499 & -0.212 \\ -0.076 & +0.180 & -0.486 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} \qquad (81a)$$

and

$$[b] = \begin{bmatrix} -0.486 & +0.180 & -0.076 \\ -0.212 & -0.499 & +0.210 \\ +0.076 & -0.180 & -0.514 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} \qquad (81b)$$

For any given loading condition, fixed-end moments can be computed from graphical representations of moment coefficients. The unbalanced moments $[u]$ can then be determined, and the corrections $[a]$ and $[b]$ can be computed by a matrix multiplication as shown in Eqs. 81. The convenience of using this method for calculating influence lines should be apparent.

Four solutions for four positions of a unit load in the second span are shown in Fig. 5. The components of the correction vectors have been computed in each case by a matrix multiplication using Eqs. 81. The fixed-end moment coefficients have been taken from a booklet issued by the Portland Cement Association.[7] The column vector of unbalanced moments is shown at the right for each case.

PART III. MATRIX DEVELOPMENT OF MOMENT DISTRIBUTION

INTRODUCTION

This development is also limited to the consideration of continuous beams on supports which are fixed against translation. The process of moment dis-

tribution consists of a sequence of cycles of numerical computations. Each cycle has two steps. In the first step all joints are balanced and in the second step the "carry-over calculation" is performed in each span. Although other sequences of performing the operations are possible, the foregoing order has generally been adopted because of the ease in checking the computations by an individual other than the original computer. A statical moment sign convention will be used through this part of the paper. (After submission of the manuscript for publication a discussion by Leon Beskin, Assoc. M. ASCE, appeared in which several matrix equations were presented corresponding closely to some of those contained in this part of the paper.[8])

Beam with One Effective Joint

It is possible to give a simple illustration of the process of moment distribution by considering a beam for which the final moments can be obtained by performing only one cycle of computations. Such a beam is one having only one effective joint. Three examples are shown in Fig. 6. These beams do not

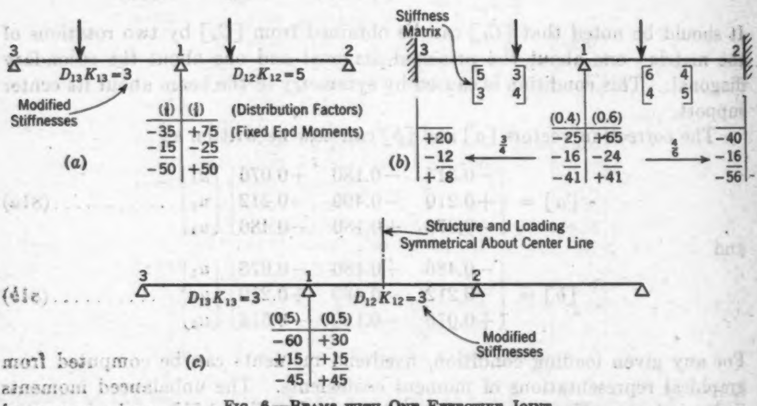

FIG. 6.—BEAMS WITH ONE EFFECTIVE JOINT

need to be prismatic. The beam in Fig. 6(*a*) has modified stiffness values, computed by using the appropriate end rotation constants. It is only necessary to perform the first step of the first cycle of moment distribution to obtain the final solution. A similar type of case is shown in Fig. 6(*c*) in which a single distribution of moments at joint 1 gives the final solution. The opportunity for using an end rotation constant in the center span arises from the symmetry of the structure and its loading. A similar opportunity would exist if the loading were antisymmetrical. In Fig. 6(*b*) is shown a beam that requires both steps of the cycle for its complete solution. The stiffness matrix for each span is shown, from which the distribution and carry-over factors are computed. The distribution factors are shown in parentheses above the moment distribution. The distribution step of the cycle yields the correction values which,

[8] *Proceedings*, ASCE, September, 1945, pp. 1111–1120.

when added to the fixed-end moments, give the final moments at joint 1. The carry-over step determines the outer end moments.

In each of the examples of Fig. 6, the computations at the effective joint conform to the following algebraic equations:

$$M_{12} = M'_{12} + a_1 \qquad (82a)$$

and

$$M_{13} = M'_{13} + b_1 \qquad (82b)$$

in which

$$a_1 = -\frac{K_{12}}{\Sigma_1 K} u_1 = -d_{12} u_1 \qquad (83a)$$

and

$$b_1 = -\frac{K_{13}}{\Sigma_1 K} u_1 = -d_{13} u_1 \qquad (83b)$$

The final moments are obtained by adding to the fixed-end moments the corrections a and b. This procedure corresponds exactly to the method of solution described in Part II and illustrated by Eqs. 76. In the present case the column vectors have only one element and, hence, are ordinary numbers. The distribution factors d_{12} and d_{13} have been introduced and defined in agreement with the usual moment distribution procedure.

Matrix Reciprocal Expressed by Power Series

As was stated in Part I, most of the work involved in solving a continuous beam of many spans lies in the evaluation of the reciprocal of the stiffness matrix $[K]$. Instead of calculating this reciprocal by using determinants as explained in Part I, it is possible to obtain this reciprocal by a converging approximation method. The method can be developed by expressing $[K]^{-1}$ as a power series of matrices. This process leads directly to a complete mathematical explanation of moment distribution.

The matrix $[K]$, for a beam with three effective joints (see Fig. 4), is given by

$$[K] = \begin{bmatrix} \Sigma_1 K & R_{12} & 0 \\ R_{21} & \Sigma_2 K & R_{23} \\ 0 & R_{32} & \Sigma_3 K \end{bmatrix} \qquad (84)$$

This matrix can be separated into two parts defined as follows:

$$[D] = \begin{bmatrix} \Sigma_1 K & 0 & 0 \\ 0 & \Sigma_2 K & 0 \\ 0 & 0 & \Sigma_3 K \end{bmatrix} \qquad (85)$$

and

$$[R] = \begin{bmatrix} 0 & -R_{12} & 0 \\ -R_{21} & 0 & -R_{23} \\ 0 & -R_{32} & 0 \end{bmatrix} \qquad (86)$$

The matrix $[D]$ is a diagonal matrix containing the diagonal elements of $[K]$. The matrix $[R]$ contains the nondiagonal elements of $[K]$ with negative signs. The reciprocal of $[D]$ will appear in the development and a convenient rule

for computing the reciprocal of a diagonal matrix can be established. Evaluating $[D]^{-1}$ by determinants gives

$$[D]^{-1} = \frac{1}{\Sigma_1 K\, \Sigma_2 K\, \Sigma_3 K} \begin{bmatrix} \Sigma_2 K\, \Sigma_3 K & 0 & 0 \\ 0 & \Sigma_1 K\, \Sigma_3 K & 0 \\ 0 & 0 & \Sigma_2 K\, \Sigma_3 K \end{bmatrix}$$

$$= \begin{bmatrix} (\Sigma_1 K)^{-1} & 0 & 0 \\ 0 & (\Sigma_2 K)^{-1} & 0 \\ 0 & 0 & (\Sigma_3 K)^{-1} \end{bmatrix} \quad \ldots\ldots\ldots\ldots\ldots (87)$$

Inspection shows that $[D]^{-1}$ is also a diagonal matrix formed by replacing each of the diagonal elements of $[D]$ by its reciprocal.

From Eqs. 84 to 86:

$$[K] = [D] - [R] \quad \ldots\ldots\ldots\ldots\ldots (88)$$

Eq. 88 may be written as

$$[K] = \{[I] - [R][D]^{-1}\}[D] \quad \ldots\ldots\ldots\ldots\ldots (89)$$

It becomes convenient to define the matrix $[Q]'$ by

$$[Q]' = [R][D]^{-1} \quad \ldots\ldots\ldots\ldots\ldots (90)$$

The physical significance of the elements of $[Q]'$ and the reason for using the transpose $[Q]'$ instead of $[Q]$ will be explained subsequently. Eq. 89 becomes

$$[K] = \{[I] - [Q]'\}[D] \quad \ldots\ldots\ldots\ldots\ldots (91)$$

To write the reciprocal of $[K]$, it is necessary to establish another rule of matrix algebra regarding the reciprocal of a product of two matrices. For example, assume that

$$[C] = [A][B] \quad \ldots\ldots\ldots\ldots\ldots (92)$$

Premultiplying both sides of Eq. 92 by $[A]^{-1}$,

$$[A]^{-1}[C] = [I][B] = [B] \quad \ldots\ldots\ldots\ldots\ldots (93)$$

Premultiplying both sides of Eq. 93 by $[B]^{-1}$,

$$[B]^{-1}[A]^{-1}[C] = [I] \quad \ldots\ldots\ldots\ldots\ldots (94)$$

Postmultiplying both sides of Eq. 94 by $[C]^{-1}$,

$$[B]^{-1}[A]^{-1} = [C]^{-1} \quad \ldots\ldots\ldots\ldots\ldots (95)$$

Comparing Eq. 95 with Eq. 92, it is apparent that the reciprocal of a product of two matrices equals the product of their reciprocals—in reverse order. From this rule, and from Eq. 91, $[K]^{-1}$ can be written

$$[K]^{-1} = [D]^{-1}\{[I] - [Q]'\}^{-1} = [D]^{-1}\left\{\frac{[I]}{[I] - [Q]'}\right\} \quad \ldots\ldots (96)$$

In general, it is not permissible to write a matrix division as a fraction because of the ambiguity that arises as explained in Part I. However, the fraction shown in Eq. 96 has the identity matrix for a numerator; and, hence, no

ambiguity arises. The reciprocal has been written in the form of a fraction in order that it can be compared with the following well-known algebraic formula:

$$\frac{1}{1-\epsilon} = 1 + \epsilon + \epsilon^2 + \epsilon^3 + \epsilon^4 + \cdots \qquad (97)$$

This infinite power series can be derived by applying the binomial theorem or by direct long division. The number unity of ordinary numbers is comparable to the identity matrix in matrix algebra. Hence, by comparison:

$$\{[I] - [Q]'\}^{-1} = [I] + [Q]' + \{[Q]'\}^2 + \{[Q]'\}^3 + \cdots \qquad (98)$$

The validity of Eq. 98 can be demonstrated by multiplying both sides by the binomial $[I] - [Q]'$. A rigorous mathematical proof of the correctness of this series requires that the power matrix $\{[Q]'\}^n$ shall approach the zero matrix as n approaches infinity. The reciprocal $[K]^{-1}$ can now be expressed by

$$[K]^{-1} = [D]^{-1}\{[I] + [Q]' + \{[Q]'\}^2 + \{[Q]'\}^3 + \cdots\} \qquad (99)$$

Moment Distribution

As was shown in Part II, the correction vectors $[a]$ and $[b]$ are given by the following formulas:

$$[a] = -[K_a][K]^{-1}[u] \qquad (100a)$$

and

$$[b] = -[K_b][K]^{-1}[u] \qquad (100b)$$

Substituting Eq. 99 into Eqs. 100,

$$[a] = -[K_a][D]^{-1}\{[I] + [Q]' + \{[Q]'\}^2 + \{[Q]'\}^3 + \{[Q]'\}^4 + \cdots\}[u] \qquad (101a)$$

and

$$[b] = -[K_b][D]^{-1}\{[I] + [Q]' + \{[Q]'\}^2 + \{[Q]'\}^3 + \{[Q]'\}^4 + \cdots\}[u] \qquad (101b)$$

The physical significance of these equations can be noted by writing the matrices in expanded form and considering the operations term by term. First, consider the two matrices in front of the heavy brace in each equation. Assume a beam having three effective joints:

$$[K_a][D]^{-1} = \begin{bmatrix} K_{12} & R_{12} & 0 \\ 0 & K_{23} & R_{23} \\ 0 & 0 & K_{34} \end{bmatrix} \begin{bmatrix} (\Sigma_1 K)^{-1} & 0 & 0 \\ 0 & (\Sigma_2 K)^{-1} & 0 \\ 0 & 0 & (\Sigma_3 K)^{-1} \end{bmatrix}$$

$$= \begin{bmatrix} d_{12} & r_{21}\,d_{21} & 0 \\ 0 & d_{23} & r_{32}\,d_{32} \\ 0 & 0 & d_{34} \end{bmatrix} \qquad (102)$$

In this matrix the diagonal elements are the distribution factors applicable at the left end of the members (or the right side of the joints) as used in moment distribution. The nondiagonal elements are products of a distribution factor

and a corresponding carry-over factor. It is convenient to represent these nondiagonal elements by a single letter q with appropriate subscripts. Thus, for example,

$$q_{21} = r_{21}\, d_{21};\ \text{and}\ q_{32} = r_{32}\, d_{32} \ldots\ldots\ldots\ldots\ldots\ldots (103)$$

It is appropriate to discuss the relationship of the quantity q to other physical quantities which are well known. If the distribution factor d_{23}, as used in moment distribution, is referred to as a primary distribution factor, then the quantity q_{23} may be called a secondary distribution factor. This is analogous to calling K_{23} the primary stiffness value and R_{23} the secondary stiffness value as introduced in Part II. In both cases the secondary value is obtained by multiplying the primary value by the carry-over factor r_{23}. Thus,

$$R_{23} = r_{23}\, K_{23};\ \text{and}\ q_{23} = r_{23}\, d_{23} \ldots\ldots\ldots\ldots\ldots\ldots (104)$$

It is also possible to compute the secondary distribution factor in a manner which is exactly the same as that used for the primary factors. Thus,

$$d_{23} = \frac{K_{23}}{\Sigma_2 K}\ ;\ \text{and}\ q_{23} = \frac{R_{23}}{\Sigma_2 K} \ldots\ldots\ldots\ldots\ldots\ldots (105)$$

Since the distribution factors can be calculated directly from the corresponding stiffness values, an analysis of a continuous beam by matrix methods does not require computation of the carry-over factor. Introducing secondary distribution factors, Eq. 102 becomes

$$[K_a][D]^{-1} = \begin{bmatrix} d_{12} & q_{21} & 0 \\ 0 & d_{23} & q_{32} \\ 0 & 0 & d_{34} \end{bmatrix} \ldots\ldots\ldots\ldots\ldots (106a)$$

and, similarly,

$$[K_b][D]^{-1} = \begin{bmatrix} d_{15} & 0 & 0 \\ q_{12} & d_{21} & 0 \\ 0 & q_{23} & d_{32} \end{bmatrix} \ldots\ldots\ldots\ldots\ldots (106b)$$

Now consider the terms of the power series of Eqs. 101, term by term. First, assume that the correction vectors are to be computed using only the first term of the series:

$$[a] = -[K_a][D]^{-1}[I][u] = -[K_a][D]^{-1}[u] \ldots\ldots (107a)$$

and

$$[b] = -[K_b][D]^{-1}[I][u] = -[K_b][D]^{-1}[u] \ldots\ldots (107b)$$

Substituting Eqs. 106,

$$\begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix} = -\begin{bmatrix} d_{12} & q_{21} & 0 \\ 0 & d_{23} & q_{32} \\ 0 & 0 & d_{34} \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} \ldots\ldots\ldots\ldots\ldots (108a)$$

and

$$\begin{bmatrix} b_1 \\ b_2 \\ b_3 \end{bmatrix} = -\begin{bmatrix} d_{15} & 0 & 0 \\ q_{12} & d_{21} & 0 \\ 0 & q_{23} & d_{32} \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} \ldots\ldots\ldots\ldots\ldots (108b)$$

When the first element of the first row of each coefficient matrix is multiplied by the first element of the vector $[u]$, the two quantities obtained are $-d_{12}u_1$ and $-d_{15}u_1$—the products of the unbalanced moment at joint 1 and the distribution factors. The contribution $-d_{12}u_1$ to the value of a_1 is thus exactly the value of the contribution to the final joint moment which is made by the first step of a moment distribution cycle applied to the unbalanced moment at joint 1. Similarly, the products of all the diagonal elements of the coefficient matrices of Eqs. 108 and the vector $[u]$ provide the same contributions to the solution as are provided by the first step of the first cycle of moment distribution in which all the joints are balanced.

Consider next the effect of the nondiagonal elements, or secondary distribution factors, of the coefficient matrices. Consider only the elements of the second row of the matrix of Eq. 108*a*. The nondiagonal element q_{32} contributes $-q_{32}u_3$ to the value of a_2. From the definition of q, the contribution is $-r_{32}d_{32}u_3$. This quantity is the contribution to the joint moment on the right side of joint 2 brought about by the carry-over calculation in span 23. Thus, the nondiagonal elements of the coefficient matrices correspond to the second step of a moment distribution cycle.

Consequently, the coefficient matrices of Eqs. 108 represent, in matrix notation, one complete cycle of moment distribution. These matrices—$-[K_a][D]^{-1}$ and $-[K_b][D]^{-1}$—when applied to a column vector $[u]$ of unbalanced moments make the same contribution to the final solution as is made by one complete cycle of moment distribution.

Consider now that the correction vectors $[a]$ and $[b]$ are to be computed by using the first two terms of the series of Eqs. 101:

$$[a] = -[K_a][D]^{-1}[u] - [K_a][D]^{-1}[Q]'[u] \qquad (109a)$$

and

$$[b] = -[K_b][D]^{-1}[u] - [K_b][D]^{-1}[Q]'[u] \qquad (109b)$$

The second terms could be expressed in a manner similar to Eqs. 108, given for the first term, if the vector $[u]$ were replaced by the product $[Q]'[u]$. In expanded form, this product (see Eq. 90) becomes

$$[Q]'[u] = [R][D]^{-1}[u]$$

$$= \begin{bmatrix} 0 & -R_{12} & 0 \\ -R_{21} & 0 & -R_{23} \\ 0 & -R_{32} & 0 \end{bmatrix} \begin{bmatrix} (\Sigma_1 K)^{-1} & 0 & 0 \\ 0 & (\Sigma_2 K)^{-1} & 0 \\ 0 & 0 & (\Sigma_3 K)^{-1} \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} \qquad (110)$$

Let

$$[u'] = [Q]'[u] \qquad (111)$$

Then

$$[u'] = -\begin{bmatrix} 0 & r_{21}d_{21} & 0 \\ r_{12}d_{12} & 0 & r_{32}d_{32} \\ 0 & r_{23}d_{23} & 0 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} = -\begin{bmatrix} 0 & q_{21} & 0 \\ q_{12} & 0 & q_{32} \\ 0 & q_{23} & 0 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} \qquad (112)$$

Consideration of the coefficient matrix $[Q]'$ of Eq. 112 shows why the transpose $[Q]'$ was introduced rather than $[Q]$. The subscripts of the elements

show that the matrix is in transposed form. Calculating the components of $[u']$ individually gives

$$u'_1 = -r_{21}\, d_{21}\, u_2 \qquad (113a)$$

$$u'_2 = -r_{12}\, d_{12}\, u_1 - r_{32}\, d_{32}\, u_3 \qquad (113b)$$

and

$$u'_3 = -r_{23}\, d_{23}\, u_2 \qquad (113c)$$

From consideration of these formulas, the components of $[u']$ are shown to be the unbalanced moments remaining at the joints after one cycle of moment distribution has been completed. Since it was previously shown that the coefficients $-[K_a][D]^{-1}$ and $-[K_b][D]^{-1}$ correspond to one cycle of moment distribution, it should now be apparent that the first term of Eqs. 109 corresponds to the first cycle of moment distribution and the second term corresponds to the second cycle.

Similarly, it can be shown that the third term of the power series of Eqs. 101 corresponds to the third cycle of moment distribution, etc. Thus, it is established that a complete mathematical statement of the method of moment distribution can be given in matrix notation as follows:

$$[M_a] = [M'_a] - [K_a][D]^{-1} \{[I] + [Q]' + \{[Q]'\}^2 + \{[Q]'\}^3 + \cdots\}[u] \qquad (114a)$$

and

$$[M_b] = [M'_b] - [K_b][D]^{-1} \{[I] + [Q]' + \{[Q]'\}^2 + \{[Q]'\}^3 + \cdots\}[u] \qquad (114b)$$

Although, by making certain limiting assumptions, R. Oldenburger proved the convergence of moment distribution, this theory has not been given very extensive treatment by mathematicians.[9] Eqs. 114 show that this convergence is dependent upon the convergence of the series within the braces. In any given practical case, a rigorous proof of convergence can be developed; but it will not be attempted here.

PART IV. VARIATIONS FROM MOMENT DISTRIBUTION

Introduction

In Part II, it was shown that a complete solution can be obtained by matrix computation methods in which the reciprocal of the stiffness matrix is computed by using determinants. With Eqs. 114, it is possible to devise a number of different converging approximation methods of solution using matrix methods of computation. The method of moment distribution, with its cycles of numerical computations, is in exact correspondence with Eqs. 114; yet it makes no use of matrix methods. It is possible to devise combined procedures which use both matrix methods and moment distribution. A development of two methods, based upon Eqs. 114, will be given.

[9] "Convergence of Hardy Cross's Balancing Process," by R. Oldenburger, *Journal of Applied Mechanics*, December, 1940, pp. A-166 to A-170.

A Combined Method

If a given beam is to be analyzed for only one loading condition, the designer who is familiar with moment distribution will undoubtedly find it the fastest method of solution available. However, if it is desired to use matrix methods, an interesting combined procedure can be developed by writing the correction vectors $[a]$ and $[b]$ as follows:

$$[a] = -[K_a][D]^{-1}[\bar{u}] \quad \text{(115a)}$$

and

$$[b] = -[K_b][D]^{-1}[\bar{u}] \quad \text{(115b)}$$

in which $[\bar{u}]$ is a vector of transformed unbalanced moments defined by

$$[\bar{u}] = [u] + [u'] + [u''] + [u'''] + \cdots \quad \text{(116)}$$

The vectors $[u']$, $[u'']$, etc., are the unbalanced moments which remain after each cycle of moment distribution and may be computed by the formulas:

$$[u'] = [Q]'[u] \quad \text{(117a)}$$

$$[u''] = \{[Q]'\}^2[u] = [Q]'[u'] \quad \text{(117b)}$$

$$[u'''] = \{[Q]'\}^3[u] = [Q]'[u''] \quad \text{(117c)}$$

Each of these vectors is computed by multiplying the previous one by $[Q]'$. It is interesting, and rather surprising, to discover that the unbalanced moments which will exist after any given number of cycles of moment distribution can be computed directly without actually writing out the moment distribution computations. The elements of the vectors $[u']$, $[u'']$, etc., decrease and rapidly approach zero. To obtain the accuracy, to three significant places, which is customary in structural design practice, in general, the four vectors of the type given by Eqs. 117 will be sufficient. Each additional vector usually gives one additional significant figure accurately. The accuracy of the final solution, however, cannot be greater than the accuracy of the fixed-end moments, which are seldom obtainable to an accuracy greater than three significant places. For several practical reasons, significant figures in excess of three are generally found of little use in design practice.

After the transformed vector $[\bar{u}]$ has been computed, the correction vectors $[a]$ and $[b]$ can be determined from Eqs. 115. However, it has been shown previously that the contributions to a solution made by premultiplying a vector of unbalanced moments by the factors $-[K_a][D]^{-1}$ and $-[K_b][D]^{-1}$ correspond to operating on the vector with one cycle of moment distribution. Thus, it becomes apparent that a solution can be obtained by first computing $[\bar{u}]$ and then performing one cycle of moment distribution with this set of unbalanced moments rather than with the actual values of $[u]$. If any joint is slightly out of balance at the end of the cycle, such a joint should be balanced. The foregoing procedure employs both matrix methods and moment distribution. It is recommended only for beams that are to be analyzed for one or two loading conditions or, more specifically, when the number of loading conditions is less than the number of effective joints.

A Matrix Method

If a continuous beam is to be analyzed for a number of loading conditions, equal to or greater than the number of effective joints, a different process of analysis will be found to require less time than the one previously described. This second method employs only matrix methods and becomes especially useful when the number of loading conditions greatly exceeds the number of effective joints. One such case is evidently the computation of influence lines by placing a unit load at various points along the beam.

Referring to Eqs. 101, the complete coefficients of $[u]$ may be evaluated to obtain the coefficient matrices $[C_a]$ and $[C_b]$ as introduced in Part II (see Eq. 75). The vectors $[a]$ and $[b]$ become

$$[a] = [C_a][u]; \text{ and } [b] = [C_b][u] \qquad (118)$$

From Eqs. 101, the formulas for $[C_a]$ and $[C_b]$ become

$$[C_a] = -[K_a][D]^{-1}\{[I] + [Q]' + \{[Q]'\}^2 + \{[Q]'\}^3 + \cdots\} \qquad (119a)$$

and

$$[C_b] = -[K_b][D]^{-1}\{[I] + [Q]' + \{[Q]'\}^2 + \{[Q]'\}^3 + \cdots\} \qquad (119b)$$

Eqs. 118 and 119 provide a method of successive corrections for calculating $[C_a]$ and $[C_b]$ that may be used instead of determinants as explained in Part II.

The method of successive corrections will be found to require less time than the method of determinants when the beam has four or more effective joints—that is, when $[Q]$ is of the fourth or higher order. Substituting Eqs. 106 into Eqs. 119,

$$[C_a] = -\begin{bmatrix} d_{12} & q_{21} & 0 \\ 0 & d_{23} & q_{32} \\ 0 & 0 & d_{34} \end{bmatrix} \{[I] + [Q]' + \{[Q]'\}^2 + \{[Q]'\}^3 + \cdots\} \qquad (120a)$$

and

$$[C_b] = -\begin{bmatrix} d_{15} & 0 & 0 \\ q_{12} & d_{21} & 0 \\ 0 & q_{23} & d_{32} \end{bmatrix} \{[I] + [Q]' + \{[Q]'\}^2 + \{[Q]'\}^3 + \cdots\} \qquad (120b)$$

The first step in the numerical computations is the evaluation of the matrix obtained by summing the power series within the large braces. Usually the fourth-degree term in the series will be the highest power of $[Q]'$ which is needed. Each term of the series is computed by multiplying the previous term by $[Q]'$. In order to perform this calculation, it is necessary for the designer to have a convenient rule for setting up the matrix $[Q]'$ in expanded form. Referring to Eq. 112, for a beam with three effective joints, $[Q]'$ has the form:

$$[Q]' = -\begin{bmatrix} 0 & q_{21} & 0 \\ q_{12} & 0 & q_{32} \\ 0 & q_{23} & 0 \end{bmatrix} \qquad (121)$$

This matrix consists solely of secondary distribution factors. Considering the matrix $[Q]$,

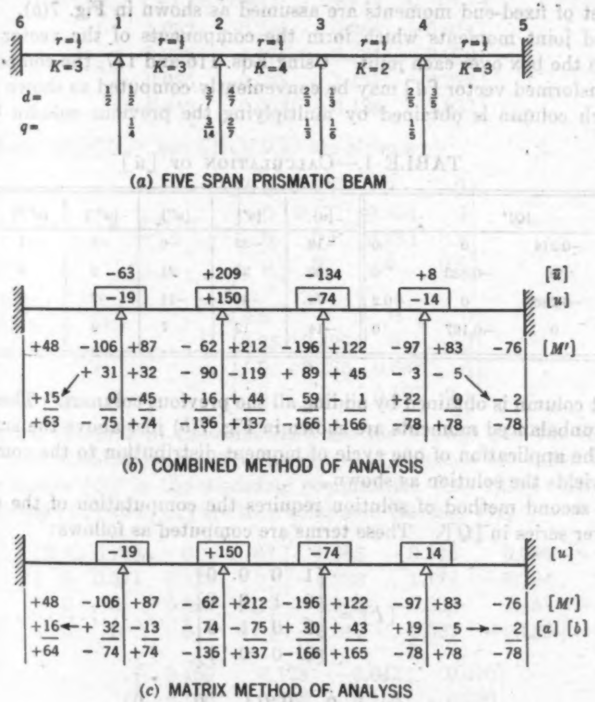
$$[Q] = -\begin{bmatrix} 0 & q_{12} & 0 \\ q_{21} & 0 & q_{23} \\ 0 & q_{32} & 0 \end{bmatrix} \qquad (122)$$

In this matrix the elements have subscripts that agree with their position in the matrix. The first subscript of an element indicates its row and the second subscript indicates its column. The q-values occupy the subdiagonals and the superdiagonals whereas all other elements of the matrix are zero. The subscripts also correspond to the joint and member, the first subscript indicating the joint. It is convenient to set up $[Q]$ first and then transpose to obtain $[Q]'$.

If the coefficient matrices of Eqs. 120 are considered, the nondiagonal elements are the same as the elements of $[Q]'$. The superdiagonal enters the formula for $[C_a]$; and the subdiagonal, the formula for $[C_b]$. The diagonal elements of these coefficients are the distribution factors for the left and right ends of the members, respectively. Consequently, the only quantities that enter the evaluation of $[C_a]$ and $[C_b]$ by Eqs. 120 are primary and secondary distribution factors.

Numerical Examples

An example will be solved using each of the two variations from moment distribution which have been described. A five-span beam, having four ef-



(a) FIVE SPAN PRISMATIC BEAM

(b) COMBINED METHOD OF ANALYSIS

(c) MATRIX METHOD OF ANALYSIS

Fig. 7.—Comparison of Methods

fective joints, is shown in Fig. 7(a). Each span is prismatic, thus having the same stiffness value at either end and a carry-over factor of one half. The

stiffness values are in boxes below the center of each span. The primary distribution factors are shown for each joint and below them the secondary factors. The matrix $[Q]$ is given by

$$[Q] = -\begin{bmatrix} 0 & q_{12} & 0 & 0 \\ q_{21} & 0 & q_{23} & 0 \\ 0 & q_{32} & 0 & q_{34} \\ 0 & 0 & q_{43} & 0 \end{bmatrix} = -\begin{bmatrix} 0 & 1/4 & 0 & 0 \\ 3/14 & 0 & 2/7 & 0 \\ 0 & 1/3 & 0 & 1/6 \\ 0 & 0 & 1/5 & 0 \end{bmatrix} \ldots (123)$$

Transposing and converting to decimals,

$$[Q]' = -\begin{bmatrix} 0 & 0.214 & 0 & 0 \\ 0.250 & 0 & 0.333 & 0 \\ 0 & 0.286 & 0 & 0.200 \\ 0 & 0 & 0.167 & 0 \end{bmatrix} \ldots\ldots\ldots\ldots (124)$$

This matrix must be used in either of the two methods of analysis.

A set of fixed-end moments are assumed as shown in Fig. 7(*b*). The unbalanced joint moments which form the components of the vector $[u]$ are noted in the box over each joint. Using Eqs. 116 and 117, the components of the transformed vector $[\bar{u}]$ may be conveniently computed as shown in Table 1. Each column is obtained by multiplying the previous column by $[Q]'$.

TABLE 1.—CALCULATION OF $[\bar{u}]$

$[Q]'$				$[u]$	$[u']$	$[u'']$	$[u''']$	$[u'''']$	$[\bar{u}]$
0	−0.214	0	0	−19	−32	−6	−5	−1	−63
−0.25	0	−0.333	0	150	29	21	5	4	209
0	−0.286	0	−0.2	−74	−40	−11	−7	−2	−134
0	0	−0.167	0	−14	12	7	2	1	8

The last column is obtained by adding all the previous columns. These transformed unbalanced moments are shown in Fig. 7(*b*) just above the actual values. The application of one cycle of moment distribution to the components of $[\bar{u}]$ yields the solution as shown.

The second method of solution requires the computation of the terms of the power series in $[Q]'$. These terms are computed as follows:

$$[I] = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \ldots\ldots\ldots\ldots\ldots\ldots (125a)$$

$$[Q]' = -\begin{bmatrix} 0 & 0.214 & 0 & 0 \\ 0.25 & 0 & 0.333 & 0 \\ 0 & 0.286 & 0 & 0.2 \\ 0 & 0 & 0.167 & 0 \end{bmatrix} \ldots\ldots\ldots\ldots (125b)$$

$$\{[Q]'\}^2 = \begin{bmatrix} 0.054 & 0 & 0.071 & 0 \\ 0 & 0.149 & 0 & 0.067 \\ 0.072 & 0 & 0.129 & 0 \\ 0 & 0.048 & 0 & 0.033 \end{bmatrix} \qquad (125c)$$

$$\{[Q]'\}^3 = -\begin{bmatrix} 0 & 0.032 & 0 & 0.014 \\ 0.038 & 0 & 0.061 & 0 \\ 0 & 0.052 & 0 & 0.026 \\ 0.012 & 0 & 0.022 & 0 \end{bmatrix} \qquad (125d)$$

$$\{[Q]'\}^4 = \begin{bmatrix} 0.008 & 0 & 0.013 & 0 \\ 0 & 0.025 & 0 & 0.012 \\ 0.013 & 0 & 0.022 & 0 \\ 0 & 0.009 & 0 & 0.004 \end{bmatrix} \qquad (125e)$$

Each matrix is obtained by multiplying the preceding matrix by $[Q]'$. Adding these matrices,

$$[I] + [Q]' + \{[Q]'\}^2 + \{[Q]'\}^3 + \{[Q]'\}^4$$
$$= \begin{bmatrix} 1.062 & -0.246 & 0.084 & -0.014 \\ -0.288 & 1.174 & -0.394 & 0.079 \\ 0.085 & -0.338 & 1.151 & -0.226 \\ -0.012 & 0.057 & -0.189 & 1.037 \end{bmatrix} \qquad (126)$$

The products $[K_a][D]^{-1}$ and $[K_b][D]^{-1}$ are given by

$$[K_a][D]^{-1} = \begin{bmatrix} 0.5 & 0.214 & 0 & 0 \\ 0 & 0.571 & 0.333 & 0 \\ 0 & 0 & 0.333 & 0.2 \\ 0 & 0 & 0 & 0.6 \end{bmatrix} \qquad (127a)$$

and

$$[K_b][D]^{-1} = \begin{bmatrix} 0.5 & 0 & 0 & 0 \\ 0.25 & 0.429 & 0 & 0 \\ 0 & 0.286 & 0.667 & 0 \\ 0 & 0 & 0.167 & 0.4 \end{bmatrix} \qquad (127b)$$

The diagonal elements of these matrices are the left-end and the right-end primary distribution factors. The nondiagonal elements are taken directly from the matrix $[Q]'$ in the preceding computation (Eq. 125b). The coefficient matrices $[C_a]$ and $[C_b]$ are then computed (see Eq. 119):

$$[C_a] = -\begin{bmatrix} 0.5 & 0.214 & 0 & 0 \\ 0 & 0.571 & 0.333 & 0 \\ 0 & 0 & 0.333 & 0.2 \\ 0 & 0 & 0 & 0.6 \end{bmatrix} \begin{bmatrix} 1.062 & -0.246 & 0.084 & -0.014 \\ -0.288 & 1.174 & -0.394 & 0.079 \\ 0.085 & -0.338 & 1.151 & -0.226 \\ -0.012 & 0.057 & -0.189 & 1.037 \end{bmatrix}$$

$$= -\begin{bmatrix} 0.469 & 0.128 & -0.042 & 0.010 \\ -0.136 & 0.558 & 0.158 & -0.030 \\ 0.026 & -0.101 & 0.346 & 0.132 \\ -0.007 & 0.034 & -0.113 & 0.622 \end{bmatrix} \qquad (128a)$$

and

$$[C_b] = -\begin{bmatrix} 0.5 & 0 & 0 & 0 \\ 0.25 & 0.429 & 0 & 0 \\ 0 & 0.286 & 0.667 & 0 \\ 0 & 0 & 0.167 & 0.4 \end{bmatrix} \begin{bmatrix} 1.062 & -0.246 & 0.084 & -0.014 \\ -0.288 & 1.174 & -0.394 & 0.079 \\ 0.085 & -0.338 & 1.151 & -0.226 \\ -0.012 & 0.057 & -0.189 & 1.007 \end{bmatrix}$$

$$= -\begin{bmatrix} 0.531 & -0.123 & 0.042 & -0.007 \\ 0.142 & 0.442 & -0.148 & 0.030 \\ -0.026 & 0.110 & 0.655 & -0.128 \\ 0.009 & -0.034 & 0.117 & 0.377 \end{bmatrix} \qquad \text{..........(128b)}$$

The correction vectors can now be written as

$$[a] = \begin{bmatrix} -0.469 & -0.128 & 0.042 & -0.010 \\ 0.136 & -0.558 & -0.158 & 0.030 \\ -0.026 & 0.101 & -0.346 & -0.132 \\ 0.007 & -0.034 & 0.113 & -0.622 \end{bmatrix} [u] \qquad \text{.......(129a)}$$

and

$$[b] = \begin{bmatrix} -0.531 & 0.123 & -0.042 & 0.007 \\ -0.142 & -0.442 & 0.148 & -0.030 \\ 0.026 & -0.110 & -0.655 & 0.128 \\ -0.009 & 0.034 & -0.117 & -0.377 \end{bmatrix} [u] \qquad \text{.......(129b)}$$

The components of the correction vectors are thus expressed as linear functions of the unbalanced moments. The elements of the coefficient matrices are dependent only on the physical characteristics of the beam. In Fig. 7(*c*) the same fixed-end moments and unbalanced moments as were assumed in the previous solution are shown. The components of the correction vectors, as computed from Eqs. 129, are written directly below the fixed-end moments. Direct addition gives the final solution. If solutions for additional loading conditions are desired, it should be apparent that the solutions could be computed very quickly from Eqs. 129.

Conclusion

The linear equations that govern continuous beams have been expressed and solved in the notation of matrix algebra. A complete algebraic statement of the method of moment distribution has been given. Matrix computation methods have been illustrated. The problem treated in this paper is the most elementary type of indeterminate structure. The joints have only one degree of freedom. This limitation in the physical scope of the paper was considered desirable in order that the emphasis could be placed on the methods and concepts of matrix algebra.

DISCUSSION

I. OESTERBLOM,[10] M. ASCE.—The use of matrices in structural engineering as presented in this paper constitutes a well-arranged review of the basic ideas and also a few sensible applications. Some matrix applications are already well known to engineers who have analyzed their continuity problems by the aid of energy, deflection, or slope methods, because all these, ultimately, lead to a system of equations for which a solution is possible only by the aid of determinants. (Among the many writers in this field, the following are noteworthy for comprehensive coverage and accessibility in American engineering libraries: Max Foerster,[11] David Molitor,[12] and J. I. Parcel and G. A. Maney.[13])

Too many engineers, however, have kept aloof from these methods, perhaps because they have been frightened by the unknown simplicity of matrix operations. Since the publication of this paper, however, they can no longer offer this as an excuse. On the other hand, others—the physics-minded type—have been led in the opposite direction. Albert Einstein's "generalized relativity" opened the entire field of physics to tensor operations, and this has led even to problems of elasticity where today, especially the French are offering most interesting simplifications[14] to some of the old and most discouraging problems; and tensors are nothing but the supreme of matrices, highly rationalized.

Perhaps there was also something beyond the matrices that frightened the early designers of indeterminate structures. It might not have been their presence but their extent. The nodal points in most commercial structures were many, as were, therefore, the elements in the matrix. It required a staff of good mathematicians under very keen leadership to set up the equations, and then to solve them, for five stories and three spans only—not to mention the many larger frames. A maximum of fifteen redundants was as much as one man could handle.

The utmost in this respect was discovered in the Zeppelin frames—with one hundred or more nodal points.[15] When these airborne visitors, on destruction bent, arrived over the British Isles during World War I fear came to every man's heart: "What can we do to master these wicked monsters?" R. V. Southwell in England and J. C. Hunsaker in the United States worked on the problem, intensely and fearfully, to build better airships. Mountain high matrices as

wide as an ocean—or so it must have seemed to those who did the work—were required.

Mr. Southwell's magnificent work now reposes in the archives of the Royal Society in London—a bewildering array of mass matrices of group elements; and a child was born out of this labor, too—the magnificent but ill-fated dirigible R101 which went to its destruction in the mountains of eastern France on its maiden trip to India. This was the only airship that was ever truly and rationally designed—so the world found when peace came. As a measure necessary to prove that the war was truly over, the foremost "matricians" of the world were ordered to surrender all their designs and calculations for the Zeppelins. It was a sorry collection they presented. The master mathematicians had been defeated by too many nodal points; they had nothing to show except reams of empiricism heavily loaded with guesswork.

This leads one to ask: "What good today are the matrices in dealing with frameworks?" If the latter are complicated, matrices are inadequate, and if they are simple, the modern relaxation methods are as good for the simple tasks as they are for the most complicated—and much simpler in application.

The engineer must think further than that, however, even though Mr. Benscoter's applications have been somewhat limited, for there are other problems—as in the field of dynamics and elasticity—many of them not yet born. When these rise out of the twilight of the unknown, designers will be thankful to Mr. Benscoter for providing such a fine light to lead them through the darkness.

Quite incidentally, the paper reveals that the stiffness of continuity may be expressed as a power series. Is this for a single sequence only, or does it apply also for a frame in two or three dimensions? For such a frame the discovery would have an epochal significance, because it would lighten the burden considerably when one has to deal with changes of sections or loads in a frame. As things are now, much guessing must be done because the actual work of rational redesign would be prohibitive for most such problems, because of the time required.

HARRIS SOLMAN,[16] M. ASCE.—By using the theory of matrices in the analysis of continuous beams, the author has made a valuable contribution to the field of structural analysis. The presentation of relationships in the form of a matrix or a system of matrices not only has the advantage of a convenient, systematic, and easily visualized arrangement but also possesses a mathematical elegance, which—it is hoped—engineers will not be too "practical" to appreciate.

Aside from the theoretical interest of the author's method, however, there is also a practical feature involved which has not been sufficiently emphasized

[16] Highway Bridge Engr., U. S. Public Roads Administration, Division 1, Albany, N. Y.

in the paper. The method presented can be utilized conveniently in setting up general values of end moments for a given system of continuous beams in terms of loads, so that they can be useful in computing influence coefficients.

A number of years ago the writer became interested in setting up general formulas to express the end moments of continuous beams on supports fixed against translation in terms of the fixed-end moments. Since a load placed at any one point on the structure produces only two fixed-end moments (one at each end of the loaded span), only two terms of each such formula would need to be evaluated for any one position of the load. Furthermore, the coefficient for each term would be a function of the beam constants only and would be an invariant for all positions of the load. Such formulas were deduced and successfully used by the writer.

These formulas, transcribed in the same general notations as those used by the author, are given subsequently. The following minor changes in notation are to be observed: The first end support (noneffective) was designated as zero, the symbol n being reserved to indicate the last effective support (the degree

Description	1			2	n	
Fixed-end moments	M'_{10}	M'_{12}	M'_{21}	M'_{23}	$M'_{n(n-1)}$	$M'_{n(n+1)}$
Distribution factors	d_{10}	d_{12}	d_{21}	d_{23}	$d_{n(n-1)}$	$d_{n(n+1)}$
Carry-over factors	0	r_{12}	r_{21}	r_{23}	$r_{n(n-1)}$	0
q-factors ($d \times r$)	0	q_{12}	q_{21}	q_{23}	$q_{n(n-1)}$	0

FIG. 8.—BEAM CONSTANTS FOR AN n-DEGREE SYSTEM

of the system). Additional symbols p and Δ were introduced for convenience and are defined by the following relationships:

$$p_{uv} \text{ (for } 0 < u \leqq n \text{ and } 0 > v \geqq n) = q_{uv}\, q_{vu} \quad \ldots\ldots\ldots (130a)$$

and, for an n-degree system:

$$\Delta_n = \text{determinant} \begin{vmatrix} 1 & q_{12} & 0 & \cdots & 0 \\ q_{21} & 1 & q_{23} & \cdots & 0 \\ 0 & q_{32} & 1 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & \cdots & 1 \end{vmatrix} \quad \ldots\ldots\ldots (130b)$$

The beam convention for the algebraic sign is used throughout, in order that the formulas may be readily applied to the beams with their proper signs without the necessity of considering the rotation effects on the joints.

In general, for an n-degree system (see Fig. 8):

$$\left.\begin{aligned}
M_{10} &= M'_{10} + b^{(n)}_{11}(M'_{10} - M'_{12}) + b^{(n)}_{12}(M'_{21} - M'_{23}) + \cdots \\
&\qquad + b^{(n)}_{1n}\left[M'_{n(n-1)} - M'_{n(n+1)}\right] \\
M_{12} &= M'_{12} + a^{(n)}_{11}(M'_{10} - M'_{12}) + a^{(n)}_{12}(M'_{21} - M'_{23}) + \cdots \\
&\qquad + a^{(n)}_{1n}\left[M'_{n(n-1)} - M'_{n(n+1)}\right] \\
M_{21} &= M'_{21} + b^{(n)}_{21}(M'_{10} - M'_{12}) + b^{(n)}_{22}(M'_{21} - M'_{23}) + \cdots \\
&\qquad + b^{(n)}_{2n}\left[M'_{n(n-1)} - M'_{n(n+1)}\right] \\
M_{23} &= M'_{23} + a^{(n)}_{21}(M'_{10} - M'_{12}) + a^{(n)}_{22}(M'_{21} - M'_{23}) + \cdots \\
&\qquad + a^{(n)}_{2n}\left[M'_{n(n-1)} - M'_{n(n+1)}\right] \\
&\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\
&\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\
M_{n(n-1)} &= M'_{n(n-1)} + b^{(n)}_{n1}(M'_{10} - M'_{12}) + b^{(n)}_{n2}(M'_{21} - M'_{23}) + \cdots \\
&\qquad + b^{(n)}_{nn}\left[M'_{n(n-1)} - M'_{n(n+1)}\right] \\
M_{n(n+1)} &= M'_{n(n+1)} + a^{(n)}_{n1}(M'_{10} - M'_{12}) + a^{(n)}_{n2}(M'_{21} - M'_{23}) + \cdots \\
&\qquad + a^{(n)}_{nn}\left[M'_{n(n-1)} - M'_{n(n+1)}\right]
\end{aligned}\right\}\ldots(131)$$

For $n = 1$, coefficient $b^{(1)}_{11} = -d_{10}$ and coefficient $a^{(1)}_{11} = d_{12}$ so that Eqs. 131 reduce to:

$$\left.\begin{aligned}
M_{10} &= M'_{10} - d_{10}(M'_{10} - M'_{12}) \\
M_{12} &= M'_{12} + d_{12}(M'_{10} - M'_{12})
\end{aligned}\right\}\ldots\ldots\ldots\ldots(132)$$

For $n = 2$, Eqs. 131 reduce to

$$\left.\begin{aligned}
M_{10} &= M'_{10} - \frac{d_{10}}{\Delta_2}(M'_{10} - M'_{12}) + \frac{q_{21}\,d_{10}}{\Delta_2}(M'_{21} - M'_{23}) \\
M_{12} &= M'_{12} + \frac{d_{12} - p_{12}}{\Delta_2}(M'_{10} - M'_{12}) + \frac{q_{21}(1 - d_{12})}{\Delta_2}(M'_{21} - M'_{23}) \\
M_{21} &= M'_{21} - \frac{q_{12}(1 - d_{21})}{\Delta_2}(M'_{10} - M_{12}) - \frac{d_{21} - p_{12}}{\Delta_2}(M'_{21} - M'_{23}) \\
M_{23} &= M'_{23} - \frac{q_{12}\,d_{23}}{\Delta_2}(M'_{10} - M'_{12}) + \frac{d_{23}}{\Delta_2}(M'_{21} - M'_{23})
\end{aligned}\right\}\ldots(133)$$

For the general n-degree system:

$$\left.\begin{aligned}
&b^{(n)}_{uv}\ (\text{for } 0 < u < n \text{ and for } 0 < v < n) = b^{(n-1)}_{uv} + b^{(n-1)}_{u(n-1)} \\
&\qquad\qquad\qquad \times a^{(n-1)}_{(n-1)v}\, r_{(n-1)n}\, q_{n(n-1)} \frac{\Delta_{(n-1)}}{\Delta_n} \\
&b^{(n)}_{un}\ (\text{for } 0 < u < n) = -\, b^{(n-1)}_{u(n-1)}\, q_{n(n-1)} \frac{\Delta_{(n-1)}}{\Delta_n} \\
&b^{(n)}_{nv}\ (\text{for } 0 < v < n) = -\, a^{(n-1)}_{(n-1)v}\, r_{(n-1)n} [1 - d_{n(n-1)}] \frac{\Delta_{(n-1)}}{\Delta_n} \\
&b^{(n)}_{nn} = \frac{p_{(n-1)n}\, \Delta_{(n-2)} - d_{n(n-1)}\, \Delta_{(n-1)}}{\Delta_n} = \frac{[1 - d_{n(n-1)}]\, \Delta_{(n-1)}}{\Delta_n} - 1 \\
&a^{(n)}_{uv}\ (\text{for } 0 < u < (n-1) \text{ and } 0 < v < n) = a^{(n-1)}_{uv} \\
&\qquad\qquad\qquad + a^{(n-1)}_{u(n-1)}\, a^{(n-1)}_{(n-1)v}\, r_{(n-1)n}\, q_{n(n-1)} \frac{\Delta_{(n-1)}}{\Delta_n} \\
&a^{(n)}_{un}\ (\text{for } 0 < u < (n-1)) = -\, a^{(n-1)}_{u(n-1)}\, q_{n(n-1)} \frac{\Delta_{(n-1)}}{\Delta_n} \\
&a^{(n)}_{(n-1)v}\ (\text{for } 0 < v < n) = a^{(n-1)}_{(n-1)v} + [a^{(n-1)}_{(n-1)(n-1)} - 1] \\
&\qquad\qquad\qquad \times a^{(n-1)}_{(n-1)v}\, r_{(n-1)n}\, q_{n(n-1)} \frac{\Delta_{(n-1)}}{\Delta_n} \\
&a^{(n)}_{nv}\ (\text{for } 0 < v < n) = -\, a^{(n-1)}_{(n-1)v}\, r_{(n-1)n}\, d_{n(n+1)} \frac{\Delta_{(n-1)}}{\Delta_n} \\
&a^{(n)}_{(n-1)n} = [1 - a^{(n-1)}_{(n-1)(n-1)}]\, q_{n(n-1)} \frac{\Delta_{(n-1)}}{\Delta_n} \\
&a^{(n)}_{nn} = d_{n(n+1)} \frac{\Delta_{(n-1)}}{\Delta_n}
\end{aligned}\right\} \quad \ldots(134)$$

Eqs. 134 operate by providing a procedure for building up the coefficients of a higher degree system from those of the lower degree system. Eqs. 132 and 133 for $n = 1$ and $n = 2$ may serve as the initial step in the progressive building up of the coefficients. These formulas are equivalent to the following matrix equations suggested in the author's presentation:

$$\begin{bmatrix} a^{(n)}_{11}\ a^{(n)}_{12} \cdots a^{(n)}_{1n} \\ a^{(n)}_{21}\ a^{(n)}_{22} \cdots a^{(n)}_{2n} \\ \cdots\cdots\cdots\cdots \\ a^{(n)}_{n1}\ a^{(n)}_{n2} \cdots a^{(n)}_{nn} \end{bmatrix} = \begin{bmatrix} d_{12} & q_{21} & 0 & \cdots 0 \\ 0 & d_{23} & q_{32} & \cdots 0 \\ 0 & 0 & d_{34} & \cdots 0 \\ \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & \cdots d_{n(n+1)} \end{bmatrix} \begin{bmatrix} 1 & q_{21} & 0 & \cdots 0 \\ q_{12} & 1 & q_{32} & \cdots 0 \\ 0 & q_{23} & 1 & \cdots 0 \\ \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & \cdots 1 \end{bmatrix}^{-1} \quad \ldots(135a)$$

and

$$\begin{pmatrix} b^{(n)}_{11}\, b^{(n)}_{12}\cdots b^{(n)}_{1n} \\ b^{(n)}_{21}\, b^{(n)}_{22}\cdots b^{(n)}_{2n} \\ \cdots\cdots\cdots\cdots \\ b^{(n)}_{n1}\, b^{(n)}_{n2}\cdots b^{(n)}_{nn} \end{pmatrix} = - \begin{pmatrix} d_{10} & 0 & 0 & \cdots 0 \\ q_{12} & d_{21} & 0 & \cdots 0 \\ 0 & q_{23} & d_{32} & \cdots 0 \\ \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & \cdots d_{n(n-1)} \end{pmatrix} \begin{pmatrix} 1 & q_{21} & 0 & \cdots 0 \\ q_{12} & 1 & q_{32} & \cdots 0 \\ 0 & q_{23} & 1 & \cdots 0 \\ \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & \cdots 1 \end{pmatrix}^{-1} \quad \text{..(135b)}$$

or, in abbreviated symbol form,

$$[a] = [K_a][D]^{-1}\{[1] - [Q']\}^{-1} \text{.............(136a)}$$

and

$$[b] = -[K_b][D]^{-1}\{[1] - [Q']\}^{-1} \text{.............(136b)}$$

The author proceeds to break up the matrix $\{[1] - [Q']\}^{-1}$ into a summation of successive approximations—$[1] + [Q'] + [Q']^2 + [Q']^3 + [Q']^4 + \cdots$.

Although this development is interesting from the standpoint of a theoretical discussion, the writer questions the advantage of such a further transformation, since it changes an absolute value for each coefficient to an approximation, for which the degree of accuracy in each case must be predetermined. Furthermore, the breaking up of the reciprocal matrix into a summation is based on the application of Eq. 97; but that relationship has a condition of convergence imposed upon it and is known not to apply to some mathematical units, as for instance to negative numbers and to complex numbers. Its application in this instance, therefore, would have to be substantiated by a rigorous proof.

Fortunately, it is not difficult to set up a matrix equal to the original reciprocal matrix without resolving it into a summation:

$$\{[1] - [Q']\}^{-1} = \begin{pmatrix} 1 & q_{21} & 0 & 0 & \cdots 0 & 0 \\ q_{12} & 1 & q_{32} & 0 & \cdots 0 & 0 \\ 0 & q_{23} & 1 & q_{43} & \cdots 0 & 0 \\ 0 & 0 & q_{34} & 1 & \cdots 0 & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & 0 & \cdots 1 & q_{n(n-1)} \\ 0 & 0 & 0 & 0 & \cdots q_{(n-1)n} & 1 \end{pmatrix}^{-1}$$

$$= \frac{\begin{pmatrix} e^{(n)}_{11}\, e^{(n)}_{12}\cdots e^{(n)}_{1n} \\ e^{(n)}_{21}\, e^{(n)}_{22}\cdots e^{(n)}_{2n} \\ \cdots\cdots\cdots\cdots \\ e^{(n)}_{n1}\, e^{(n)}_{n2}\cdots e^{(n)}_{nn} \end{pmatrix}}{\Delta_n} \text{....................(137)}$$

For $n = 1$, the e-matrix of Eq. 137 is 1; for $n = 2$, the e-matrix is $\begin{bmatrix} 1 & -q_{21} \\ -q_{12} & 1 \end{bmatrix}$;

and, for $n = 3$, the e-matrix is $\begin{pmatrix} 1 - p_{23} & -q_{21} & q_{21}q_{32} \\ -q_{12} & 1 & -q_{32} \\ q_{12}q_{23} & -q_{23} & 1 - p_{12} \end{pmatrix}$. In general, in the

e-matrix of degree *n*:

$$
\begin{aligned}
e^{(n)}_{uv} \text{ (for } 0 < u < \underline{n-1} \text{ and } 0 < v < \overline{n-1}) &= e^{(n-1)}_{uv} - p_{(n-1)n}\, e^{(n-2)}_{uv} \\
e^{(n)}_{u(n-1)} \text{ (for } 0 < u < \overline{n-1}) &= e^{(n-1)}_{u(n-1)} \\
e^{(n)}_{(n-1)v} \text{ (for } 0 < v < \overline{n-1}) &= e^{(n-1)}_{(n-1)v} \\
e^{(n)}_{un} \text{ (for } 0 < \overline{u} < n) &= -\, e^{(n)}_{u(n-1)}\, q_{n(n-1)} \\
e^{(n)}_{nv} \text{ (for } 0 < v < n) &= -\, e^{(n)}_{(n-1)v}\, q_{(n-1)n} \\
e^{(n)}_{nn} &= \Delta_{(n-1)}
\end{aligned}
$$

Thus, in general, the elements of the *e*-matrix of any degree can be built up from the elements of the *e*-matrices of the lower degrees in a way analogous to the formation of the coefficients in the writer's formulas.

That Eqs. 134 yield the same results as those obtained from the matrix equations (Eqs. 135) is evident, except for the values of $a^{(n)}_{uv}$ and $b^{(n)}_{uv}$, from a study of the general properties of matrices and their adjoints as explained in the author's presentation. The values of $a^{(n)}_{uv}$ and $b^{(n)}_{uv}$ are not evident from the general matrix properties but can be derived from a special characteristic of the *e*-matrix, namely:

$$e^{(n)}_{un}\, e^{(n)}_{nv} = e^{(n)}_{uv}\, \Delta_{(n-1)} - e^{(n-1)}_{uv}\, \Delta_n \quad \ldots\ldots\ldots\ldots (138)$$

which relationship can be proved by mathematical induction.

The writer's formulas were developed some time ago independently of matrix analysis and do not depend on matrix analysis for their derivation. In deducing these formulas the writer made use of the relationship quoted by the author as Eq. 97 but in the reverse order from that used by the author—that is, the fractional form was obtained from the infinite series.

For a two-degree system, apply a unit fixed-end moment at each of the beam ends, successively, and in each case distribute in accordance with the principle of moment distribution. Fig. 9 shows such a distribution for a fixed-

FIG. 9.—COEFFICIENTS OF $(M'_{10} - M'_{12})$ FOR A TWO-DEGREE SYSTEM

end moment at 12. (Note that $1 - p_{12} = \Delta_2$). Other coefficients are obtained similarly. For each final end moment an infinite power series is obtained in p_{12}. The latter can be proved greater than zero and less than one, which is a necessary and sufficient condition for the convergence of the power series and the validity of relationship expressed by Eq. 97. The end moment coefficients are therefore summed up in accordance with this relationship.

The same procedure can be used for higher degree systems, but the power series becomes complicated as the degree of the system increases and the con-

vergence of the series becomes less evident. The relationships expressed by Eqs. 134 then become useful. To derive these relationships, the writer divided the n-degree system into two parts, the first part containing supports 1 to $(n - 1)$, inclusive, and the second part containing support n.

Fig. 10 shows the coefficients of fixed-end moments applied at points $v(v - 1)$

Fixed-end moment at point $(n - 1)n$	$-b^{(n-1)}_{(n-1)(n-1)}$	$-a^{(n-1)}_{(n-1)(n-1)}$	$r_{(n-1)n}\, a^{(n-1)}_{(n-1)(n-1)}$

FIG. 10.—COEFFICIENTS FOR THE FIRST PART OF THE n-DEGREE SYSTEM

and $(n - 1)n$ for the end moments at the various supports of the first part of the system and for carry-overs to the second part. The carry-overs act as fixed-end moments in the second part and bring back corresponding carry-overs to the first part to act as new fixed-end moments at $(n - 1)n$. The sum total of all the carry-over moments induced in the first part is an infinite power series which can be summed up by Eq. 97. The coefficients of the second part were treated similarly. The effects of both the original fixed-end moments and the summation of the infinite series of carry-overs combine to yield Eqs. 134.

The summation of the carry-overs and the final form of Eqs. 134 are conditioned on the following relationships:

$$0 < q_{n(n-1)}\, r_{(n-1)n}\, a^{(n-1)}{}_{(n-1)(n-1)} < 1 \ldots\ldots\ldots\ldots (139)$$

$$a^{(n)}{}_{nn} = \frac{d_{n(n+1)}\, \Delta_{(n-1)}}{\Delta_n} \ldots\ldots\ldots\ldots (140)$$

and

$$q_{n(n-1)}\, r_{(n-1)n}\, a^{(n-1)}{}_{(n-1)(n-1)} = \frac{p_{(n-1)n}\, \Delta_{(n-2)}}{\Delta_{(n-1)}} \ldots\ldots\ldots\ldots (141)$$

These relationships are interdependent and can be proved together by mathematical induction, remembering that

$$\Delta_n = \Delta_{(n-1)} - p_{(n-1)n}\, \Delta_{(n-2)} \ldots\ldots\ldots\ldots (142)$$

which follows from the peculiar characteristic of the determinant Δ.

Although the higher degree coefficients are thus obtained from those of the lower degrees, the writer has found it convenient to develop Eqs. 131 for a system of a sufficiently high degree and to apply them also to lower degree systems by equating to zero the constants of those spans which are not a part of the system under consideration.

The moments for a five-degree system (which is probably of a high enough degree for ordinary work with continuous beams) are as follows:

$$
\left.
\begin{aligned}
M_{10} = {} & M'_{10} - \frac{d_{10}(1 - p_{23} - p_{34} - p_{45} + p_{23}\,p_{45})}{\Delta_5}(M'_{10} - M'_{12}) \\
& + \frac{d_{10}\,q_{21}(1 - p_{34} - p_{45})}{\Delta_5}(M'_{21} - M'_{23}) - \frac{d_{10}\,q_{21}\,q_{32}(1 - p_{45})}{\Delta_5} \\
& \times (M'_{32} - M'_{34}) + \frac{d_{10}\,q_{21}\,q_{32}\,q_{43}}{\Delta_5}(M'_{43} - M'_{45}) \\
& \qquad - \frac{d_{10}\,q_{21}\,q_{32}\,q_{43}\,q_{54}}{\Delta_5}(M'_{54} - M'_{56}) \\
M_{12} = {} & M'_{12} + \frac{d_{12}(1 - p_{23} - p_{34} - p_{45} + p_{23}\,p_{45}) - p_{12}(1 - p_{34} - p_{45})}{\Delta_5} \\
& \times (M'_{10} + M'_{12}) + \frac{(1 - d_{12})\,q_{21}(1 - p_{34} - p_{45})}{\Delta_5}(M'_{21} - M'_{23}) \\
& - \frac{(1 - d_{12})q_{21}\,q_{32}(1 - p_{45})}{\Delta_5}(M'_{32} - M'_{34}) + \frac{(1 - d_{12})\,q_{21}\,q_{32}\,q_{43}}{\Delta_5} \\
& \times (M'_{43} - M'_{45}) - \frac{(1 - d_{12})\,q_{21}\,q_{32}\,q_{43}\,q_{54}}{\Delta_5}(M'_{54} - M'_{56}) \\
M_{21} = {} & M'_{21} + \frac{q_{12}\,p_{23}(1 - p_{45}) - q_{12}(1 - d_{21})\,(1 - p_{34} - p_{45})}{\Delta_5} \\
& \times (M'_{10} - M'_{12}) - \frac{(d_{21} - p_{12})\,(1 - p_{34} - p_{45})}{\Delta_5}(M'_{21} - M'_{23}) \\
& + \frac{q_{32}(d_{21} - p_{12})\,(1 - p_{45})}{\Delta_5}(M'_{32} - M'_{34}) - \frac{q_{32}\,q_{43}(d_{21} - p_{12})}{\Delta_5} \\
& \times (M'_{43} - M'_{45}) + \frac{q_{32}\,q_{43}\,q_{54}(d_{21} - p_{12})}{\Delta_5}(M'_{54} - M'_{56}) \\
M_{23} = {} & M'_{23} + \frac{q_{12}\,p_{23}(1 - p_{45}) - q_{12}\,d_{23}(1 - p_{34} - p_{45})}{\Delta_5} \\
& \times (M'_{10} - M'_{12}) - \frac{p_{23}(1 - p_{45}) - d_{23}(1 - p_{34} - p_{45})}{\Delta_5} \\
& \times (M'_{21} - M'_{23}) + \frac{q_{32}(1 - d_{23} - p_{12})\,(1 - p_{45})}{\Delta_5}(M'_{32} - M'_{34}) \\
& - \frac{q_{32}\,q_{43}(1 - d_{23} - p_{12})}{\Delta_5}(M'_{43} - M'_{45}) \\
& \qquad + \frac{q_{32}\,q_{43}\,q_{54}(1 - d_{23} - p_{12})}{\Delta_5}(M'_{54} - M'_{56}) \\
M_{32} = {} & M'_{32} + \frac{q_{12}\,q_{23}(1 - d_{32} - p_{34} - p_{45} + d_{32}\,p_{45})}{\Delta_5}(M'_{10} - M'_{12}) \\
& - \frac{q_{23}(1 - p_{34} - p_{45} - d_{32} + d_{32}\,p_{45})}{\Delta_5}(M'_{21} - M'_{23}) \\
& + \frac{(p_{23} - d_{32} + d_{32}\,p_{12})\,(1 - p_{45})}{\Delta_5}(M'_{32} - M'_{34}) \\
& - \frac{q_{43}(p_{23} - d_{32} + d_{32}\,p_{12})}{\Delta_5}(M'_{43} - M'_{45}) \\
& \qquad + \frac{q_{43}\,q_{54}(p_{23} - d_{32} + d_{32}\,p_{12})}{\Delta_5}(M'_{54} - M'_{56})
\end{aligned}
\right\} \quad \ldots (143)
$$

and

$$\Delta_5 = 1 - p_{12} - p_{23} - (1 - p_{12})p_{34} - (1 - p_{12} - p_{23})p_{45} \quad \ldots\ldots(144)$$

The remainder of the moments can be obtained from the foregoing through the symmetry of the system. In matrix form,

$$\begin{bmatrix} M_{12} - M'_{12} \\ M_{23} - M'_{23} \\ M_{34} - M'_{34} \\ M_{45} - M'_{45} \\ M_{56} - M'_{56} \end{bmatrix} = \begin{bmatrix} d_{12} & q_{21} & 0 & 0 & 0 \\ 0 & d_{23} & q_{32} & 0 & 0 \\ 0 & 0 & d_{34} & q_{43} & 0 \\ 0 & 0 & 0 & d_{45} & q_{54} \\ 0 & 0 & 0 & 0 & d_{56} \end{bmatrix} \frac{[e]^{(5)}}{\Delta_5} \begin{bmatrix} (M'_{10} - M'_{12}) \\ (M'_{21} - M'_{23}) \\ (M'_{32} - M'_{34}) \\ (M'_{43} - M'_{45}) \\ (M'_{54} - M'_{56}) \end{bmatrix} \quad \ldots(145a)$$

and

$$\begin{bmatrix} M_{10} - M'_{10} \\ M_{21} - M'_{21} \\ M_{32} - M'_{32} \\ M_{43} - M'_{43} \\ M_{54} - M'_{54} \end{bmatrix} = \begin{bmatrix} -d_{10} & 0 & 0 & 0 & 0 \\ -q_{12} & -d_{21} & 0 & 0 & 0 \\ 0 & -q_{23} & -d_{32} & 0 & 0 \\ 0 & 0 & -q_{34} & -d_{43} & 0 \\ 0 & 0 & 0 & -q_{45} & -d_{54} \end{bmatrix} \frac{[e]^{(5)}}{\Delta_5}$$

$$\times \begin{bmatrix} (M'_{10} - M'_{12}) \\ (M'_{21} - M'_{23}) \\ (M'_{32} - M'_{34}) \\ (M'_{43} - M'_{45}) \\ (M'_{54} - M'_{56}) \end{bmatrix} \quad \ldots(145b)$$

in which

$$[e]^{(5)} = \begin{bmatrix} 1-p_{23}-p_{34}-p_{45}(1-p_{23}) & -q_{21}(1-p_{34}-p_{45}) & q_{21}\,q_{32}(1-p_{45}) & -q_{21}\,q_{32}\,q_{43} & q_{21}\,q_{32}\,q_{43}\,q_{54} \\ -q_{12}(1-p_{34}-p_{45}) & 1-p_{34}-p_{45} & -q_{32}(1-p_{45}) & q_{32}\,q_{43} & -q_{32}\,q_{43}\,q_{54} \\ q_{12}\,q_{23}(1-p_{45}) & -q_{23}(1-p_{45}) & (1-p_{12})\,(1-p_{45}) & -q_{43}(1-p_{12}) & q_{43}\,q_{54}(1-p_{12}) \\ -q_{12}\,q_{23}\,q_{34} & q_{23}\,q_{34} & -q_{34}(1-p_{12}) & 1-p_{12}-p_{23} & -q_{54}(1-p_{12}-p_{23}) \\ q_{12}\,q_{23}\,q_{34}\,q_{45} & -q_{23}\,q_{34}\,q_{45} & q_{34}\,q_{45}(1-p_{12}) & -q_{45}(1-p_{12}-p_{23}) & 1-p_{12}-p_{23}-p_{34}(1-p_{12}) \end{bmatrix} \quad \ldots(146)$$

In conclusion, the writer is grateful for the opportunity of having the results of his own studies verified by a new approach and hopes that this discussion will contribute to the general study of the subject.

RUFUS OLDENBURGER,[17] ESQ.—In a paper[18] by the writer, matrices were introduced to clarify the mathematics of the Cross method of structural analysis[19] because the operations involved in this analysis are linear, and the convergence questions can be expressed simply in terms of matrices. The Cross method is an infinite process whereby fixed joints are relaxed so that the moment distribution for a given structure is obtained from the moment distribution when all joints are fixed.

Mr. Benscoter shows that by matrices one can proceed directly from the fixed joint moments to the final moment distribution. This method, however, involves computation of the inverse of a matrix. Because generally it is exceedingly difficult to obtain the inverse of a matrix directly, the series (Eq. 98) is used, in which $[I]$ is the identity matrix and $[Q]$ is a matrix of the same order. This expansion is suggested by the similar expansion (Eq. 97) for $1/(1 - \epsilon)$ in the case of a number ϵ.

That one can work directly from the initial to the final moment distribution by matrices follows from the fact that the final moments can be obtained from the initial moments by solving linear equations. By "directly" is meant "in a finite number of steps." The importance of Mr. Benscoter's use of matrices lies in the fact that this point of view leads to an infinite process through the use of Eq. 98. It is sometimes simple to obtain successive powers of a matrix $[Q]$, so that if the series converges rapidly, a good approximation to the inverse of $[I] - [Q]$ is obtained. Computation of complicated determinants is thus avoided; but to use Eq. 98 is to employ an approximation method of computation. In fact, it has been shown that each term in that equation corresponds to a standard computation cycle and that each cycle is composed of two steps. "In the first step all joints are balanced and in the second step the carry-over calculation is performed in each span."

The great value of Eq. 98 thus lies in the fact that the terms in the series correspond to the standard accepted procedure for "balancing" moments. It is, however, only one method out of infinitely many for applying the Hardy Cross type of method. The approach in the writer's paper[18] on the subject is general and therefore covers the balancing process corrresponding to Eq. 98. In particular, the convergence theory contained in that paper can be applied to Eq. 98. For reasons of exposition both Mr. Benscoter and the writer have restricted themselves to the case of the continuous beam. If the numbers 1, 2, 3, $\cdot\cdot\cdot$, n be assigned to the supports along a given beam, the convergence proof of the writer for balancing alternately odd-numbered and even-numbered supports goes over without change to the standard process corresponding to Eq. 98.

---

[17] Prof. of Math., Illinois Inst. of Tech., Chicago, Ill.

[18] "Convergence of Hardy Cross's Balancing Process," by Rufus Oldenburger, *Journal of Applied Mechanics*, December, 1940, pp. A-166 to A-170.

[19] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, *Transactions*, ASCE Vol., 96, 1932, pp. 1-10.

In the writer's matrix treatment of continuous beams the vector $[M]$ of the desired moments is computed from the relation:

$$[M] = \lim_{n\to\infty} [A]^n [M'] \qquad (147)$$

for the vector $[M']$ of given moments, provided that the balancing process is a cycle repeated forever. For the elements of the vectors occurring in Eq. 147 the total moments at the supports have been used. This was done for mathematical simplicity. Mr. Benscoter's technique of working with left end moments and right end moments, instead of lumping the moments at each support, has considerable value for understanding the theory of the balancing process, and is needed to determine the final left end moments and right end moments. However, the writer's treatment readily extends to the case where the elements in the vectors of Eq. 147 are the individual unlumped moments. Of course, $[A]$ must be changed accordingly.

Matrices are of unquestionable value in understanding methods for obtaining moment distributions in structures. When it comes to actual computations the situation is different. The writer has still to see a computational process in which the explicit use of matrices gives an economy of effort, although matrices are often of great value in prescribing what computational process should be employed. In any case, it is easier to use Eq. 147 for left end moments and right end moments, obtaining the result by computing powers of a matrix, than to use Eq. 98, where one must perform the additional operation of adding powers after they have been computed.

Mr. Benscoter's paper is an excellent exposition of the matrix point of view in structural analysis, and sheds much light on what moment balancing really is. There is still a need, however, for more specific information on the convergence of the Hardy Cross process, in particular for the case where the moments at supports are not lumped. Above all the problem of the rapidity of convergence should be studied. The designer should know how many steps must be taken to obtain a given accuracy. Because of the importance of the subject a complete physical and mathematical treatment should appear in a book on general structures, beginning from basic fundamentals. In such a treatment matrices would play a dominant role.

Horace A. Johnson,[30] Assoc. M. ASCE.—A service has been done for the engineering profession by the presentation of the subject of matrices and determinants. It has always been a source of wonder to the writer that so few engineers are acquainted with these powerful mathematical tools, or even with the most elementary use of determinants.

However, the author has possibly been overenthusiastic in the use of matrices. For example, Eqs. 36 are expressed as $[A][x] = [k]$ in Eq. 39. Although Eq. 39 is a more succinct expression of Eqs. 36, it conveys less

[30] Engr. (Civ.), Corps of Engrs., War Dept., Sacramento, Calif.

meaning to a person not using matrices frequently, as is the case with most engineers, and it in no way reduces the amount of work required for the numerical solution of Eqs. 36.

Eqs. 36 may be solved easily by use of determinants as follows:

$$x_1 = \frac{\begin{vmatrix} 2 & 1 & -2 \\ 1 & 2 & 3 \\ 3 & -1 & 4 \end{vmatrix}}{\begin{vmatrix} 3 & 1 & -2 \\ 1 & 2 & 3 \\ 2 & 1 & 4 \end{vmatrix}} = \frac{41}{45}; \quad x_2 = \frac{\begin{vmatrix} 3 & 2 & -2 \\ 1 & 1 & 3 \\ 2 & 3 & 4 \end{vmatrix}}{45} = -\frac{13}{45};$$

$$x_3 = \frac{\begin{vmatrix} 3 & 1 & 2 \\ 1 & 2 & 1 \\ 2 & -1 & 3 \end{vmatrix}}{45} = \frac{10}{45} = \frac{2}{9}$$

In each of these cases the solution is obtained by substituting the constant terms for the coefficients of the desired unknown in the numerator determinants, the remaining terms being the coefficients of the other unknowns. The denominator determinant in each case is composed of the coefficients of the unknowns. This procedure seems simpler than the solution given by the author.

Solution of simultaneous equations by the use of determinants is a systematic approach to the problem. It does not, however, avoid a large amount of numerical work as the expansion of an nth-order determinant gives $n!$-terms; thus, the expansion of a fifth-order determinant gives 120 terms.

Lloyd T. Cheney,[21] Jun. ASCE.—The possible advantages of matrix algebra in various methods of structural analysis are called to the attention of engineers by the author of this commendable paper. The painstaking explanation of elementary operations gives the engineer a condensation of these processes, which would otherwise be found only after considerable search in one or more mathematics texts. This explanation should serve to demonstrate the relative ease of manipulation of matrix algebra and to reassure the engineer that with the necessary practice it can become a most powerful instrument.

Structural engineers are generally introduced to series of simultaneous equations in applying the classical theorem of three moments or the method of slope deflection.[22] A frequently suggested method of solution is that of arranging the coefficients and constant terms in tabular form.[23] By successive manipulations the series is reduced to a single equation containing a single

[21] Asst. Prof. of Civ. Eng., Cornell Univ., Ithaca, N. Y.

[22] *Engineering Studies No. 1*, Univ. of Minnesota, Minneapolis, Minn.

[23] "Structural Theory," by Hale Sutherland and Harry Lake Bowman, John Wiley & Sons, Inc., New York, N. Y., 1935, p. 212.

unknown variable. With the variable thus determined, successive substitutions are made until all variables have been found. For example, the system illustrated in Eqs. 36*a*, 36*b*, and 36*c*, Table 2, has been arranged with the steps numbered and the operations noted so that the table is self-explanatory.

TABLE 2.—FORM FOR SOLUTION OF SIMULTANEOUS EQUATIONS

Step number	Operation	COEFFICIENTS			Right side of equation, k
		x_1	x_2	x_3	
(1)	(2)	(3)	(4)	(5)	(6)
1	Eq. 36*a*	3	1	−2	2
2	Eq. 36*b*	1	2	3	1
3	Eq. 36*c*	2	−1	4	3
4	Step 2 × step 1	6	2	−4	4
5	....	1	2	3	1
6	Step 2 × step 3	4	−2	8	6
7	Step 4 + step 6	10	0	4	10
8	Step 5 + step 6	5	0	11	7
9	Step 2 × step 8	10	0	22	14
10	Step 9 − step 7	0	0	18	4

Step 10 of Table 2 gives the value for x_3. Study of the table discloses that within it are the matrices shown by Eq. 37, but that no advantage has been taken of matrix algebra in the solution. This suggests that engineers have been working with matrices but have hesitated to use them as such.

Attention has been called to the fact that other methods yield quicker results for a single condition of load because of the possibility of lengthy computations in evaluating the reciprocal of the stiffness matrix $[K]$. It might be well to emphasize that methods for evaluating more cumbersome determinants are not so frightening as the size of the determinant itself would suggest.

The algebraic sum of the products of the elements of a row and their corresponding minors will give a quick means of evaluating larger determinants. Employing this method with the 4-by-4 determinant:

$$\begin{vmatrix} a_{11} & a_{12} & a_{13} & a_{14} \\ a_{21} & a_{22} & a_{23} & a_{24} \\ a_{31} & a_{32} & a_{33} & a_{34} \\ a_{41} & a_{42} & a_{43} & a_{44} \end{vmatrix} = a_{11} \begin{vmatrix} a_{22} & a_{23} & a_{24} \\ a_{32} & a_{33} & a_{34} \\ a_{42} & a_{43} & a_{44} \end{vmatrix} - a_{12} \begin{vmatrix} a_{21} & a_{23} & a_{24} \\ a_{31} & a_{33} & a_{34} \\ a_{41} & a_{43} & a_{44} \end{vmatrix}$$

$$+ a_{13} \begin{vmatrix} a_{21} & a_{22} & a_{24} \\ a_{31} & a_{32} & a_{34} \\ a_{41} & a_{42} & a_{44} \end{vmatrix} - a_{14} \begin{vmatrix} a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \\ a_{41} & a_{42} & a_{43} \end{vmatrix} \ldots\ldots\ldots\ldots\ldots (148)$$

Still larger determinants may be evaluated by expressing them in terms of the algebraic sum of the products of smaller determinants. Consider the 6-by-6 determinant:

$$\begin{vmatrix} a_{11} & a_{12} & a_{13} & a_{14} & a_{15} & a_{16} \\ a_{21} & a_{22} & a_{23} & a_{24} & a_{25} & a_{26} \\ a_{31} & a_{32} & a_{33} & a_{34} & a_{35} & a_{36} \\ a_{41} & a_{42} & a_{43} & a_{44} & a_{45} & a_{46} \\ a_{51} & a_{52} & a_{53} & a_{54} & a_{55} & a_{56} \\ a_{61} & a_{62} & a_{63} & a_{64} & a_{65} & a_{66} \end{vmatrix} = | A | \ldots\ldots\ldots\ldots (149)$$

Making the substitutions—

$$\left.\begin{matrix} |\,B\,| = \begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix} & |\,C\,| = \begin{vmatrix} a_{14} & a_{15} & a_{16} \\ a_{24} & a_{25} & a_{26} \\ a_{34} & a_{35} & a_{36} \end{vmatrix} \\ |\,D\,| = \begin{vmatrix} a_{41} & a_{42} & a_{43} \\ a_{51} & a_{52} & a_{53} \\ a_{61} & a_{62} & a_{63} \end{vmatrix} & |\,E\,| = \begin{vmatrix} a_{44} & a_{45} & a_{46} \\ a_{54} & a_{55} & a_{56} \\ a_{64} & a_{65} & a_{66} \end{vmatrix} \end{matrix}\right\} \ldots\ldots(150)$$

—Eq. 149 becomes:

$$|\,A\,| = |\,B\,|\,|\,E\,| - |\,C\,|\,|\,D\,| \ldots\ldots\ldots\ldots\ldots(151)$$

By using a combination of these methods, plus manipulations to reduce some of the elements to zero, the evaluations may be accomplished. However, although these computations will be routine, there is no avoiding the fact that they will be time consuming.

The new application of matrix algebra should stimulate interest in this mathematical instrument and result in its wider application to common engineering problems.

Paul W. Norton,[24] M. ASCE.—Attention has been directed by Mr. Benscoter to interesting possibilities in the use of matrix algebra for the solution of structural problems involving simultaneous equations. By taking advantage of the implement afforded by the matrix notation, the author achieves a noteworthy abbreviation of the process of solution by means of determinants in two important respects: (1) For the several determinant ratios expressing the several unknown quantities, he substitutes a single matrix expression, comprehending in itself the solution for all the unknowns; and (2) the reduction of this expression to the final numerical results involves, not the evaluation of as many determinants as there are unknown quantities, but the evaluation of only one, plus a relatively simple operation on the matrices.

The application of these methods to the determination of moments in rectangular frames, such as those commonly encountered in building construction, is of particular interest to the writer. Some earlier studies of a similar nature, followed by careful reading of this paper, have confirmed him in the conclusions that, as applied to such problems, the formation of the fundamental matrix equation follows even more immediately and obviously from an inspection of the stiffness properties of the frame, and of readily derived functions of its loading, and the indicated numerical operations can be done by processes even less laborious than revealed by the author.

To present clearly a discussion which seems to be justified by this view, and by the hope that its demonstration may contribute something to the usefulness of the author's paper, it will be expedient to show the application of the methods

[24] Cons. Engr., Boston, Mass.

under consideration to the solution of a specific example. The derivation of the determinant and matrix expressions, and the routine of computation will be illustrated, with such explanatory comment as seems useful to the purpose. The adaptability of the method to frames in which occur members having varying moments of inertia, and to those subject to translation of joints, or sidesway, will be indicated without details of analysis or numerical illustration.

Notation.—In addition to the notation of the paper the following symbols are introduced:

M_{pq} = clockwise moment acting at point P on the member (or part of member) PQ.

M_f = Fixed-end moment

$M_{f,pq}$ = a moment M_f at point P; that is, the value of M_{pq} if member PQ were fixed at both ends.

$M'_{f,pq}$ = a modified value of M_f; that is, the value of M_{pq} if member PQ were fixed at point P and freely supported at point Q; for a prismatic member, $M'_{f,pq} = M_{f,pq} - \frac{1}{2} M_{f,qp}$.

$\sum M_{f,p}$ = summation of all values of M_f or $(M_f)'$ for all members intersecting at joint P.

K_{pq} = stiffness coefficient of member PQ at end P; the actual stiffness divided by the constant $4\,E$. For a prismatic member K_{pq} is the $\frac{I}{L}$-value of member PQ. This is the stiffness coefficient as defined in the familiar form of the slope-deflection equation. Its value is one fourth of that defined by the author, and is preferable because it avoids fractions and simplifies numerical work.

K'_{pq} = a value of K_{pq} modified to account for freedom at end Q. For a prismatic member, $K'_{pq} = \frac{3}{4} \times K_{pq}$.

$\sum K_p$ = the summation of all values of K, or K', for all members intersecting at joint P.

Φ = the angular clockwise rotation of joint P, multiplied by $2\,E$.

z = a parameter moment; z_{pq} and z_{qp} are parameter moments pertaining to member PQ, the derivation of which (by methods to be described) leads to a determination of moment conditions throughout span PQ.

Determinant of the Frame.—The frame in Fig. 11 is that used by Hardy Cross, M. ASCE, to illustrate the procedure described in his paper, "Analysis of Continuous Frames by Distributing Fixed-End Moments."[25] The data are here transcribed as given by Professor Cross except: (*a*) The signs of the fixed-end moments are altered to conform to the convention here established; and (*b*) for the member hinged at point F the "modified" stiffness coefficient and fixed-end moment at point C are used. These are:

$$K'_{cf} = \tfrac{3}{4} \times K_{cf} = \tfrac{3}{4} \times 2 = 1.5 \ldots\ldots\ldots\ldots\ldots (152a)$$

[25] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, *Transactions*, ASCE, Vol. 96, 1932, p. 8, Fig. 2.

and

$$M'_{f,ef} = M_{f,ef} - \tfrac{1}{2} M_{f,fe} = 80 - \tfrac{1}{2}(-60) = 110 \quad \ldots\ldots (152b)$$

In Fig. 11, stiffness coefficients are indicated by numerals in circles, and fixed-end moments by unenclosed numerals at ends of members.

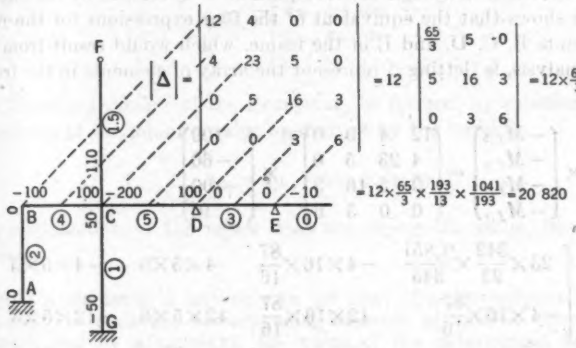

FIG. 11

If the slope-deflection equation were to be used to express the moment at each interior joint in terms of the rotations at that and at adjacent joints, four equations would result relating the four rotations at points B, C, D, and E. One method of solving this set of equations simultaneously involves forming a determinant whose elements are the coefficients of the unknown rotations. This determinant, often called the "determinant of the set of equations," will be referred to herein as $|\Delta|$, the determinant of the frame. It is important in the analysis of the frame, either by determinants or by the author's matrix expressions; it is independent of the loading; and it can be derived by inspection. For its elements, it has functions of the K-values of the members, related to the array of values recorded on the diagram of the frame as illustrated by Fig. 11. The order of $|\Delta|$ is equal to the number of interior joints; the principal diagonal consists of the double sum of the K-values of all members meeting at the corresponding joints; the adjacent diagonals (superdiagonal and subdiagonal) consist of the K-values of the members, in order; and all other elements are zero. Thus, the general expression for the determinant of such a frame, in which interior joints are denoted by B, C, D, E, is:

$$|\Delta| = \begin{vmatrix} 2\sum K_b & K_{cb} & 0 & 0 \\ K_{bc} & 2\sum K_c & K_{dc} & 0 \\ 0 & K_{cd} & 2\sum K_d & K_{ed} \\ 0 & 0 & K_{de} & 2\sum K_e \end{vmatrix} \quad \ldots\ldots\ldots (153)$$

(it being understood that modified values K' and $(M_f)'$ are to be used in place of K and M_f for members hinged at the remote end).

Rotations of the Joints.—To continue with the analysis of the frame by means of determinants it would be necessary to form another determinant corresponding to each joint, and involving the load terms, or fixed-end moments. These also can be derived by inspection, and the numerical computations can be comparatively brief.

However, there is a marked advantage in being able to express the solution for all parts of the frame in a single matrix equation, as developed by the author. Mr. Benscoter shows that the equivalent of the four expressions for the rotations at the joints B, C, D, and E of the frame, which would result from the determinant analysis, is (letting Δ represent the array of elements in the frame determinant):

$$\begin{Bmatrix} \Phi_b \\ \Phi_c \\ \Phi_d \\ \Phi_e \end{Bmatrix} = [\Delta]^{-1} \times \begin{Bmatrix} -M_{f,b} \\ -M_{f,c} \\ -M_{f,d} \\ -M_{f,e} \end{Bmatrix} = \begin{pmatrix} 12 & 4 & 0 & 0 \\ 4 & 23 & 5 & 0 \\ 0 & 5 & 16 & 3 \\ 0 & 0 & 3 & 6 \end{pmatrix}^{-1} \times \begin{Bmatrix} 100 \\ -60 \\ -100 \\ 10 \end{Bmatrix}$$

$$= \frac{1}{20{,}820} \begin{bmatrix} 23\times\frac{343}{23}\times\frac{1{,}851}{343} & -4\times16\times\frac{87}{16} & 4\times5\times6 & -4\times5\times3 \\ -4\times16\times\frac{87}{16} & 12\times16\times\frac{87}{16} & 12\times5\times6 & -12\times5\times3 \\ 4\times5\times6 & -12\times5\times6 & 12\times\frac{65}{3}\times6 & -12\times\frac{65}{3}\times3 \\ -4\times5\times3 & 12\times5\times3 & -12\times\frac{65}{3}\times3 & 12\times\frac{65}{3}\times\frac{193}{13} \end{bmatrix}$$

$$\times \begin{Bmatrix} 100 \\ -60 \\ -100 \\ 10 \end{Bmatrix} = \frac{1}{20{,}820} \begin{pmatrix} 1{,}851 & -348 & 120 & -60 \\ -348 & 1{,}044 & -360 & 180 \\ 120 & -360 & 1{,}560 & -780 \\ -60 & 180 & -780 & 3{,}860 \end{pmatrix} \times \begin{Bmatrix} 100 \\ -60 \\ -100 \\ 10 \end{Bmatrix}$$

$$= \frac{1}{20{,}820} \begin{Bmatrix} 185{,}100 & +20{,}880 & -12{,}000 & -600 \\ -34{,}800 & -62{,}640 & +36{,}000 & +1{,}800 \\ 12{,}000 & +21{,}600 & -156{,}000 & -7{,}800 \\ -6{,}000 & -10{,}800 & +78{,}000 & +38{,}600 \end{Bmatrix}$$

$$= \frac{1}{20{,}820} \begin{Bmatrix} 193{,}380 \\ -59{,}640 \\ -130{,}200 \\ 99{,}800 \end{Bmatrix} = \begin{Bmatrix} 9.288 \\ -2.864 \\ -6.253 \\ 4.793 \end{Bmatrix} \quad \text{(154)}$$

—that is, $\Phi_b = 9.288$; $\Phi_c = -2.864$; $\Phi_d = -6.253$; and $\Phi_e = 4.793$.

Before proceeding, attention may be directed to the process of reducing a determinant to a numerical value, such as the 20,820 in Fig. 11, and to the routine of computation in determining the elements of the matrix reciprocal, as illustrated by Eq. 154.

Evaluation of a Determinant.—Numerical evaluation of a determinant by repeated summation of minors, as described in most elementary texts are illustrated by the author in Eqs. 2*a* and 2*b*, is a process that becomes increasingly

laborious for those of orders higher than the third. (A determinant of the tenth order, with no zeros among the elements, would require writing and evaluating 2,606,500 minors of all orders.) A much briefer method, illustrated by the numerical work of Fig. 11, and of general application, is the following: In any determinant,

$$|D| = \begin{vmatrix} a_{11} & a_{12} & a_{13} & \cdots \\ a_{21} & a_{22} & a_{23} & \cdots \\ a_{31} & a_{32} & a_{33} & \cdots \\ \cdots & \cdots & \cdots & \cdots \end{vmatrix} \quad \cdots\cdots\cdots\cdots (155)$$

let a "modified minor" of the element a_{11} be formed, by substituting for each element a_{jk} of the minor a value b_{jk} derived by the formula:

$$b_{jk} = a_{jk} - (a_{1k} \times a_{j1}/a_{11}) \quad \cdots\cdots\cdots\cdots (156)$$

This modification of the minor does not change its value, by virtue of the theorem:

> "If the elements of any column (or row) of a determinant be altered by adding to each the corresponding element of another column (or row), multiplied by a constant, the value of the determinant is thereby unchanged."

Then $|D|$ has the form:

$$|D| = \begin{vmatrix} a_{11} & 0 & 0 & \cdots \\ a_{21} & b_{22} & b_{23} & \cdots \\ a_{31} & b_{32} & b_{33} & \cdots \\ \cdots & \cdots & \cdots & \cdots \end{vmatrix} = a_{11} \begin{vmatrix} b_{22} & b_{23} & \cdots \\ b_{32} & b_{33} & \cdots \\ \cdots & \cdots & \cdots \end{vmatrix} \quad \cdots\cdots\cdots\cdots (157)$$

and the evaluation will have proceeded by reduction of the determinant of the nth order to one of the $(n-1)$th order. The numerical value of any element b_{jk} is usually ascertainable mentally with small effort. Thus, in $|\Delta|$ of the example considered, the element a_{22} is 23, and the "modified" element b_{22} is $23 - 4 \times 4/12 = 65/3$. The presence of zeros among the elements also greatly facilitates the computation; thus, the element a_{23} in $|\Delta|$ is 5, and $b_{23} = 5 - 0 \times 4/12 = 5$, no modification of the element resulting. Furthermore, the successive reductions in order accomplished by this process result in a continued product of numbers, which, expressed as fractions, invariably lead readily to the final result by cancellations of like figures in numerators and denominators.

Formation of the Reciprocal Matrix.—The author has shown (see Eq. 33) that the reciprocal of $[\Delta]$,

$$[\Delta]^{-1} = \frac{\text{adjoint of } [\Delta]}{|\Delta|} \quad \cdots\cdots\cdots\cdots (158)$$

The value of $|\Delta|$ having already been found, it remains to discover the most direct and rapid way to write the adjoint. The author remarks that in this lies the chief difficulty of the computation; it seems to the writer that the

device whereby the matrix reciprocal is expressed in the form of a power series (see heading, "Matrix Reciprocal Expressed by Power Series") is of academic interest, and makes little progress toward facilitating the computation.

In obtaining the results in the problem used as an example it has not been necessary to write down any figures other than those appearing in Eq. 154. The fact that all elements of $[\Delta]$ are zero, except those in the principal and two adjacent diagonals, makes easy the formation of its adjoint.

Let a matrix of this form, and of the nth order, be

$$[M] = \begin{bmatrix} a_{11} & a_{12} & 0 & 0 \\ a_{21} & a_{22} & a_{23} & 0 \\ 0 & a_{32} & a_{33} & a_{34} \\ 0 & 0 & a_{43} & a_{44} \end{bmatrix} \qquad (159)$$

Proceeding to form the adjoint by substituting for each element its cofactor, and to evaluate each cofactor (which is a determinant of the $(n - 1)$th order) by the process outlined herein under the heading, "Evaluation of a Determinant," and illustrated in the equation in Fig. 11, a matrix (still of the nth order) is obtained such that each element is the product of $(n - 1)$ factors, as follows:

Adjoint of $[M]$

$$= \begin{bmatrix} a_{22}\,a'_{33}\,a''_{44} & -a_{21}\,a_{33}\,a'_{44} & a_{21}\,a_{32}\,a_{44} & -a_{21}\,a_{32}\,a_{43} & \cdots \\ -a_{12}\,a_{33}\,a'_{44} & a_{11}\,a_{33}\,a'_{44} & -a_{11}\,a_{32}\,a_{44} & a_{11}\,a_{32}\,a_{43} & \cdots \\ a_{12}\,a_{23}\,a_{44} & -a_{11}\,a_{23}\,a_{44} & a_{11}\,a'_{22}\,a_{44} & -a_{11}\,a'_{22}\,a_{43} & \cdots \\ -a_{12}\,a_{23}\,a_{34} & a_{11}\,a_{23}\,a_{34} & -a_{11}\,a'_{22}\,a_{34} & a_{11}\,a'_{22}\,a''_{33} & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots \end{bmatrix} \qquad (160)$$

Observation of easily stated rules to which the elements of the adjoint conform enables one to write it at once for a continuant matrix of any order:

(*a*) The subscripts of the $(n - 1)$ factors of each element of the adjoint are, in order, those of the elements in the principal diagonal of the cofactor of the corresponding element of the matrix.

(*b*) The sign of the element is the sign of the cofactor.

(*c*) Primes occur only on factors whose two subscripts are equal, and greater by unity than the two equal subscripts of the factor next preceding. Such a factor immediately following a primed factor is double primed.

(*d*) The numerical value of a primed factor (as a'_{77}) is a modified value of the corresponding element a_{77} of $[M]$, derived by the formulas:

$$a'_{77} = a_{77} - a_{67} \times a_{76}/a_{66} \qquad (161a)$$

and

$$a''_{77} = a_{77} - a_{67} \times a_{76}/a'_{66} \qquad (161b)$$

The application of these principles leads to the matrix shown in Eq. 154 as the adjoint of $[\Delta]$. For example, the cofactor of the element $b_{22} = 23$ of $[\Delta]$ is:

$$\begin{vmatrix} 12 & 0 & 0 \\ 0 & 16 & 3 \\ 0 & 3 & 6 \end{vmatrix} = 12 \times 16 \left(6 - \tfrac{9}{16}\right) = 1{,}044 \qquad (162)$$

—and similarly for the evaluation of the other cofactors. The factors of each element of the adjoint can be written quickly, either by using Eq. 160 as a formula, or directly from an inspection of the matrix. (It helps in concentrating the attention on the diagonal of the cofactor if one obscures the row and column of the matrix which contain the element whose cofactor is being observed.)

Bending Moments in Members of the Frame.—The solution for the joint rotations as shown by Eq. 154 leads easily to graphical determination of end moments in the members of the frame. Two parameters, z_{pq} and z_{qp}, are ntroduced for each member PQ, as defined in the notation. For example, for member CD, Fig. 11:

$$z_{cd} = K_{cd}\,\Phi_c = 5\,(-2.8645) = -14.323 \quad \text{(163a)}$$

and

$$z_{dc} = K_{dc}\,\Phi_d = 5\,(-6.2536) = -31.268 \quad \text{(163b)}$$

These quantities have the character and dimensions of bending moments.

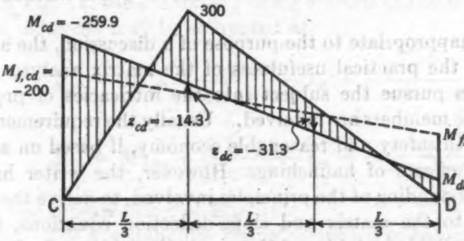

FIG. 12

From points C and D, Fig. 12, ordinates $M_{f,cd}$ and $M_{f,dc}$ (representing the fixed-end moments) are erected, and from the line joining them, at the third points of the span, the values of z_{cd} and z_{dc} are laid off, in the direction indicating negative rotation about points C and D, respectively. The extremities of these lie on the moment line M_{cd}-M_{dc}, whose ordinates at the ends of the span represent the end moments in span CD, under the given conditions of loading and restraint.

The analytical equivalent of the foregoing construction is the expression for the end moments given by the slope-deflection equations:

$$M_{cd} = M_{f,cd} + 2\,z_{cd} + z_{dc} = -200 - 28.645 - 31.268 = -259.913 \quad \text{(164a)}$$

and

$$M_{dc} = M_{f,dc} + 2\,z_{dc} + z_{cd} = 100 - 62.536 - 14.323 = 23.141 \quad \text{(164b)}$$

The intercepts of the ordinates between the line M_{cd}-M_{dc} and the moment diagram for member CD simply supported (supplied in Fig. 12 from data not given, but consistent with the fixed-end moments produced) show graphically the bending moment conditions throughout the span CD.

Sidesway.—The occurrence of joint translation, or sidesway, introduces into the problem additional unknown quantities relating to each of the members subject to rotational movement. The order of the matrices and determinants involved in the solution is increased correspondingly. For the ordinary rectangular building frame subject to horizontal displacement of joints, the number of different unknowns so involved is equal to the number of stories; thus for a one-story frame one additional row and column of elements occur in the matrix.

The matrix expression for the solution of this problem is derived without difficulty; however, the fact that the matrix contains elements other than zero in all diagonals, increases the labor of computation considerably, because the derivation of the reciprocal by inspection as illustrated in Eq. 154 is not possible.

Nonprismatic Members.—The method of analysis by matrix computations is applicable also to frames having haunched members. It is necessary, however, to derive modified values of the stiffness factors and load terms relating to the haunched members, and to generalize the fundamental expressions. The author has illustrated the procedure for the case of a continuous beam (see heading, "Numerical Example," and Fig. 5), using values derived from charts published by the Portland Cement Association,[7] and the method of moment distribution.

It is perhaps inappropriate to the purpose of a discussion, the aim of which is to demonstrate the practical usefulness of the matrix analysis in ordinary building design, to pursue the subject into the intricacies of precise results where nonprismatic members are involved. Usually the requirements of design can be satisfied with safety and reasonable economy, if based on a qualitative knowledge of the effects of haunching. However, the writer has found it helpful to his understanding of the principles involved, to derive the generalized values entering into the matrix and slope-deflection equations, in terms of constants made available in tables of the properties of haunched members by Walter Ruppel, M. ASCE.[26] The additional notation is as defined by Mr. Ruppel,[27] except that to avoid conflict I_e is used to represent the minimum moment of inertia of a member; and K_e, to represent the ratio I_e/L.

The stiffness coefficients and fixed-end moments are given by the following formulas:

$$K_{ab} = K_e \times \frac{1 - v}{4\,p\,(1 - u - v)} \qquad K_{ba} = K_e \times \frac{1 - u}{4\,q\,(1 - u - v)} \ldots (165a)$$

$$K'_{ab} = K_e \times \frac{1}{4\,p\,(1 - v)} \qquad K'_{ba} = K_e \times \frac{1}{4\,q\,(1 - u)} \ldots\ldots (165b)$$

$$M_{f,ab} = W\,L \times \frac{t\,u - s\,(1 - v)}{1 - u - v} \qquad M_{f,ba} = W\,L \times \frac{t\,(1 - u) - s\,v}{1 - u - v} \ldots (165c)$$

$$(M_{f,ab})' = -\,W\,L \times \frac{t}{1 - v} \qquad M_{f,ba} = W\,L \times \frac{s}{1 - u} \ldots\ldots\ldots (165d)$$

$$z_{ab} = \frac{K_e}{2\,p} \times \Phi_a \qquad z_{ba} = \frac{K_e}{2\,q} \times \Phi_b \ldots\ldots\ldots\ldots\ldots (165e)$$

[26] *Transactions*, ASCE Vol. 90, 1927, p. 152.

[27] *Ibid.*, p. 158.

Eqs. 165 are general expressions, yielding the values for prismatic beams when the dimensions of the haunch disappear. The matrix expression (corresponding to Eq. 154 for prismatic beams) is:

$$\begin{Bmatrix} \Phi_a \\ \Phi_b \\ \Phi_c \\ \Phi_d \\ \cdots \end{Bmatrix} = \begin{bmatrix} 2\sum K_a & \frac{2u}{1-u}K_{ba} & 0 & 0 & \cdots \\ \frac{2v}{1-v}K_{ab} & 2\sum K_b & \frac{2u}{1-u}K_{cb} & 0 & \cdots \\ 0 & \frac{2v}{1-v}K_{bc} & 2\sum K_c & \frac{2u}{1-u}K_{dc} & \cdots \\ 0 & 0 & \frac{2v}{1-v}K_{cd} & 2\sum K_d & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots \end{bmatrix}^{-1} \times \begin{Bmatrix} -\sum M_{f,a} \\ -\sum M_{f,b} \\ -\sum M_{f,c} \\ -\sum M_{f,d} \\ \cdots \end{Bmatrix} \qquad (166)$$

When the joint rotations, Φ, have been ascertained, and the parameters, z, computed by Eq. 165*e*, the graphical construction for moments may proceed exactly as in Fig. 12, the ordinates z being erected at the u and v points of the span; or the moments may be computed as

$$M_{ab} = M_{f,ab} + \frac{1-v}{1-u-v} z_{ab} + \frac{u}{1-u-v} z_{ba} \qquad (167a)$$

and

$$M_{ba} = M_{f,ba} + \frac{1-u}{1-u-v} z_{ba} + \frac{v}{1-u-v} z_{ab} \qquad (167b)$$

these being the general forms of Eqs. 164.

Summary.—For a rectangular frame composed of columns and beams, the matrix expression for the joint rotations is derived directly from an inspection of the frame, without the writing of equations. The numerical evaluation of the expression follows an established series of arithmetical operations, which is accomplished easily, with little likelihood of error, and after a little practice, relatively rapidly. The result of the evaluation is translated at once, algebraically, into expressions for end moments in all members, or graphically, into a bending moment diagram for the entire frame.

The matrix solution is a routine of computation rather than a method of analysis. It has the merit of precision, being neither an approximate method nor a method of successive approximations, but an exact method just in so far as the physical data on which the solution is based can be said to be exact. From one point of view (which seems to the writer well grounded) the method shares a defect common to all formula methods. No visualization of the manner of action of the structure attends the solution. The process of computation is mechanical—one feeds the data into the receiving end and, all operations being faithfully performed, extracts the correct result. There is no possibility of applying common sense or judgment to detection of errors at intermediate stages. In this respect the process of approaching results by such means as moment distribution will continue to appeal to most designers as having advantages quite outweighing those of an analysis by equations or formulas.

Nevertheless, Mr. Benscoter's contribution is a valuable one, not only in its application to the analysis of indeterminate structures in the limited field covered by this discussion, but more importantly in promoting acquaintance with an algebraic notation, that is somewhat unfamiliar to many engineers, but which is capable of serving as a powerful tool in the solution of problems involving a number of linearly related unknown quantities.

A. FLORIS,[28] ESQ.—From an academic viewpoint the paper is highly interesting and instructive. To a reader with a theoretical turn of mind, the study of this paper will undoubtedly be a source of pleasure and inspiration. Practicing engineers, however, have at their disposal other more elementary methods of stress analysis, which do not require the mathematical training and equipment necessary for the intelligent use of the method presented.

A brief and unusually clear introduction to the matrix algebra is given by the author for the benefit of those not familiar with the subject. Nevertheless, without a systematic study of matrices it is doubtful whether the author's methods can be used profitably.

The main practical difficulty arising in the stress analysis of hyperstatic structures is the solution of linear nonhomogeneous algebraic equations obtained from considerations of structural deformation. To a certain extent, the best methods are those which reduce the number of these elastic equations to a minimum, or eliminate them entirely. The relaxation methods of stress analysis meet this requirement. However, by their very nature the matrix methods do not.

The solution of linear nonhomogeneous algebraic equations by means of matrices is identical to G. Cramer's rule given in the theory of determinants. Although this rule leaves nothing to be desired theoretically, in practice it is almost useless. By the same token, matrix methods for formal, shorthand solutions have no equals. In numerical problems, however, their usefulness is rather restricted. The greatest success has been achieved in the application of matrix methods to the solution of linear ordinary differential equations with constant coefficients. In this case, use is made of the matric-exponential function.[29,30]

The statement is made that the stiffness factors are always positive. This is, of course, only true if the deformation due to shears, which are produced by the moments at the joints, is neglected. If this shearing deformation is greater than the bending deformation, the stiffness factors become negative.[31,32]

Inasmuch as the division of two matrices cannot be performed directly, the great importance of the inverse matrix, which transforms the division into multiplication, becomes apparent. Therefore, a mnemonic check on the correctness of the computed inverse matrix can be of some value. Using the

Fig. 13.—Mnemonic Check of Inverse Matrix

The inverse of a two-row square matrix is obtained in a simple manner by changing the signs of the elements in the secondary diagonal and by interchanging those in the principal diagonal. The result is then divided by the determinant of the original matrix, which for a unit matrix is equal to one.

Practically, the application of matrix methods to the analysis of continuous beams by means of the slope-deflection equations and the three-moment equations is not simple, although formally the process is excellent. It requires more numerical work than the corresponding older methods. In addition, the slope-deflection equations are solvable by iteration, and if the shearing deformation predominates, the three-moment equations can also be solved by iteration.[33]

The most valuable section of the paper is the treatment of the moment-distribution method from an advanced mathematical point of view. Here, as in the previous parts of the paper, the reader is refreshed by the exact formulation and generality of the statements as contrasted to the oversimplified and, to some extent, dull treatment accorded them in the ordinary textbooks.

The continuous beam is a comparatively simple element in the analysis of hyperstatic structures. It is to be regretted that the author did not include the more complicated continuous and multiple-story frames, inasmuch as the acid test of any new method lies in the analysis of multiple-story frames, for which simple and speedy methods are much needed.

[33] "Shear Deformation Included in Three-Moment Equation," by A. Floris, *Civil Engineering*, October, 1937, p. 711.

In conclusion, the writer wishes to congratulate the author upon his efforts to bring to the attention of structural engineers the fruitful and elegant methods of matrix algebra through this pioneer work of considerable scientific value.

Sven Olof Asplund,[34] M. ASCE.—How matrices may be applied in the analysis of continuous beams is shown very constructively by the author, who uses matrix methods to demonstrate that the result of the iterative moment distribution method developed by Hardy Cross, M. ASCE, approaches that of the exact classical solution. Obviously in recognition of the generality of matrix methods, Mr. Benscoter suggests the possibility of useful application of matrices to the analysis of other statically indeterminate structures. The writer has actually employed matrices in the analysis of pile groups. In such a case the matrices originate from the vectors used in determining the acting forces and their positions.

In European practice[35] pile groups have for many years[36] been calculated according to the elastic theory. For plane pile groups the calculations are easily accomplished,[37] but for spatial pile groups the computation will become almost prohibitive if matrices are not employed.

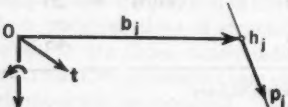

Fig. 14.—Vectors Representing Pile Forces and Movements of Pile Group

The external forces acting upon the rigid pile pier cause a small translation, defined by a vector $\mathbf{t}$ (Fig. 14), and a small rotation, r, about an axis of rotation, $\mathbf{r}$, through the origin O. The pile heads, h_j, in the pier are located by the vectors $\mathrm{O\,h}_j = \mathbf{b}_j$, and the total movement of the pile head is given by $\mathbf{t} + [\mathbf{r}\,\mathbf{b}_j]$ (brackets indicate vector products). The projection of this movement upon the unit vector $\mathbf{p}_j$ along the pile axis is the scalar product $\mathbf{p}_j\,(\mathbf{t} + [\mathbf{r}\,\mathbf{b}_j]) = \mathbf{p}_j\,\mathbf{t} + [\mathbf{b}_j\,\mathbf{p}_j]\,\mathbf{r}$. The pile shortens by this length, causing an elastic pile reaction:

$$\lambda_j\,\mathbf{p}_j\,(\mathbf{p}_j\,\mathbf{t} + [\mathbf{h}_j\,\mathbf{p}_j]\,\mathbf{r}) \qquad (168)$$

Aside from the pile reactions, all other forces that act upon the pier may be reduced to a force, $\mathbf{f}$, and a moment, $\mathbf{m}$, about O. The equilibrium of the pier demands that

$$\mathbf{f} = \Sigma\lambda\,\mathbf{p}\,(\mathbf{p}\,\mathbf{t} + [\mathbf{b}\,\mathbf{p}]\,\mathbf{r}) = \mathbf{T}\,\mathbf{t} + \mathbf{U}\,\mathbf{r} \qquad (169a)$$

$$\mathbf{m} = \Sigma\lambda\,[\mathbf{b}\,\mathbf{p}] \times \mathbf{p}\,\mathbf{t} + \Sigma\lambda\,[\mathbf{b}\,\mathbf{p}] \times [\mathbf{b}\,\mathbf{p}]\,\mathbf{r} = \mathbf{U}'\,\mathbf{t} + \mathbf{V}\,\mathbf{r} \qquad (169b)$$

or, in Mr. Benscoter's matrix notation,

$$[f] = [T]\,[t] + [U]\,[r] \qquad (170a)$$

$$[m] = [U]'\,[t] + [V]\,[r] \qquad (170b)$$

This matrix notation appears to the writer to be unnecessarily laborious.

[37] "Beregning av Paelevaerker," by Chr. Nøkkentved, Gad, Copenhagen, 1923.

Henry Margenau and G. M. Murphy[38] and Harold Jeffreys[39] use bold face letters to denote matrices, whereas Richard Courant and David Hilbert[40] use ordinary letters:

$$\left.\begin{aligned} f &= T\,t + U\,r \\ m &= U'\,t + V\,r \end{aligned}\right\} \qquad (171)$$

The symbols T, U, and V may be recognized as third-order square matrices with elements $T_{kl} = \Sigma\lambda\, p_k\, p_l$, $U_{kl} = \Sigma\lambda\, p_k\, [\mathbf{b}\,\mathbf{p}]_l$, etc. The symbol U' is the transpose of U. The solution of Eq. 171 is easily found to be

$$\left.\begin{aligned} t &= T^{-1}{}_0\, f - T^{-1}{}_0\, U\, V^{-1}\, m \\ r &= -\,V^{-1}{}_0\, U'\, T^{-1}\, f + V^{-1}{}_0\, m \end{aligned}\right\} \qquad (172)$$

in which $T_0 = T - U\,V^{-1}\,U'$ and $V_0 = V - U'\,T^{-1}\,U$. Substitution of Eqs. 172 in Eq. 168 yields the force in each pile. The numerical computations may be systematically and effectively carried through according to Eqs. 172.

It is often possible to add to an actual pile group one or more fictive piles in such a manner that the resulting pile group may be more expediently analyzed —for example, by resulting symmetry. The forces that the original external forces **f**, **m** induce in the fictive piles are evaluated and added to **f**, **m** to neutralize the reactions from the fictive piles upon the pier. The added forces cause further reactions from the fictive piles which are again added, etc. This iteration often converges, and it is possible by summation of geometric matrix series (Neumann series) as explained by the author to show that the final result is identical to a direct solution of the actual original pile group in accordance with Eq. 172.

Stanley U. Benscoter,[41] Assoc. M. ASCE.—The discussions contain several interesting additions to the paper. Several writers question the usefulness of matrix methods in more complicated problems such as the analysis of frameworks with joint translations. In such problems matrix algebra provides a convenient process of formulating and defining the various calculating procedures that may be used. The best method of calculation will depend on such factors as the type of computing device to be used, the size of the matrix of coefficients, and the number of times that the equations are to be solved (number of loading conditions). One should not expect to analyze an enormous framework on a slide rule any more than one would expect to dig an enormous excavation with a hand spade. Just as large electrical or mechanical shovels are used for large excavation jobs, so must one use large electrical or mechanical computing machines for analyzing large frameworks.

For solving a general system of equations, evaluating a determinant, or computing a reciprocal matrix, on a hand-operated calculating machine, the

method of P. D. Crout[42] is the most efficient that is known to the writer. This method is being adopted quite generally throughout the United States in design and research work. More powerful calculating machines have been developed in recent years such as the punch card machine and the sequence-controlled electronic or electrical relay machines. These machines operate automatically with iteration procedures and perform successive matrix multiplications conveniently. They solve as many as one hundred simultaneous equations and provide the only real answer to the civil engineers' need for a method of analyzing large frameworks. Matrix algebra and the modern calculating machine are complementary tools for use in the solution of physical problems for which solutions in terms of analytical functions cannot be obtained. Both of those tools must be developed simultaneously to obtain the maximum benefit from either.

The historical note by Mr. Oesterblom is interesting. His question concerning the possibility of representing the reciprocal of the stiffness matrix for a framework by a power series can be answered by stating that the reciprocal of any square matrix can be represented by a power series if the determinant of the matrix does not vanish. Re-analysis of a structure for loading changes involves the use of the same stiffness matrix and, hence, is not a serious problem in design. Re-analysis for framework dimension changes is an entirely different matter because this procedure involves changes in the stiffness matrix, which require a new computation of the reciprocal matrix. However, if the changes in stiffness values are small relative to the originally assumed stiffnesses, a convenient method of obtaining the new reciprocal matrix can be developed.

Assume that the original stiffnesses give the square matrix $[K]$ as the coefficient matrix in the equation of three slopes (Eq. 67). From a stress analysis it is found that changes in the dimensions of the members are required. The new stiffness matrix becomes $[K + \Delta K]$. The square matrix $[\Delta K]$ contains small numbers representing the changes in stiffness of the members. Define the square matrix $[\delta]$ by

$$[\delta] = [K]^{-1} [\Delta K] \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (173)$$

Eq. 173 can be computed immediately since the reciprocal matrix $[K]^{-1}$ is known. The new stiffness matrix may be written as

$$[K + \Delta K] = [K][I + \delta] \ldots\ldots\ldots\ldots\ldots\ldots (174)$$

The reciprocal may be written as

$$[K + \Delta K]^{-1} = \{[I] - [\delta] + [\delta]^2 - \cdots\}[K]^{-1} \ldots\ldots (175)$$

Since the elements of $[\delta]$ are small relative to unity, the second and higher degree terms in the series may be neglected:

$$[K + \Delta K]^{-1} = [L - \delta][K]^{-1} \ldots\ldots\ldots\ldots (176)$$

Thus, the original reciprocal matrix is easily converted into the new reciprocal matrix. The development of practical design procedures on the basis of this theory is a worthwhile objective for future research study.

[42] "A Short Method for Evaluating Determinants and Solving Systems of Linear Equations with Real or Complex Coefficients," by P. D. Crout, *Transactions*, A.I.E.E., Vol. 60, 1941, pp. 1235–1240.

The formulas for moments given by Mr. Solman form an important contribution to the analysis of continuous beams. Since there are a number of other problems in both civil and aeronautical design which lead to a system of equations having a continuant matrix, the possibility of developing such formulas is of considerable interest. The formulas become especially useful with symmetrical structures. The simple formulas of Eqs. 132 and 133 may be used to analyze symmetrical beams having as many as six spans. This classification includes a large part of all highway bridges.

It is clearly shown by the formulas of Mr. Solman that the solution for moments is dependent only on the fixed-end moments and the primary and secondary distribution factors. The convenience of introducing product factors $p_{ij} = q_{ij}\, q_{ji}$ is also evident. The significant feature of these scalar formulas, from a general mathematical viewpoint, lies in the fact that they arise from formulas for the elements of the reciprocal of the matrix $\{[I] - [Q]'\}$. The development of the formulas, as given by Mr. Solman, is so brief as to be difficult for a reader to follow. The development employs certain special properties of a continuant matrix and its adjoint that are not known to the majority of readers.

The special case of two effective joints has been noted by Hardy Cross,[43] M. ASCE. In this case the power series of matrices degenerates into a scalar geometric series and direct formulas for the solution are readily developed.

The writer is in agreement with the comments of Professor Oldenburger. It was the classical paper of Professor Oldenburger[9] that inspired the writer to take up the study of matrix algebra. Studies of the convergence of the power series, which defines moment distribution, lead to new methods of computing the critical, or characteristic, values of buckling or vibratory loads. The problem of framework buckling is in serious need of research attention so that more rational methods of design may be developed.

Mr. Johnson has illustrated the use of the Cramer rule in solving a system of equations. The formula for computing a reciprocal matrix as given in Eq. 33, without proof, would be developed by using this rule. The Cramer rule is very useful for solving either two or three simultaneous equations when the equations are to be solved only once (one loading condition). For more than three equations other methods should be used even when solving the equations only once.

Professor Cheney has illustrated the standard engineering textbook method of successive elimination of unknowns. The evaluation of a 4×4 determinant, as given in Eq. 148, is correct. However, the evaluation of a 6×6 determinant, as shown in Eqs. 150 and 151, is erroneous. Unfortunately, the task cannot be simplified in this manner.

Mr. Norton has illustrated in Fig. 11 the association that exists between the stiffness matrix for a continuous beam and the structure itself. He has also explained in detail the Gauss method of pivotal condensation[44] for evaluating determinants. By using the Gaussian method it is found that the elements of the adjoint of a continuant matrix may be expressed as given by Eq.

[43] "Continuous Frames of Reinforced Concrete," by Hardy Cross and N. D. Morgan, John Wiley & Sons, Inc., New York, N. Y., 1932, p. 125.

[44] "Determinants and Matrices," by A. C. Aitken, Interscience Publishers, Inc., New York, N. Y., 1939, p. 45.

160. This development is of considerable importance for a number of different structural problems. The pattern of formation of the adjoint is clear and convenient to use. The calculations are easily performed when the factors of an element are expressed as continued fractions. Consider the element of the first row and first column of the matrix of Eq. 160. Apply the formula to the matrix $\{[I] - [Q]'\}$ of the fifth order; thus:

$$A_{11} = a_{22}\, a'_{33}\, a''_{44}\, a'''_{55}$$
$$= 1 \times (1 - p_{23}) \left(1 - \frac{p_{34}}{1 - p_{23}}\right) \left[1 - \frac{p_{45}}{1 - \dfrac{p_{34}}{1 - p_{23}}}\right] \ldots\ldots (177)$$

in which $p_{ij} = q_{ij}\, q_{ji}$. If the multiplication indicated in Eq. 177 is performed, the resulting formula will be found to correspond to the first element of the matrix of Eq. 146, as given by Mr. Solman. The determinant of the matrix may also be expressed as a product of continued fractions.

Mr. Floris mentions the possibility of negative stiffness values when shearing deformations are considered. There is some doubt as to whether rotational stiffnesses are affected by shearing deformation—whether they are or are not is dependent on the definition of stiffness. There are at least two possible methods. The problem is in need of still further attention by research workers. It is possible that only the translational stiffnesses (which are not mentioned in the paper) are affected. The complicating effect of considering shear deformation is that it brings about a discontinuity in the slope of the elastic curve at points of application of concentrated loads or reactions. In the case of an applied load the magnitude of the discontinuity is known, whereas in the case of a reaction the magnitude is unknown.

The simple rule for inverting a 2×2 matrix, as noted by Mr. Floris, is very useful. The writer has used it many times in design and research work. The adjoint is formed by interchanging the diagonal elements of the matrix and by merely changing the signs of the nondiagonal elements.

Mr. Asplund has illustrated the use of matrices in the solution of a very interesting problem. The analysis of pile groups has received little attention in American literature. The plane problem was treated by C. P. Vetter,[45] M. ASCE. The space group with arbitrary pile batter, pile length, and head position is a more complex problem.

Since the development of the formulas for the elements of the matrices has been given by Mr. Asplund in the language of vector algebra, it may be interesting to show the same development in the language of matrix albebra. This statement is especially true since vector products arise in the analysis. Vectors in vector notation will be equated to vectors (column vectors or row vectors) in matrix notation. The equality sign must be understood to mean equality of the components of the vectors.

The pier translation is indicated by the vector:

$$\mathbf{t} = [t]' = [t_1\, t_2\, t_3] \ldots\ldots\ldots\ldots\ldots\ldots\ldots (178)$$

The pier rotation is indicated by

$$\mathbf{r} = [r]' = [r_1\, r_2\, r_3] \ldots\ldots\ldots\ldots\ldots\ldots\ldots (179)$$

[45] "Design of Pile Foundations," by C. P. Vetter, *Transactions*, ASCE, Vol. 104, 1939, pp. 758-811.

In developing relationships for a single pile, the subscript, j, will be omitted for convenience. The vector from the origin to the pile head is given by

$$\mathbf{b} = [b]' = [b_1\, b_2\, b_3] \quad \ldots\ldots\ldots\ldots\ldots\ldots (180)$$

To define vector products in matrix notation, it is necessary to introduce two skew-symmetric matrices that may be constructed from the components of the vectors $[r]$ and $[b]$:

$$[R] = \begin{bmatrix} 0 & -r_3 & r_2 \\ r_3 & 0 & -r_1 \\ -r_2 & r_1 & 0 \end{bmatrix} \quad \ldots\ldots\ldots\ldots (181)$$

$$[B] = \begin{bmatrix} 0 & -b_3 & b_2 \\ b_3 & 0 & -b_1 \\ -b_2 & b_1 & 0 \end{bmatrix} \quad \ldots\ldots\ldots\ldots (182)$$

A skew-symmetric matrix is one that is equal to the negative of its transpose:

$$[R] = -[R]'; \quad [B] = -[B]' \quad \ldots\ldots\ldots\ldots\ldots (183)$$

A vector product may now be illustrated; thus:

$$\mathbf{r} \times \mathbf{b} = [R][b] = -[B][r] \quad \ldots\ldots\ldots\ldots\ldots\ldots (184)$$

The resultant translation of the pile head may then be expressed by

$$\mathbf{t} + \mathbf{r} \times \mathbf{b} = [t] + [R][b] = [t] - [B][r] \quad \ldots\ldots\ldots (185)$$

A unit vector along the pile axis is indicated by

$$\mathbf{p} = [p]' = [p_1\, p_2\, p_3] \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (186)$$

The components of this vector are the direction cosines of the pile axis. The shortening of the pile is given by

$$\mathbf{p} \times (\mathbf{t} + \mathbf{r} \times \mathbf{b}) = [p]'\{[t] - [B][r]\} \quad \ldots\ldots\ldots\ldots (187)$$

The quantity on either side of Eq. 187 is a scalar number. When multiplied by an axial stiffness constant, λ, the magnitude of the pile reaction force is obtained. If this value is then multiplied by the vector, $\mathbf{p}$, the reaction will be expressed as a vector:

$$\lambda\, \mathbf{p}\, [\mathbf{p}\cdot\mathbf{t} + \mathbf{p}\cdot(\mathbf{r} \times \mathbf{b})] = \lambda\, [p]\{[p]'[t] - [p]'[B][r]\} \quad \ldots\ldots (188)$$

or

$$\lambda\, \mathbf{p}\, [\mathbf{p}\cdot\mathbf{t} + \mathbf{p}\cdot(\mathbf{r} \times \mathbf{b})] = \lambda\, \{[P][t] - [P][B][r]\} \quad \ldots\ldots (189)$$

in which

$$[P] = [p][p]' = \begin{bmatrix} p_1^2 & p_1\, p_2 & p_1\, p_3 \\ p_2\, p_1 & p_2^2 & p_2\, p_3 \\ p_3\, p_1 & p_3\, p_2 & p_3^2 \end{bmatrix} \quad \ldots\ldots\ldots (190)$$

In the analysis given by Mr. Asplund five of the six stiffnesses that may be defined for the pile have been regarded as negligible relative to the axial stiffnesses. The neglected stiffnesses are the bending translational stiffnesses, the bending rotational stiffnesses, and the twisting rotational stiffness. The assumption is most directly applicable to piles driven through soft ground to

bedrock. In the case of friction piles the foundation itself participates to a considerable extent in the action to complicate the problem. The assumption of a constant of proportionality between reaction force and displacement function should be replaced by a more general functional relationship, as determined by an appropriate influence function. To the equilibrium solution given by Mr. Asplund should be added a linear combination of a finite set of self-equilibrating characteristic distributions to allow for the foundation effect. The mathematical difficulties of obtaining such a solution are, at present, insurmountable. The theory of Mr. Asplund is probably as good, in most cases, as the commonly used assumption of planar distribution of reaction beneath piers, walls, dams, etc., without piles.

The summation of all reaction forces and their moments must equal the applied force, $[f]$, and the applied moment, $[m]$. The subscript, j, will now be introduced where necessary for the summation:

$$\Sigma\lambda_j \{[p_j][t] - [P_j][B_j][r]\} = [f] \quad \text{(191)}$$

$$\Sigma\lambda_j [B_j]\{[P_j][t] - [P_j][B_j][r]\} = [m] \quad \text{(192)}$$

Substituting Eq. 183 in Eq. 192 gives

$$\Sigma\lambda_j [B_j]' \{ - [P_j][t] + [P_j][B_j][r]\} = [m] \quad \text{(193)}$$

The following matrices may be introduced:

$$[T] = \Sigma\lambda_j [P_j] \quad \text{(194)}$$

$$[U] = - \Sigma\lambda_j [P_j][B_j] \quad \text{(195)}$$

$$[V] = \Sigma\lambda_j [B_j]' [P_j][B_j] \quad \text{(196)}$$

These matrices were introduced by Mr. Asplund to give the two matrix formulas (Eq. 170*a* and Eq. 170*b*). The two equations may be written as a single equation, thus:

$$\begin{bmatrix} T & U \\ U' & V \end{bmatrix} \begin{bmatrix} t \\ r \end{bmatrix} = \begin{bmatrix} f \\ m \end{bmatrix} \quad \text{(197)}$$

The matrix equation (Eq. 197) represents six linear algebraic equations that must be solved simultaneously. In the case of general 6 × 6 matrices the method of Professor Crout[37] will usually be found to be the most rapid on a hand-operated calculating machine. Partitioning of the matrices, as illustrated by Mr. Asplund, becomes advantageous when the submatrices $[T]$, $[U]$, and $[V]$ have special simplified forms. A study of these simplified forms for various typical pile arrangements would be an interesting research problem. It should be noted that the representation of matrix division by fractions, as shown in Eq. 172, is ambiguous. It does not indicate the correct order of the matrix multiplication.

The discussions have revealed a number of additional suggestions for the use of determinants and matrices in the solution of linear equations of structures. The paper has introduced only the simplest concepts of matrix algebra. It is to be hoped that there will be continued advancement in the application of matrix theory to structural analysis problems.

Paper No. 2324

CORRECTION OF TAILWATER EROSION AT PRAIRIE DU SAC DAM

By C. N. Ward,[1] M. ASCE, and Henry J. Hunt,[2] Esq.

With Discussion by Messrs. George P. Steinmetz, Louis M. Laushey, Abraham Streiff, R. H. Keays, and C. N. Ward and Henry J. Hunt.

Synopsis

The hydroelectric power plant at Prairie du Sac, Wis., on the Wisconsin River was placed in operation in 1914.[3,4,5] A general lowering of the tailwater and of the river bottom downstream from the plant became obvious a few years later. Because of the presence of a large island immediately below the east half of the spillway section of the dam when constructed, the recession of the tailwater level was not appreciable until 1920 when the island had been completely removed. From then until 1932 the recession of tailwater was more rapid. The average rate of recession of minimum monthly tailwater levels over a 17-year period, 1915–1931, inclusive, was 0.43 ft per yr. Such river controls as an old bridge foundation, two highway bridges, and a railroad bridge and gravel shoals over certain river stretches caused the rate of recession to decrease to 0.10 ft per yr from 1932 to 1936, inclusive, and to practically a stable condition from 1937 to 1944, inclusive. During 1929 hydraulic model tests were made to determine a method of reducing excessive erosion of the river bed immediately downstream from the dam.

Expensive and extensive methods of improvement were not considered in the first study because a new power dam was then under consideration which would, when constructed, restore tailwater levels at Prairie du Sac. Model tests were confined to changes which could be built on the prototype without the need of a cofferdam. A partial or temporary remedy was all that was expected. A wooden baffle was designed on the basis of model tests and was constructed on the prototype in 1930.

Note.—Published in October, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

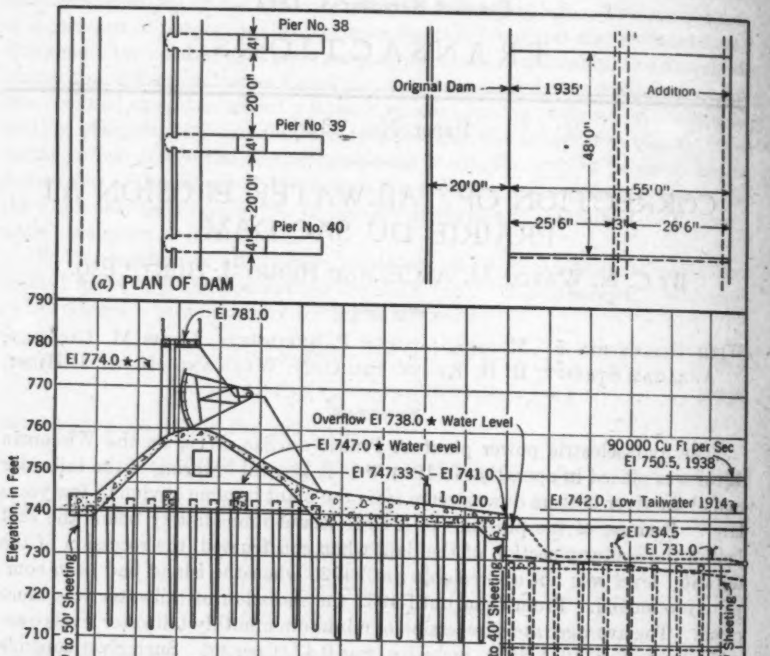

FIG. 1.—PLAN AND PROFILES OF THE

In 1933 it was decided that a new dam would not be constructed in the near future downstream from Prairie du Sac and that works would be designed and constructed at the site to reduce erosion further and to improve other unfavorable conditions arising from lowered tailwater. A new series of tests was then run to determine a basis for design of an improvement which would be complete in itself.

This paper briefly describes the model tests and types of improvements adopted and presents a general comparison of performance of models with that of the prototype.

General Description of Plant

There is an earth embankment about 1,700 ft long on the east side of the river. In the main channel there are forty-one Tainter gates (20 ft wide by 14 ft high) with 4-ft piers, a lock 35 ft wide, a closed dam and sluices 38 ft long, and a powerhouse 329 ft long. Profiles of the river bottom downstream from the dam in a region of maximum bed cutting are shown in Fig. 1. Fig. 2, which was used as a form sheet in recording the direction of water currents and other data in some of the 1933 model tests, is a diagrammatic plan, showing the main structures of the plant and the contours of the river bottom as of 1932. The most serious erosion of the bottom of the river occurred about 220 ft downstream from the end of the original apron below gates Nos. 36 to 41 and near the east side of the lock. The deepest erosion extended 54 ft below the top of the original apron.

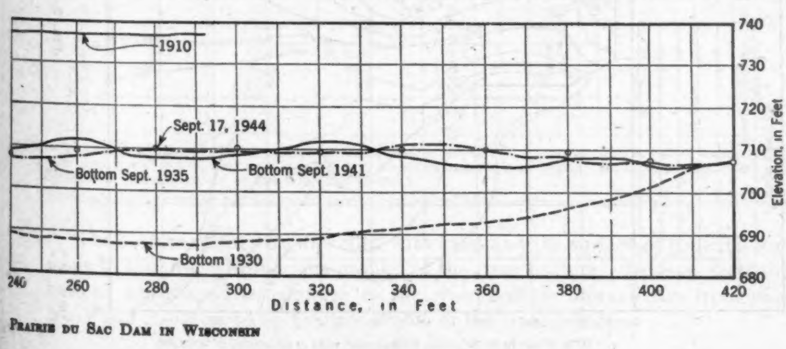
"Tailwater discharge" curves are shown for the period from 1909 to 1931 in Table 1. During this time the tailwater receded about 5.8 ft for a flow of 5,000



Prairie du Sac Dam in Wisconsin

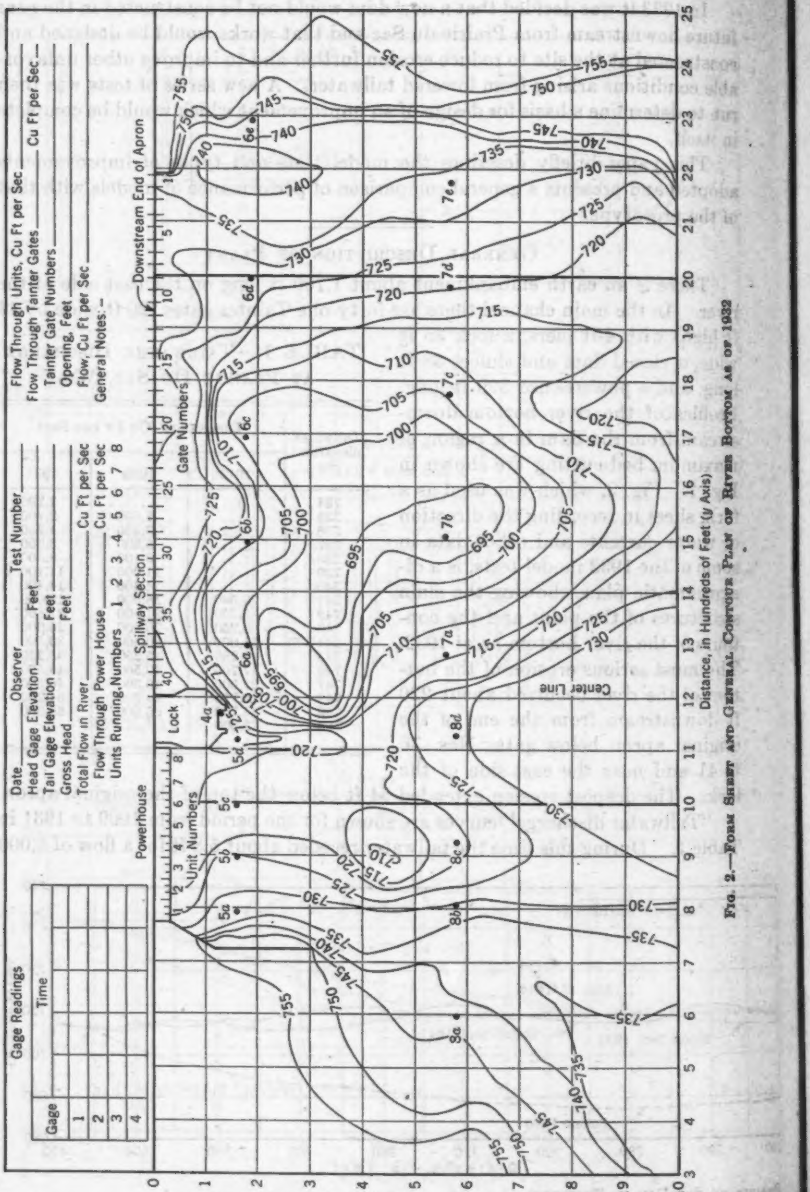


FIG. 2.—FORM SHEET AND GENERAL CONTOUR PLAN OF RIVER BOTTOM AS OF 1932

cu ft per sec and 3.3 ft for a flow of 50,000 cu ft per sec. The actual period of recession began in 1914 so that the rate for 5,000 cu ft per sec was 0.34 ft per yr; and, for 50,000 cu ft per sec, the rate was 0.20 ft per yr.

1929 Tests

A model of three gates of the dam to a scale of 1 to 20 was used in the 1929 tests at the Hydraulic Laboratory of the University of Wisconsin at Madison. The dam, constructed of wood, was tested in a wooden box 30 ft long, which had glass sides permitting visual inspection of flow conditions on the apron of the dam for a distance of 70 ft (on prototype) downstream from the end of the apron. All measurements in the tests were recorded and are referred to in terms of units applicable to the prototype. Two venturi meters (4 in. and 8 in.) were used to measure the flow of water. Water was admitted to the space underneath the dam and apron which acted as a stilling basin. Baffles caused the water to flow to the gates smoothly. A gate used at the downstream end of the box to control tailwater levels was designed to allow water to discharge so that normal vertical velocity curves would occur a short distance upstream from the gate.

The control gate was of the register type consisting of two wooden members, each having rectangular orifices, all the same height and arranged in horizontal rows with different spacing at various depths. One member was fixed; and the other was placed in contact with it and was vertically adjustable. The orifices were designed to discharge water at different levels, thus giving a normal vertical velocity distribution in the model for the average conditions to be tested. The gate was found to be very effective in controlling tailwater heights, and velocity measurements made with a pitot tube showed that normal and desired velocity distribution actually occurred a short distance upstream from this gate.

[a] The samples of the sands were taken at the following places: No. 1, center of river below locks; No. 2, near west shore; No. 3, near east shore; No. 4, center of tailrace near island; No. 5, Janesville, Wis.; and Nos. 6 and 7, model sands, at the Wisconsin foundry.

The bottom of the box was filled with sand and the surface of the sand was made to conform with various profiles of the river bottom. In some tests the bottom was shaped to conform to the river bottom downstream from gate No. 9 and in others to an average profile of the river bottom.

Since the exact laws of similitude relating to movement of soil grains by water were not known, it was decided to use the finest sand readily attainable for the bottom of the channel of the model. Sieve analyses of sand from the prototype are shown in Table 2, sands Nos. 1, 2, 3, and 4, and the sand used in the model is designated as sand No. 6. Sand No. 7 was rejected because it contained a large amount of fine material that was carried in suspension with a very slight movement of water. It was decided that a study of bed movement in the model would be relatively indicative of results attainable in the prototype even though the exact quantitative relationship was not known.

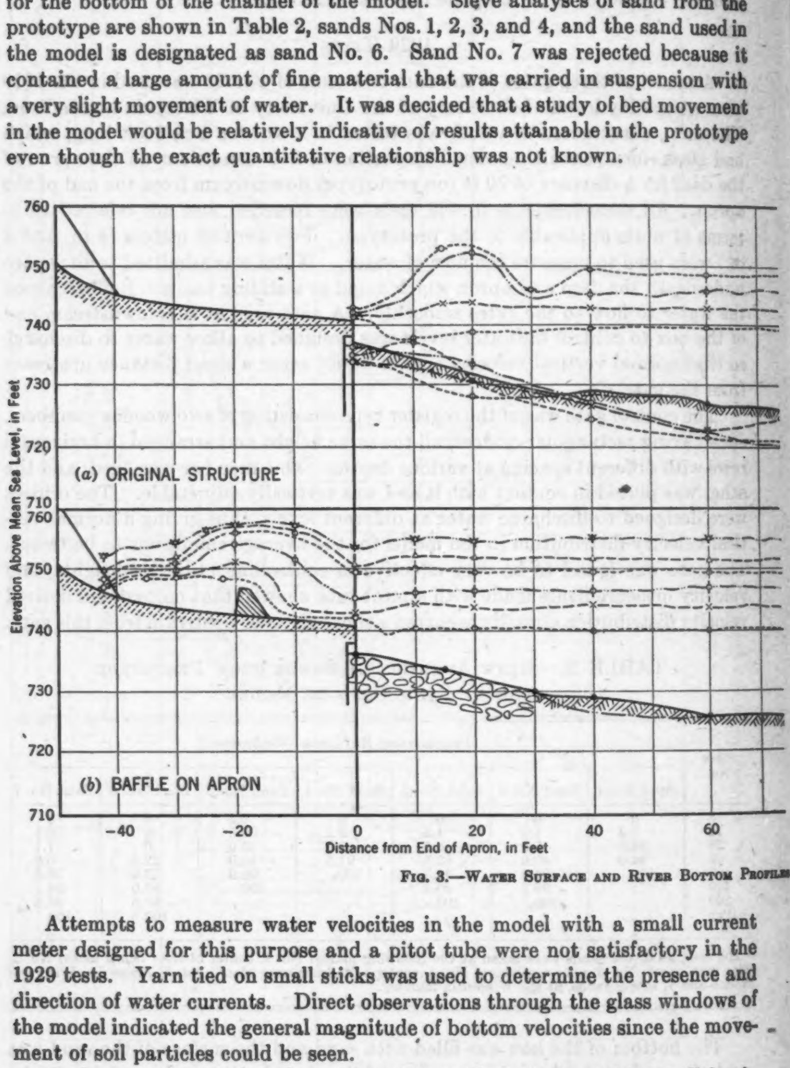

FIG. 3.—WATER SURFACE AND RIVER BOTTOM PROFILES

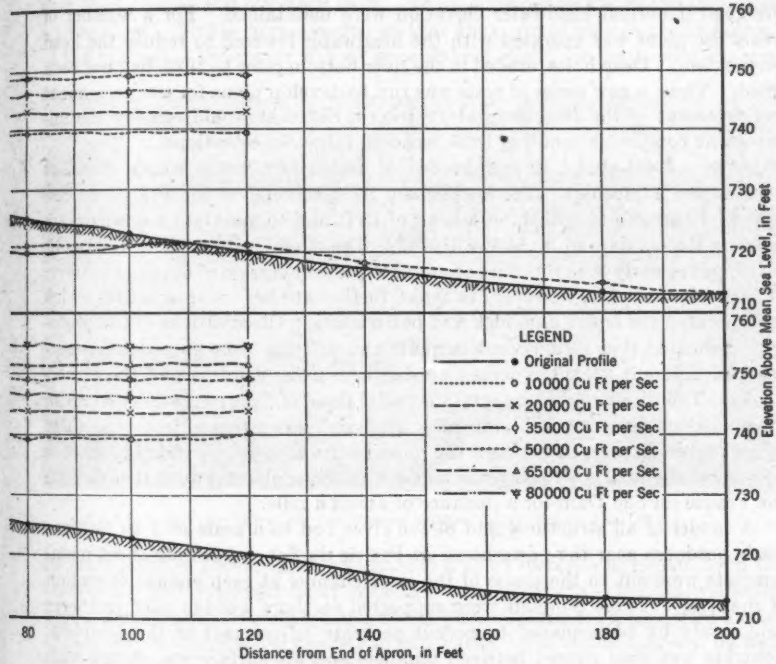
Attempts to measure water velocities in the model with a small current meter designed for this purpose and a pitot tube were not satisfactory in the 1929 tests. Yarn tied on small sticks was used to determine the presence and direction of water currents. Direct observations through the glass windows of the model indicated the general magnitude of bottom velocities since the movement of soil particles could be seen.

Early tests showed that the sand in the model reached a stable condition in about 1 hour after a run was started. Each of thirty-four different arrangements of the model were tested under from four to six rates of flow varying from

10,000 cu ft per sec to 80,000 cu ft per sec. Tailwater rating curves used in tests usually followed the 1924 rating curve.

Water profiles and sand bottom profiles were taken during and after each run.. Fig. 3(*a*) shows water profiles and bottom profiles in one test with the original dam; and Fig. 3(*b*), a similar test with the exception of a 52-in. baffle wall placed on the apron of the dam. The sand lost from the bottom in the first 200 ft downstream from the dam for flows up to 50,000 cu ft per sec was 270 cu yd per gate (in terms of the prototype), for the dam as originally constructed, whereas no measurable loss resulted with the same range of flows when



FROM TESTS OF A 1-to-20 SCALE MODEL (1929 TESTS)

the 52-in. baffle was used. A baffle 52 in. high, 20 ft from the downstream end of the apron, appeared to improve conditions materially. Such a baffle was then constructed on the prototype below two Tainter gates. Because of the river flow conditions, the tailwater could not be built up to flood stages. However, the two gates were opened to discharge at rates equivalent to a flood flow of 30,000 cu ft per sec in the river. Flow conditions over the baffle appeared generally similar to those observed on the model. The pool in front of the baffle was maintained on the prototype as in the model. No movement of river bed material downstream from the gates occurred.

A baffle 52 in. high was built across the entire length of the prototype dam in 1930. It was constructed with 8-in. timbers used as stop logs supported by 12-in. H-beams placed in the apron of the dam. From 1930 to 1933 this baffle improved conditions materially.

1933 Tests

It was definitely decided in the early part of 1933 that a new dam downstream from Prairie du Sac would not be constructed in the near future. Because of recession of the tailwater, the Prairie du Sac Dam would have been subjected to a head considerably greater than that for which it was originally designed if normal headwater elevation were maintained. For a number of years the plant was operated with the headwater lowered to reduce the head on the dam. Deep holes, eroded in the river bottom prior to 1930, had not been filled. Thus, a new series of tests was run to develop plans for the permanent improvement of the structures at Prairie du Sac that would remedy the unfavorable conditions resulting from receding tailwater elevations.

After a brief study, it was decided to design new works which would be constructed adjacent to and downstream from the end of the Prairie du Sac apron—itself able to withstand a head of 13 ft and to maintain a downstream head on the old dam up to about El. 742. The model tests made in 1930 indicated quite clearly the procedure required to prevent erosion of the sand bottom. It was felt desirable, however, to make further studies using a model which incorporated the entire dam lock and powerhouse. Observations of the prototype indicated that serious crosscurrents and eddying were caused when currents of different velocities joined downstream from the dam and the powerhouse. The discharge from certain combinations of Tainter gates resulted in obvious disturbances. Eddying also appeared downstream from the lock, where water discharged through the gates and water discharged through the powerhouse joined. A survey was made of the river channel downstream from the Prairie du Sac Dam for a distance of about a mile.

A model of all structures and of the river bed to a scale of 1 to 100 was made outdoors near the powerhouse at Prairie du Sac. Accurate sheet metal templets were cut to the shape of the river channel at each change of section of the river. These templets were supported on short wooden piles and were held firmly by bolts placed to permit accurate adjustment of the templets. Concrete was then poured between templets and the surface was struck with a straight edge. Great care was taken to reproduce, accurately, the channel of the prototype. All details of the dam and the power plant which concerned river flow were carefully reproduced in the model. A gate at the downstream end of the model which controlled the tailwater consisted of a plank hinged at the bottom with its top cut to conform generally to the shape of the section of the river. In whatever position it was placed, the gate allowed water to be released from the model so that the distribution of flow across the section was very nearly the same as that in the prototype. The model of the river bottom was poured with concrete composed of white cement and light-colored sand. The concrete bottom was divided into 1-ft squares by coordinates painted with asphalt. One coordinate was parallel to the end of the apron of the dam.

Ten different arrangements (a total of one hundred and six runs) of the model were tested under various flood flows with different distributions of flow through the powerhouse and over the dam and with various combinations of gates to discharge flood flows. Fig. 4 shows one view of the 1-to-100 scale model. Average vertical velocities in the model were studied with small vertical floats loaded so that they would float with one end slightly exposed. Floats were started near the end of the original apron of the dam. One observer plotted the path of each float on the form sheet shown in Fig. 2 by observing the movement of the float relative to the reference lines painted on the surface of the model. Another observer with a stop watch noted the time at which each float crossed the reference lines. These time observations were recorded on the sheet. Floats were selected so that they would just clear the bottom of the channel. Whenever a float encountered shallower water and dragged

FIG. 4.—MODEL OF THE PRAIRIE DU SAC PLANT; SCALE, 1 to 100

on the bottom, a shorter float was started a short distance upstream from the obstruction and observations of velocities were continued. Bottom velocities were observed with wooden spheres about ½ in. in diameter which were loaded so that they would sink very slowly in still water. The course followed by each ball and the time were recorded as for the vertical staff floats.

It was decided that a new apron 55 ft wide would be constructed on the prototype at the downstream end of the old apron with the top elevation at El. 731 or 10 ft below the top of the end of the original apron. The 1929 tests indicated that the baffle placed on the old apron would be effective with the new apron. Tests were then run on the 1-to-20 scale model (which had been used in the 1929 tests) to determine the effect of a baffle wall on the new apron and to verify conclusions reached in the studies with the 1-to-100 scale model. Nine different conditions were studied on the 1-to-20 scale model; and it was found that there was no erosion in the bed of the model with: (*a*) The new apron constructed at El. 731; (*b*) the baffle on the old apron as built in 1930; or (*c*) an

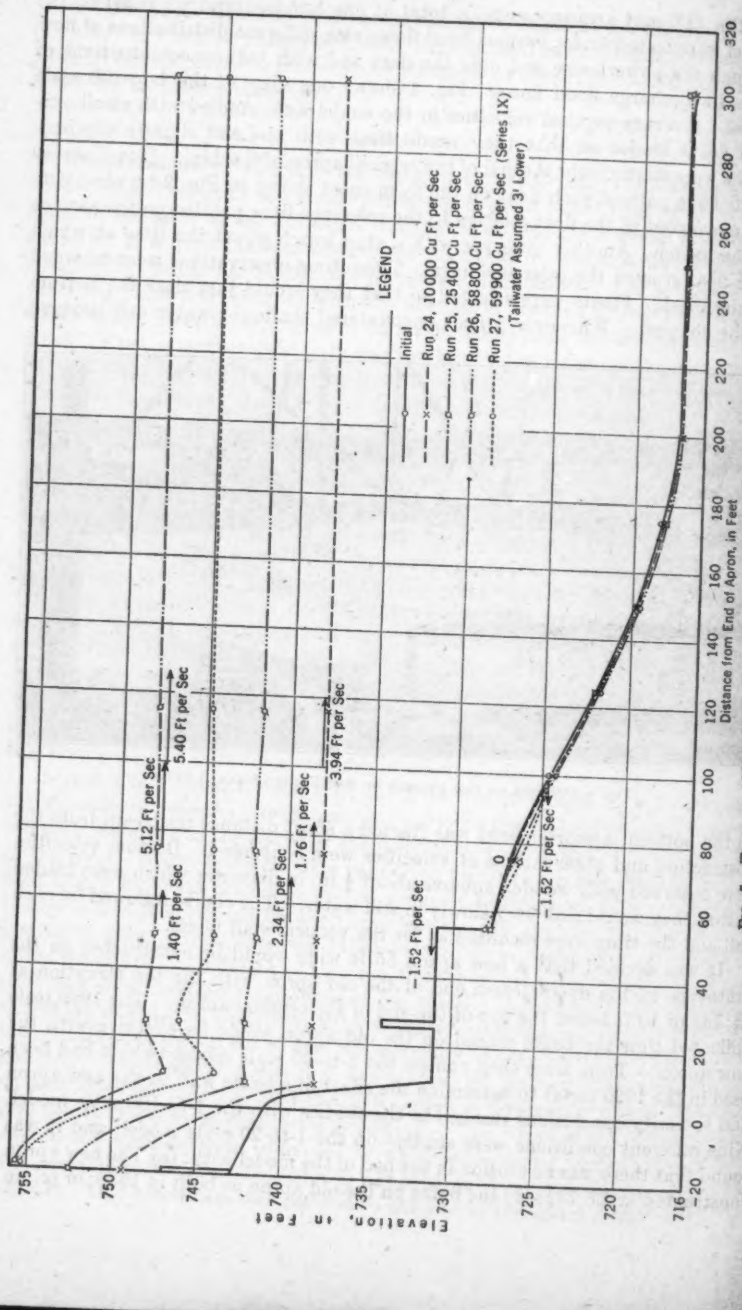


FIG. 5.—TESTS IN 1933; 1-to-20 SCALE MODEL WITH NEW APRON AND BAFFLES

additional baffle 3.5 ft high on the new apron about 30 ft from the downstream end of the new apron.

Tests with the 1-to-100 scale model with the new apron at El. 731 were made with the depressions in the river bottom all filled to El. 710, and bottom velocities were found satisfactory under this condition. Fig. 5 shows the results of the test of the 1-to-20 scale model for the arrangement which was finally adopted with various flows and with tailwater elevations in accordance with the 1929 rating curve. In this test, erosion of the river bed was very small.

The velocities of flow were measured in the model with a pitot tube at the end of the new apron, 20 ft downstream and 45 ft downstream, for surface, midsection, and bottom. In Fig. 5 one set of these velocities for run No. 26, series VIII, 58,800 cu ft per sec, shows the relative positions of observations and the magnitude of each. A tabulation of the velocities for the other runs shown in Fig. 5 is given in Table 3.

A new apron was constructed on the prototype in 1935 at El. 731 with a baffle at El. 734.5 and with a smooth transition section from El. 741 to the top of the new apron.

Figs. 6(*a*) and 6(*b*) are photographs of the model with the new apron and baffles which were finally adopted. Fig. 6(*a*) shows the baffles and apron of the model; and Fig. 6(*b*), a flood flow of 58,800 cu ft per sec on the model. A flood of 90,000 cu ft per sec occurred on September 15, 1938, and was the highest recorded flood at Prairie du Sac. The second largest flood—82,000 cu ft per sec—occurred on April 14, 1922.

The new apron was designed with a water seal between it and the old apron so that either structure could move somewhat without causing a reaction on the other. Sheet piling was placed at the downstream end of the new apron. The apron was supported on wood bearing piles placed to withstand uplift—so that the new structure would safely withstand a head of 13 ft or any head up to El. 743. A drain was constructed of porous concrete under the new apron which discharged normally at El. 738.0 into manholes at the ends of the dam. Stop logs were provided in the manholes which permitted adjustment of the water level under the new structure. The hydraulic gradient on a section

across the spillway structure would be: Headwater elevation, 774.0 ft; elevation within the hollow spillway section, 747.0 ft; elevation for drainage overflow at new apron, 738.0 ft; and minimum tailwater elevation, 732.0 ft.

The line labeled "September, 1935," in Fig. 1, represents the profile of the river bottom as it was just after construction of the apron on the prototype. The solid line shows the position of the river bottom in 1941; and the circles, the bottom in 1944. There has been no loss of material in the first 200 ft downstream from the end of the old apron. In fact, the river bottom has been raised somewhat by deposition of material brought upstream from points 400 ft

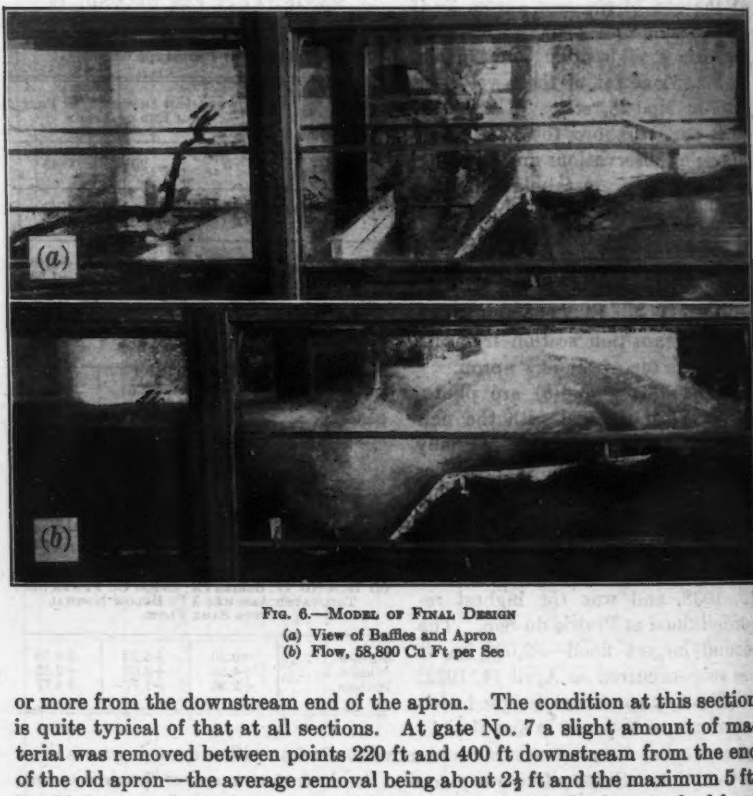

FIG. 6.—MODEL OF FINAL DESIGN
(a) View of Baffles and Apron
(b) Flow, 58,800 Cu Ft per Sec

or more from the downstream end of the apron. The condition at this section is quite typical of that at all sections. At gate No. 7 a slight amount of material was removed between points 220 ft and 400 ft downstream from the end of the old apron—the average removal being about 2½ ft and the maximum 5 ft. In this region where there was a slight loss of material, the bottom had been left somewhat above the general bottom elevation of adjacent sections at the time of construction. In general, there has been no loss of material except in very small isolated areas which were not leveled off to conform with general elevations of surrounding areas. The new construction has been subjected to a greater range of flow conditions than had occurred within the period of record

prior to the construction of the new apron. The greatest flow ever recorded passed the river at Prairie du Sac at 8 a.m. on September 15, 1938. Soundings have been taken every year since the apron was completed; and there has never been any material change in the river bottom since 1935—except tendencies toward general raising of the river bottom in the first 200 ft downstream from the old apron and toward leveling off high spots which were left after construction.

Both the 1-to-100 scale model tests and the 1-to-20 scale model tests indicated that removal of bed material below the dam was caused by upstream currents which existed from a distance at least 180 ft downstream from the end of the old apron to the apron. In no case did the jet from the old apron plunge under causing high bottom velocities in a downstream direction. Excessive bottom cutting in the model was always caused by upstream currents which occupied about two thirds of the depth of the channel.

Conclusions

At various times during the tests of the 1-to-100 scale model at Prairie du Sac, the model was adjusted to simulate conditions then existing on the prototype. Both the model and the prototype could be observed at one time. Under one condition, there was a pronounced surface current in the prototype which began about 1,200 ft downstream from the powerhouse and extended across the channel upstream toward the center of the Tainter gate section of the dam. With comparable flow distribution and tailwater level, such a condition was found to exist in the model. In a similar manner various combinations of powerhouse units that caused eddies in the tailrace were duplicated on the model. The distribution and direction of currents in the two sizes of models were nearly alike. High-velocity upstream currents on the river bottom occurred over essentially the same areas in the two models.

In the model tests the new apron and baffles reduced bottom velocities near the dam under all conditions—the highest bottom velocities were small and were generally in an upstream direction. The baffle on the old dam used with the new apron gave good results; but a material improvement was experienced when the baffle was placed on the new apron.

The design of improvements, based on model tests, has proved entirely satisfactory. The profiles of river bottoms in Fig. 1 show that bottom velocities have been reduced so that there is no objectionable cutting of the river bed near the dam.

High bottom velocities and considerable river bed movement occurred in the models under conditions which caused serious erosion in the prototype. Ten years of experience with the new structures indicate that the new apron and baffles were as effective in eliminating erosive velocities in the prototype as they were in the model.

DISCUSSION

GEORGE P. STEINMETZ,[6] M. ASCE.—The correction of tailwater erosion at the Prairie du Sac Dam (Wisconsin) by the construction of an additional apron and baffles was well planned, thoroughly investigated, and has proved to be highly successful. This project again emphasizes the economic advisability of careful model testing to determine the most advantageous corrective methods, as well as the nature of operation to be followed in making maximum use of corrective facilities after they have been installed. The erosion, necessitating corrective measures, further emphasizes the economy and desirability of model testing before initial construction of new projects when the behavior of foundation material cannot be anticipated with certainty. It is appreciated, however, that at the time this dam was constructed the science of model testing of this nature was not well developed.

The increase in bottom velocities in run No. 27 over run No. 26, with tailwater below normal in the latter run, as shown in Table 3, indicates the advisability of a gradual building up of tailwater elevation to normal before the gates are opened to the full extent necessary to pass a given flood so that excessive bottom velocities may be avoided.

The effects of flow distribution, as it might be controlled by particular combinations of gate openings, are indicated in the first paragraph of the "Conclusions." The determination and adoption of the most advantageous combinations of gate opening for various rates of flood and power generation discharges may be particularly important.

The entire problem of controlling tailwater erosion at the Prairie du Sac Dam resulted from the characteristics of the shifting sand bed of this stretch of the Wisconsin River. Some understanding of these conditions can be obtained by reading the 1913 and 1916 articles concerning the construction of the dam which were cited in the paper.[3,4,5] In this section of the river, where the sand bed is not controlled by a dam or other barrier, the bed is in a continual process of moving downstream in the form of moving sand bars. This movement is particularly evident at the stream gaging station at Muscoda, Wis., on the Wisconsin River, a number of miles downstream from the dam. At this gaging station, which was established at about the same time as the Prairie du Sac Dam was constructed, it is a common occurrence to observe a sand bar upstream from the gaging station during the early part of the open water season. As the season progresses, the bar moves closer to the station, finally reaching it; and at that time a normal depth of water of from 8 ft to 9 ft at the gaging station is replaced by 6 in. to 1 ft of water over the surface of the bar.

Soundings at the Muscoda Bridge for regular discharge measurements during the period 1914-1929 give some indication of the amplitude of moving sand bars. At eleven representative stations across the channel the extreme

[6] Chf. Engr., Public Service Comm., Madison, Wis.

changes in bottom position were from 4 ft to 22 ft in 15 years, with an average range of nearly 8 ft for the eleven stations. Airplane photographs of the river show the sand bars quite clearly. No reliable information exists, however, on the speed with which these bars pass downstream, or the bed-load volume involved. Historically, this movement of sand bars has been in progress since early log rafting days on the river, but it appears that the downstream movement had not been seriously considered. When a large pond is created by a dam on the river, the drifting bars above the dam are arrested in the pond, but downstream from the dam the movement continues, thereby lowering the stream bed and the tailwater at the dam. Immediately downstream from the dam the movement of material is greatly accelerated by the new and rapid currents introduced by the dam.

It appears that until such time as it may become economically feasible to develop slack water throughout the sandy reach of this river, about 200 miles in length, any dam constructed on the sand bed will experience a lowering of the stream bed similar to that experienced at Prairie du Sac, and, therefore, measures to retard or to take advantage of such erosion will be advisable. It is doubtful if such retardation can be effected without the creation of a deep pool or stilling basin, such as was rapidly created by nature at the Prairie du Sac Dam through the erosive action of flood discharges.

Perhaps the initial construction of an apron and baffle system on any future projects, such as has been developed at the Prairie du Sac Dam, over a period of time, would result in the creation of a relatively stable stilling basin in the sand bed by the natural action of floodwater discharge.

In the event that a project was designed, as indicated herein, to create a stilling basin or pool through designed erosion, it would be advisable to determine by model tests the extent of erosion in different periods of time and so to design draft tube outlets, locks (if any), and other parts of the structure for the ultimate tailwater elevation and head that would be created.

The piling foundation of the apron addition, which is designed to withstand an uplift of about 13 ft of head, is unique in Wisconsin. It is particularly important in this project, in that it allowed the effective head on the original structure to be decreased and, at the same time, allowed the total head on the project to be increased. The result was that the output was increased, particularly during periods of low stream flow when tailwater is lowest and firm power most essential.

LOUIS M. LAUSHEY,[7] JUN. ASCE.—Different methods have frequently been used to dissipate the kinetic energy possessed by the high-velocity jet on the apron, the best of which has probably been the use of a hydraulic jump. The problem at Prairie du Sac was a gradual lowering of the tailwater to such a depth that apparently a jump would not form on the apron for all discharges.

If the discharge and initial depth are known, the downstream depth required

[7] Instructor in Civ. Eng., Carnegie Inst. of Tech., Pittsburgh, Pa.

for the jump to form can be computed from the momentum equation. When the tailwater depth is insufficient, a jump will not form on the apron. The authors have used the common method of interposing a baffle or sill in the path of the jet to create an additional upstream force to aid in the formation of the jump at the desired position. The obstructions also have the additional value of deflecting the high-velocity filaments toward the surface, the result being to keep the velocities on the bottom at a minimum. Frequently, a roller can be produced that actually causes the bottom velocities downstream from the end sill to travel toward the dam and to build up any scoured material behind the sill.

Tests are being made at Carnegie Institute of Technology in Pittsburgh, Pa., to determine the effectiveness of a rectangular end sill on the production of a hydraulic jump when the tailwater depths are below normal. Some experiments have been made in a rectangular channel 12 in. wide and 30 ft long. A thin, high-velocity jet was admitted to the upstream end by confining the discharge between the channel bottom and a low, rigid plate which extended across the channel and was parallel to the bottom. The inlet plate was adjusted to different depths in such a manner that the water surface upon exit into the channel was parallel to the bottom. The jump was formed at the lower end of the channel after traveling about 20 ft. It was assumed that a velocity distribution would be produced at the beginning of the jump closely resembling that of the discharge after flowing down the spillway of a dam. The initial and final depths, and the discharge, were measured when a jump was formed on the apron without a sill, and with sills of various heights. Tailwater depths were measured with piezometers at 2-ft intervals for a distance of 6 ft downstream from the sills. An adjustable gate at the lower end of the channel made it possible to adjust the tailwater to obtain the minimum depth required to form a jump. Minimum depth was defined as the lowest depth for which the piezometers downstream from the sills recorded the same height. This setup insured that the depth recorded in the model would be comparable to the actual depth in the prototype rating curve. Furthermore, any depth below this minimum caused a wavy surface that was highest over the sill, and the possibility of high velocities being deflected toward the bottom was considered more likely than when the depth downstream was constant. The use of a second baffle, as at Prairie du Sac, would decrease the piling up over a single baffle with a resulting drop in the water surface to the actual tailwater elevation.

Analysis of Fig. 3(*b*), given for the 1929 tests by the authors, shows that at low discharges a jump does not form to increase the depth below the sill. Actually the baffle for the smaller flows, when the tailwater is very low, acts as an overflow weir. As a result the water drops below critical depth on the apron downstream from the baffle to nearly its original depth. This condition holds true to a lesser extent for the higher flows. Any increase of tailwater depth to the height over the sill would not cause the jump to move upstream. The fact that a small amount of scouring resulted during operation of the spillway is probably a result of the small velocities at low flows, and of the higher depths and the increased effectiveness of the baffle to form a jump at the larger dis-

charges. An added protection against scouring was obtained by placing the baffle 20 ft from the end of the apron. The "drop-off" from the end of the apron to the unpaved stream bed, obtained in the 1929 tests, would aid in giving good results by reducing the velocities because of the added depth of flow.

Perhaps of most importance in the correction of the erosion was the excellent velocity distribution obtained by the authors as shown in Fig. 5 where the bottom velocities either were zero or were directed upstream when the new apron was installed. This is a necessary function of any sill or baffle— the formation of a low bed velocity. The effect that such a device has on dissipating energy and forming a jump at lower tailwaters than otherwise required is of little importance if high velocities reach the bottom.

From experimental curves and work in process at Carnegie Institute of Technology, an attempt has been made to analyze the height of baffle of 52 in. used in the 1929 tests for forming a jump with low tailwater depths. The initial jet depth for 50,000 cu ft per sec (50.8 cu ft per sec per ft of apron), from Fig. 3(*b*), scales between 1.5 ft and 2 ft. For the former initial depth, it would be possible to produce a jump, with no drop in elevation anywhere downstream, with an actual stream depth only 80% of that required without a baffle. Using the other limit of the range would require a depth of 87% of normal. The ordinary hydraulic jump formula would require a tailwater depth at the baffle of between 8 ft and 9.5 ft, depending on the assumed initial depth. Thus, the required elevation of tailwater for 50,000 cu ft per sec with no baffle is between 751 ft and 752.5 ft. Fig. 3(*b*) shows an actual depth of 749 ft or a depth, without a baffle, at 20 ft, of 6 ft of water. This yields a percentage ratio, at the distance −20 ft, of depth available to depth required for a jump on the apron of between 63% to 75%. Therefore, it seems that the tailwater depth is about 15% too low for a jump with no loss in depth to form at this discharge. That this estimate is perhaps reasonable can be seen by inspection of the profile in Fig. 3(*b*) where the height over the baffle is about 6 ft above the stream elevation. Experiments indicate that at this flow a baffle less than two thirds of the height used would have produced a jump at 50,000 cu ft per sec. Of course, the baffle would have to be designed for 65,000 cu ft per sec, and this flow would require a higher baffle. The maximum discharge seems to be drowned out on the bucket, and the depth at distance −42 ft from the end of the apron seems to be high for the jet depth. Therefore, it is unfortunate that a similar analysis could not be made for this discharge. At any rate, the amount of scouring is of most importance, and undoubtedly the 56-in. baffle was used on the basis of best protection from scour, and not just on the formation of a hydraulic jump.

Abraham Streiff,[8] M. ASCE.—An important contribution toward the solution of several questions involved in the design of dams is contained in this paper. In particular, the publication of the 33-year experience record of the Prairie du Sac Dam is a valuable addition to the literature on scour below dams. This dam, on a sand foundation, designed by Daniel W. Mead, Hon. M. and Past-President, ASCE, is a remarkable structure in many respects. The

[8] Fargo Eng. Co., Jackson, Mich.

authors describe mainly the conditions and corrections of tailwater erosion, which will be discussed first. Several other features are also mentioned which warrant special discussion.

The main and important conclusion to be drawn from the paper is the following: To be considered successful, a dam structure should be permanent and secure. To this end the paper demonstrates that it is unnecessary to design against the occurrence of all erosion below the apron and that the aim of the designer should be to prevent such erosion. If the design is such that the erosion itself is stable, and does not endanger the structure, the design may be considered completely successful. Experience has taught how to attain this end.

There are many dams with erosion below the apron, not only on friable soil foundations, but also on the hardest rocks, such as gneiss.[9] In many of these cases corrective measures have been taken; but in others, with equally successful results, no such measures were necessary. These structures, built since the late 1880's, all illustrate the truth of the foregoing statement. An important additional proof has been given by the paper.

This principle should be emphasized because recent discussions frequently center around the building of aprons so that: (1) Erosion downstream is prevented; (2) the hydraulic jump is created; and (3) erosion occurs on the apron.

(1) *Prevention of Downstream Erosion.*[10]—This requirement is frequently advanced, but the necessity of preventive measures is not sustained by actual experience, nor is it followed in actual design. The Prairie du Sac Dam in Wisconsin is only one of many examples. It is important because the maximum erosion, of one and one-half times the normal head, occurred in a sand foundation. The dam is apparently entirely secure.

The width of the structure—104 ft from upstream sheet piling to downstream end of apron—is very short considering the head of 32 ft and the sand foundation. Comparison with the structures, listed in Table 4(*a*) built during the same period and on similar foundation material, reveals that they have aprons much longer than the apron of the original Prairie du Sac Dam. Hence, none of these dams shows any erosion below the apron. Although this condition is satisfactory, the question arose as to whether a considerable saving in cost might not be attainable by making shorter aprons and by allowing a certain amount of stable erosion, especially since a number of existing and older structures show that this result is quite feasible as has been proved again by the paper. The original apron of the Prairie du Sac Dam was lengthened 50 ft. The baffle directs the flow upward, and thus corrects the original downward inclination of the apron. The same effect is also obtainable by a toe weir with inclined upstream face. A number of dams built later than the Prairie du Sac Dam, on soil foundations, have shorter aprons and have permanent but harmless erosions below the structure (see Table 4(*b*)). These

[9] "Technisch wirtschaftliche Fortschritte auf dem Gebiete der Wasserkraftanlagen in der Schweiz," by E. Meyer-Peter, World Power Conference, Vol. IX, 1930, p. 77.

[10] "Development and Hydraulic Design, Saint Anthony Falls Stilling Basin," by Fred W. Blaisdell, *Proceedings*, ASCE, February, 1947, p. 123.

dams have experienced maximum flood discharges of 115,000 cu ft per sec several times, and have permanent but harmless downstream erosions.

There are much older structures on soil foundations which have permanent and harmless deep erosions downstream. An example is the Trowbridge Dam on the Kalamazoo River, in Michigan, which was built in the 1890's on a silt and sand foundation. The head is 22 ft and a permanent erosion 40 ft deep exists downstream from the pole apron.

[a] Length from upstream sheet piling to end of apron. [b] Various years between 1927 and 1931.

Many dams with permanent downstream erosions also exist on rock foundations.[11,12] Other examples, in Europe and in the United States, are numerous.[13,14,15] The only requirements are that the erosions be stable and that they not tend to undermine the structure. Considerable experience is recorded to assist in determining how such results can be attained. The paper clearly states this important conclusion.

(2) *Creation of a Hydraulic Jump.*—At low heads and at discharges of great depth, the hydraulic jump is an imperfect method of destroying energy, as may be noted from available tables of hydraulic jump data.[16] Therefore, there is no merit in attempting (as so often is done) to create a sufficient depth on the apron to cause the formation of a hydraulic jump at low heads. The authors illustrate this fact clearly in Fig. 6(*b*) where, although the upper baffle is too high to create a true jump, it, nevertheless, proved effective.

(3) *Locating the Jump on the Apron.*—In low-head design, this often-specified requirement has been proved unnecessary. It is more important to direct the nappe toward the surface, which the authors achieve by baffles, as stated under "Conclusions." This procedure creates as much room as possible for the upstream bottom velocities of the "ground whirl." The erosion caused by the extension of the turbulence below the apron, as the authors show, is permanent and harmless, even though the erosion depth is 20 ft below the new apron and the foundation consists of sand. Experience with many other structures, some of which are listed in Table 4, illustrates this fact.

(4) *Lowering of Tailwater Elevation.*—The lowering of tailwater is a familiar phenomenon on many rivers in alluvial beds. The dam intercepts the movement of bed load, and below the dam the existing grade creates new bed load and degrades the tailwater. The total for the Prairie du Sac Dam was fortunately not great; apparently it was not more than 6 ft after which it seems to have been stabilized. Greater increases have occurred in some Michigan dams. At the Junction Dam on the Manistee River the tailwater was lowered 10 ft and was only stabilized by the construction of a weir downstream, which is only temporary. The degradation continues. In 1917, when the dam was designed, previous experience with the Croton Dam on the Muskegon River caused the writer to place the Junction draft tubes 10 ft lower than necessary. Even this amount proved insufficient, for the draft tubes have been corrected since, and later a counter weir was built to stabilize the head. The apron, which was previously submerged, is "high and dry" at low water. This lowering of tailwater is much in evidence in the southwestern United States—for instance, at Boulder Dam.

(5) *Other Features of Prairie du Sac Dam.*—Several other interesting and successful features of the Prairie du Sac Dam are shown in the paper. Since there is no base slab, the upstream sheet piling forms the principal cutoff. There is no horizontal percolation distance; the reduction in head by the sheet piling is 27 ft or 75% of the present head. At the Mio Dam, which has a base slab, the upstream piling reduces the head by 50%. The advantage of the design shown in Fig. 1 is obvious and apparently has been quite successful.

The dam has forty-one Tainter gates 20 ft wide by 14 ft high. The dam is on a large river in an area that has a severe winter climate. Apparently a multiplicity of rather small gates has not been a handicap under severe ice conditions. It would be of great interest to learn from the authors how the spillway is guarded against ice thrust and is kept operative during the winter and during the breakup of the ice.

R. H. Keays,[17] M. ASCE.—The project described by the authors is very interesting to the writer, as several years ago he had a similar problem in connection with the flood control works on the Struma River in Macedonia, Greece.

The term "tailwater erosion" is not strictly accurate; the authors would do better to state that the erosion was caused by the turbulent flow from the

[17] Jackson Heights, N. Y.

dam. It is understood that the tailwater elevation is measured after the turbulent area is passed and the river has assumed a normal flow.

The "Synopsis" states that in the course of time there was a general lowering in the tailwater level and the river bottom downstream from the dam. It had been expected that long since, another dam would have been constructed downstream, which, presumably, would have backed up the water enough to maintain the tailwater elevation and prevent erosion of the river bed. As this was not done, however, erosion continued and a sharp drop developed at the Prairie du Sac Dam, in Wisconsin. It would be interesting, therefore, to know how much erosion has occurred at a distance from the dam sufficient to be free from the influence of the turbulent flow.

FIG. 7.—DOWNSTREAM VIEW OF WEIR, SHOWING ARTICULATED BLOCK PAVING AND DENTATED SILL

The Kerkini weir on the Struma River near the north end of the Struma Plain is a structure similar to the Prairie du Sac Dam (see Fig. 7). It also is built on a floating foundation in sand with a line of steel sheet piling at the upstream and downstream ends. In all respects it is similar to the barrages on the Nile River in Egypt, and was designed by an engineer with long experience in the Nile Irrigation Service.

The weir creates a large detention basin Kerkini Lake to regulate a flood of 4,000 cu m (141,000 cu ft) per sec, and this basin catches all the sediments brought down through the Rupel Gorge from the watershed in the mountains of Bulgaria to discharge into the Struma Plain.

The design of the weir was referred to Karl Rehbock at Karlsruhe in Germany, and his modifications of the design were based on hydraulic model experiments in his laboratory. Professor Rehbock's design included what he called a dentated sill. The dentations were a row of concrete "teeth" projecting upward at the downstream edge of the apron. They corresponded to the baffle wall described by the author. Professor Rehbock laid great stress on the importance of these dentations in breaking up the velocity of the current.

With this design it was calculated that a so-called "roll" would develop in the flow downstream from the apron. A roll can be described as a vertical eddy with the return flow at the bottom. The experiments showed that the erosion downstream from the apron would be in the form of a shallow depression extending for only a hundred feet or so.

Apparently, Professor Rehbock gave no consideration to the fact that the Struma River was a heavy sediment carrier. The result was that the relatively clear water discharge from the weir soon began to erode the bottom downstream from the weir for a long distance. This erosion was neutralized to some extent by material brought down by tributaries below the weir, but it was increased because of a cutoff having been made in the river some distance below the weir to shorten its course. This was a permanent lowering of the bed as no new sediment was coming down as a replacement.

This lowering of the bed, if carried far enough, would endanger the stability of the weir. As nearly as the writer can remember, the weir was designed for a flood flow of 1,200 cu m (42,400 cu ft) per sec. There was no reason to anticipate, however, that the weir would ever have to operate at more than 500 cu m (17,700 cu ft) per sec. It is reported that, at one time in 1935, it was probably operated by revolutionists at a rate considerably in excess of 500 m per sec.

The weir consists of a series of ten steel vertical lift gates supported by intermediate piers and wing walls at the ends, all supported on a concrete foundation on wood piles in a sand formation. To prevent seepage, lines of steel sheet piling are driven at the upstream and downstream ends.

The weir was well along to completion when the writer became chief engineer on the project in 1932. One of the first studies undertaken thereafter was to examine the question of the prospective erosion downstream. Even with a flow of 500 cu m per sec, or less, it was calculated that it would not be long before the stability of the weir would be in danger because of the difference in head allowing water to find its way under the steel sheet piling.

The weir was placed in operation in February, 1933. There was a small flow through the weir for some time—just enough to wash away some small sand deposits above the weir and deposit them on the flatter slope below the weir. As soon as these deposits were exhausted, however, erosion began downstream all along the course of the lower river.

There is no reliable information available as to the present condition of the Struma improvements. It is reported that they were largely destroyed during World War II. The upper works of the Kerkini weir certainly were destroyed as evidenced by photographs in possession of the writer.

C. N. WARD,[18] M. ASCE, AND HENRY J. HUNT, ESQ.[19]—A number of pertinent and interesting factors associated with erosion below dams were emphasized by the various discussions of the paper. The writers appreciate the favorable comments as to the final plans of improvement which were adopted and as to the use of models in such studies.

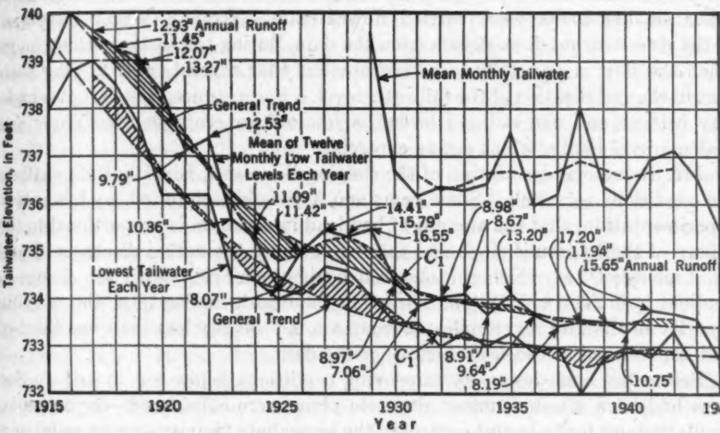

FIG. 8.—TAILWATER DROP AT PRAIRIE DU SAC PLANT ON WISCONSIN RIVER

At the time the Prairie du Sac Dam, Wisconsin, was designed and constructed, 1910-1914, little was known about drop in tailwater due to the movement of stream bed material. Inasmuch as this dam design was unique in many ways, and a departure from the standard practice, a careful check has been maintained on the structure from year to year. From the hourly plant records many interesting curves have been prepared, of which Fig. 8 is highly significant. For example, to understand the curves marked C_1, let a, b, c, d, and e be the annual tailwater elevations for successive years. Then C_1, the progressive mean for the middle year (in which the actual value is C), is expressed as:

$$C_1 = \frac{a + 4\,b + 6\,c + 4\,d + e}{16} \qquad (1)$$

The general trend of the drop in the lowest tailwater experienced each year since 1915 is shown on the lower curve. A similar curve for the mean of the twelve monthly low tailwater levels for each year is also shown for the same period, and the mean monthly tailwater levels for the period 1929 to 1947.

The general trend, as shown by Fig. 8, is toward a stabilized tailwater level. Several conditions may be mentioned that probably have a bearing on this stabilization. Originally, the slope of the river for some distance downstream

[18] Partner, Clayton N. Ward–John A. Strand, Cons. Engrs., Madison, Wis.; formerly Partner, Mead, Ward & Hunt, Cons. Engrs., Madison, Wis.

[19] Partner, Mead & Hunt, Cons. Engrs., Madison, Wis.; formerly Partner, Mead, Ward & Hunt, Cons. Engrs., Madison, Wis.

was about 2.5 ft per mile, whereas today the slope in the first 7 miles is about 1.5 ft per mile. For corresponding flows, the channel width is greater and the area larger now (1947) than in 1915 because of the reduced slope and velocity. The amount of material moved out of the first 7 miles of river is estimated at 11,000,000 cu yd. A large part of this material was from the first 2 miles below the dam, in which reach one large island and several other smaller areas were carried downstream. From a visual inspection of the river bottom downstream from the dam, during the early morning hours when the flow is especially low, it is obvious that several controls play their part in the stabilization of the tailwater level. For instance, there are two highway bridges and one railroad bridge, a few old government wing dams and coarse gravel banks, which act as controls.

Mr. Steinmetz' description of the shifting Wisconsin River bottom outlines the conditions very well. Some years ago A. Schoklitsch found, by laboratory experimentation, that the amount of bed load in a stream is proportional to the square of the hydraulic slope and the difference of the actual discharge Q and the discharge Q_o at which the material begins to move. With the change in gradient from 2.5 ft to 1.5 ft per mile below the Prairie du Sac Dam, the carrying capacity in the first seven miles downstream is probably less than one third of that experienced in the early history of the dam.

Before the final design for improving conditions below the Prairie du Sac Dam had been selected, many alternate plans were considered—for example, auxiliary dams for tailwater control in the immediate vicinity downstream, or a combined power plant and dam some distance downstream which would control the minimum tailwater at the Prairie du Sac plant. With the apron added in 1935 and the control weir with crest at El. 734 below the powerhouse, it was found that a maximum amount of benefit could be obtained with a minimum of expenditure. Prior to the improvement, the maximum head permitted was 32 ft, so that as the tailwater dropped the headwater was maintained accordingly. With the improvement make, the stability of the structure was assured, and the average annual output increase was estimated at 15,000,000 kw-hr per yr. For a low water year, this increase was estimated at 22,000,000 kw-hr per yr.; and for a high water year only 6,000,000 kw-hr per yr. On the basis of the average yearly increase in output at only 5 mills per kw-hr for the energy, the increase in income for four average years was sufficient to pay the cost of the improvement. In addition to the financial benefits, the stability of the structure is excellent. The step down of the hydraulic gradient through the structure is a valuable improvement.

Observations on the 100-to-1 scale model of the entire dam, lock, and powerhouse were quite convincing in their testimony that the island below the east half of the spillway and the method of gate operation were factors in the development of the 57-ft hole some distance below the lock and dam. It was soon found that all Tainter gates should be opened uniformly across the dam for best results. Much time was spent on the location of the baffle on the new apron, with and without the old baffle, the width of the new apron, and the depth of setting until all of these were adjusted so that the velocity at the end of the new

apron was as nearly zero as possible; or, if any velocity were present, it was small and in an upstream direction, with the highest velocity on the surface of the water.

Mr. Steinmetz emphasized the economic advisability of model testing. The paper described only a few of the model tests. Many of them were run using types of improvements developed in other places and as suggested by engineers with many years of experience in the design of protective works on dams. Most of these corrective measures proved to be of little or no value. It is much more feasible to arrive at the solution of such a problem by a trial-and-error method in the laboratory than in the field. The adequacy of the hydraulic jump in destroying energy of flowing water was appreciated at the time the model testing started. The early testing consisted of using different methods of causing turbulence on the apron of the dam to destroy energy so that a depth of flow near the bucket of the dam could be attained which would permit the formation of a jump on or near the apron. Blocks attached to the apron to increase roughness and staggered piers were found to be somewhat effective under certain limited conditions of flow. A so-called "cutter pier," with an edge pointed upstream and with curved sides extending downstream and outward shaped like the moldboard of a plow, was placed with its center line downstream from each gate. It was of no value because it accentuated erosion at the end of the apron under certain conditions of flow. Water rose over this pier nearly to headwater elevation and dropped to the river bottom, eroding deep holes at the end of the apron. A continuous wall or weir of proper height, and placed a certain distance from the end of the apron, was found to be the most effective protection for the original dam and for the new apron.

Mr. Laushey describes the interesting work done at Carnegie Institute of Technology, Pittsburgh, Pa., including the conditions under which the baffle on the old apron of the Prairie du Sac Dam was effective in producing a hydraulic jump. It is true, as he states, that the production of a jump is of little importance if high velocities reach the bottom. In the model tests, particular attention was given to bottom velocities rather than to the formation and the exact location of the jump.

Mr. Streiff is quite right in stating that erosion below dams is not confined to friable soil foundations, but may occur with any type of foundation. The rapidity of the drop in tailwater depends upon the original natural slope in the river, the kind of material, and the location of the structure relative to the tailwater levels for various flows. A dam on the Niobrara River near Spencer, Nebr., was inspected in 1928, and again in 1934. This structure is on shale foundation, and the original slope of the river was about 7 ft per mile. In this 6-year period the tailwater had dropped 7 ft. The dam on the Wisconsin River at Wisconsin Dells, known as the Kilbourn Dam, is on sandstone rock, but the river bottom downstream is similar to that at the Prairie du Sac Dam. The tailwater at this plant dropped from El. 813 in 1909 to El. 806 in 1935 when modifications were made in this structure.

Mr. Streiff cites two dams in which tailwater erosion occurred on a rock bottom. Model testing is often advantageous even though the site of a dam is

on rock and no future lowering of the tailwater elevations is anticipated. Subsequent to the Prairie du Sac Dam tests another model of an existing dam was tested because considerable erosion had occurred in a sandstone bottom of the prototype. This erosion resulted from the plunging of the jet from the apron to the river bottom through a considerable depth of tailwater. This unfavorable condition would have existed had there been no recession of general tailwater elevations. An interesting condition was noticed in the last mentioned test. It was found, under certain conditions of flow, that the jet might either plunge to the bottom, causing high erosive bottom velocities, or it might remain on top. Over a certain range of flow in the model this jet could be caused to plunge or to remain on top by directing it with a shovel or a board. On a rising flood the jet might continue to plunge to the bottom over a "flow-tailwater head" range in which it would remain near the surface on a receding flood. During the period of model testing, which was run at the dam site, a high flood occurred in the river. It was noted that the conditions of the jet as observed on the prototype appeared to be precisely the same as disclosed by the model. The model tests showed that a comparatively narrow apron with a continuous baffle wall would eliminate bottom erosion. There was found to be only one height and one location of baffle which would be effective under all conditions. At this dam, bottom velocities were influenced more by changes in the height and position of the baffle than on any other dam studied by the writers.

Generally, a dam should be designed, at the very beginning, to discharge flood flows without serious tailwater erosion. It is usually much more costly to add protective works at a later date. After serious erosion occurs, the old structure is usually less safe and there is often some hazard involved during the progress of construction of new protective works. Some provision should be made in the original design to take care of conditions should there be some future lowering of the tailwater due to the presence of the dam itself or to other changes such as removal of bridges or straightening of the river channel downstream from the dam.

On the other hand, it may be more economical to construct the original dam on a stream in a safe manner, but not design it for the ultimate expected drop in tailwater. Then, as necessity requires, model tests may be made and a design made to meet the conditions. In all probability the general plan of procedure used on the Prairie du Sac Dam was the economical way to do this work. The power company could not have spent the additional amount for the extra work in 1914, and to carry the extra investment over a long period of years would have been a burden.

The forty-one Tainter gates, 14 ft by 20 ft (mentioned by Mr. Streiff in item (5)), are capable of passing 160,000 cu ft per sec. The maximum flood since 1873 occurred in 1938 and amounted to 90,000 cu ft per sec. The pond area is about 9,000 acres at a normal water level of 774.0 ft. No difficulties from ice have been experienced. The ice usually deteriorates and softens before passing the gates. There has been no excessive ice pressure, and the pond is permitted to freeze with no provision for relieving the pressure. The turbine units are capable of using about 15,000 cu ft per sec, which is 1.65 cu ft per sec per sq

mile on the 9,125 sq miles of drainage area. Since the power load on the company's system is large enough to absorb the output, there is little need to open the gates until a substantial flood reaches this plant. This gives sufficient time for the ice to break up.

It was stated in the paper that small current meters and pitot tubes did not give satisfactory results in the 1929 tests. In subsequent studies of various models of dams the use of pitot tubes has been found very feasible. In fact, the results of the velocity measurements would be relied upon in future tests. A type of pitot tube and its use was developed which avoided most of the troubles encountered in 1929. The pitot tubes were made from 1/8-in. glass tubes using a blow torch to form the bent ends. For approximate and preliminary studies, a rubber bulb attached to both legs of the tube permitted raising the liquid in the glass legs above water level in the channel where the differential head could be observed. Air carried in the flowing water and entering the pitot tube which gave so much trouble in other pitot tubes could readily be detected when it entered the glass tubes. For more accurate determinations a differential fluid gage, using gasoline, was connected to the pitot tube. A method of flushing was developed which permitted successful removal of air from the tubes. Because of great turbulence in most of the model tests and the considerable amount of entrained air, the pitot tubes and differential gage as originally used were not practicable. Clear water under pressure was brought to the gage below the lowest gage fluid level. A valve in each branch hose connecting to the legs could be adjusted so that when the flushing water was turned on the flow in each leg was such as not to cause the gage fluid to be blown out. The procedure was to place the pitot tube in proper position, open the flushing valve, close flushing valve, and read the gage. This was repeated until two or three consecutive readings gave consistent results. The pitot tubes were calibrated by observing the differential head as recorded by the differential gage when the tube openings were held near the surface of flowing water in a channel. The actual velocity of flow was determined by timing the motion of floats.

Mr. Keays took some exception to the writers' use of the term "tailwater erosion." Although tailwater elevations were measured downstream from the turbulent area, the disturbed or turbulent reach was considered to be "tailwater." The general lowering of the bed of the Struma River in Macedonia appears quite similar to that of the lower Wisconsin River. It is possible that flood flows of 500 cu m (17,700 cu ft) per sec or greater may not have created any greater erosion at the dam on the Struma River than existed at lower flows. Maximum floods at Prairie du Sac did not cause maximum erosion. Floods of about one-half maximum resulted in deeper cutting of the river bottom near the end of the apron than greater floods.

The idea submitted by Mr. Keays to develop a roll in the flow downstream from the apron does not seem desirable because of the varying size of floods that may be encountered. However, the design might work perfectly under certain conditions of flood and tailwater level. The Spencer Dam on the Niobrara River was designed so that the water formed a roll which ultimately cut back under the dam as the tailwater receded, and the dam finally failed.

Mr. Steinmetz compared bottom velocities in runs No. 27 and No. 26 and emphasized the need for building up the tailwater to normal for a given flood. Operation on this basis is vital where erosion of appreciable magnitude has occurred. All gates should be opened progressively, allowing flood flows to discharge as uniformly over the entire length of the dam as is practicable at all times. If only one gate at Prairie du Sac were opened to discharge 2,000 cu ft per sec it would be discharging into a tailwater at an elevation of about 735 ft. Since the rate for one gate corresponds to a flood flow of about 80,000 cu ft per sec for the entire dam, the single gate would be discharging into a tailwater which is about 15 ft too low. Erosion increases quickly with tailwater lowered below normal. When using models with sand bottoms, care must be taken to prevent the lowering of tailwater below the desired limit to be tested. Tailwaters must be adjusted downward in the tests.

EFFECT OF STRESS DISTRIBUTION ON YIELD POINTS

BY F. G. ERIC PETERSON,[1] ASSOC. M. ASCE

WITH DISCUSSION BY MESSRS. F. P. SHEARWOOD, EDWIN H. GAYLORD, L. J. MENSCH, GEORGE WINTER, O. SIDEBOTTOM AND T. J. DOLAN, J. E. BAKER AND J. W. RODERICK, R. K. BERNHARD, AND F. G. ERIC PETERSON.

SYNOPSIS

In practice, the yield point of mild and structural steel is obtained by a standard axial tension test. The stress-strain diagram for compression has been found to agree closely with that for tension. After the yield point has been obtained by this standard tension test it is commonly assumed that when any fiber in a steel structure reaches such stress intensity, yielding will occur. Such is not the case; yielding does not occur until higher stress intensities are reached when the distribution of stress over the critical section is not uniform. The stress at which yielding occurs is dependent on type of stress distribution and the shape of the cross section under stress.

The application of loads on a beam to cause bending, and eccentric tension tests, are two of the simplest ways in which to produce a nonuniform stress distribution. Both of these methods have been used in obtaining the data for this paper.

PART I. THEORIES OF PLASTIC FAILURE IN BENDING

Two theories of ultimate moment resistance, M_u, of a given cross section have been developed (1).[2] These will be referred to as the "old theory" and the "new theory." Both theories, no doubt, idealize the actual conditions that exist.

The "Old Theory."—This theory is based on an idealized stress-strain diagram (work line) as shown in Fig. 1(*a*) by the broken line OAB which is substituted for the curved line and is a very close approximation to the curved line. Fig. 1(*b*) shows the stress distribution over a given cross section in pure bending with the extreme fiber stress σ_y below the yield point. Fig. 1(*c*)

NOTE.—Published in April, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Lecturer, Div. of Mech. Eng., Univ. of California, Berkeley, Calif.

[2] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (see Appendix).

shows the stress distribution after some of the outer fibers have exceeded the yield point and, on the basis of the idealized stress-strain relation, would be as shown in Fig. 1(*d*) where all moment resistance M_u is practically exhausted.

This theory assumes that the ultimate moment resistance is reached when all fibers (both tension and compression) have reached the lower yield point as determined by the usual tension test. It can be seen that to have fibers

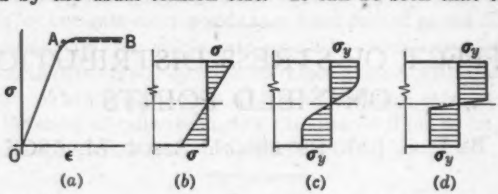

FIG. 1

very near to the neutral axis reaching the yield point the necessary strain requires considerable curvature of the member at the cross section and theoretically cannot actually hold right up to the neutral axis. Nevertheless, this conception of yielding gives values that are good approximations to the actual since fibers very near to the neutral axis contribute very little to the moment resistance in any event. When a section has reached the ultimate value of M_u it is said to act as a yield hinge. The action of such a hinge is not reversible since the behavior on reversing becomes elastic. In the case of I-beams with the web vertical, failure is likely to occur before the "yield-hinge" condition is reached because the compression flange will usually buckle soon after this entire flange has reached the yield point.

The "New Theory."—This theory is based on the idea that the yield point as obtained by the usual tension test does not necessarily hold for cases of nonuniform stress distribution. In the simple tension test of structural steel the yield point is determined by the occurrence of one or more phenomena. These are: (*a*) The drop of the scale beam of the testing machine, (*b*) the scaling off of the surface material in hot-rolled steel, and (*c*) the appearance of Lueders lines or yield lines in the case of a polished specimen. The appearance of Lueders lines in the polished specimen is without doubt the same phenomenon that causes the scaling of the surface in the hot-rolled specimen. In polished specimens which are subjected to nonuniform stress conditions the forming of Lueders lines occurs at a higher stress than in the simple tension test. From tests by A. Thum and F. Wunderlich (2) of pure bending of various forms of cross sections, the stress at which Lueders lines appear is dependent on the shape of the cross section. More particularly it seems to be dependent on whether the greater part of the material is distributed close to the neutral axis (as in the case of a round bar) or most of the material is distant from the neutral axis (as in the case of an I-beam or wide flange section). In the first case the yield point in bending appears to be raised a considerable amount (about 65% in the case of a round bar (3)) whereas in the second case the increase is not so marked. In the case of a rectangular cross section the increase in the yield

point is somewhat more than 40%. Tests by the writer (detailed report of which immediately follows this discussion) seem to bear out these contentions. In the case of pure bending of two polished rectangular specimens the writer found that the stress at which Lueders lines formed was, respectively, 40.5% and 44.0% higher than in the simple tension test, for an average value of about 42.2%. In these tests readings of deflection of the beam at the midpoint were also taken. It is interesting to note (shown subsequently in Fig. 5) that the load-deflection line appears to continue to be a straight line practically up to the appearance of the Lueders lines. This tends to confirm the idea that the yield point is actually raised since otherwise the load-deflection line should tend toward the horizontal at points where the extreme fiber stress is higher than the yield point obtained from the simple tension test.

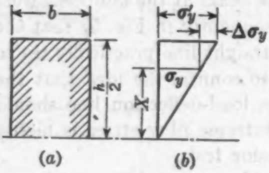
Further tests by the writer, as reported in Part II, were made on four specimens in eccentric tension to determine whether similar results would be obtained, and also to determine whether the ratio of thickness to width had any bearing on the results. These specimens were also of rectangular cross section. In all four cases the apparent raising of the yield point was more than 40% and the ratio of thickness to width seemed to have little effect. In the thinner specimens the Lueders lines or yield lines formed at right angles to the load, indicating yield across the thickness of the specimen governed. In the thickest specimen, lines were formed perpendicular to the load and also at 45° to the load indicating yield across the thickness and the width of the specimen simultaneously. It is well known that these lines form along the directions of maximum shear stress.

In the tests by Messrs. Thum and Wunderlich (2) a tension test on part of a bar of steel showed it to have a yield point of 38,400 lb per sq in. Next a rectangular specimen was cut from the same bar, polished, and then subjected to bending. A load which, by the usual bending formula, would cause an extreme fiber stress of 49,000 lb per sq in., or 27.5% greater than the tension yield point, was applied 200 times consecutively without the appearance of yield lines or any other sign of failure.

This "new theory" contends that in the case of nonuniform stress the yield point is higher than in the uniform state as indicated by the usual tension test. It also states that the increase $\Delta\sigma_y$ over the tension yield point σ_y is dependent on the shape of the cross section and that when this increased yield point is reached yield occurs suddenly and that the stress then subsides to the tension yield point. This phenomenon has been likened to the case of the delayed boiling of a liquid (4). The explanation of the phenomenon possibly lies in the field of metallography. A. M. Freudenthal, Assoc. M. ASCE (4), states that it is confined to metals that have a "stereocentric" type of lattice structure and is not evident in the "planocentric" or more simple types of lattice structure. The phenomenon of the raising of the yield point, no doubt, is confined to metals that have a very well-defined yield point and therefore includes mild steel and structural steel.

With the knowledge that is available at present it is probably impossible to give a rigid mathematical treatment of the phenomenon. A basic difficulty presents itself in the fact that all the investigator can measure is strain—that

is, he cannot measure stress directly. The difficulty from the mathematical viewpoint is that although much is known about elastic behavior, and also about completely plastic behavior, little knowledge is available concerning the range between these states where plastic regions are surrounded by elastic material, and elastic portions are surrounded by plastic regions.



(a) (b)

FIG. 2

Nevertheless, W. Kuntze (3) has developed a method of determining the apparent increase in the yield point which agrees well with the results of numerous tests performed. This method can be stated as follows: Assuming that the triangular distribution of stress in bending holds, even if the tension yield point is exceeded, divide the total stress on one side of the neutral axis into two equal parts; then set the stress at the point which divides these two parts equal to the tension yield-point stress.

For illustration, assume that a rectangular bar is subjected to bending, neglecting the shearing stresses. Fig. 2 shows the upper half of a rectangular cross section in bending, in which X is the distance from the neutral axis to the point that divides the total stress into two equal parts. Then

$$X = \tfrac{1}{2} h \frac{\sigma_y}{\sigma'_y} \qquad \text{(1a)}$$

and

$$\frac{\sigma'_y}{2} \times \frac{b\,h}{2} = b\,X\,\frac{2\,\sigma_y}{2} \qquad \text{(1b)}$$

Eliminating X from Eqs. 1: $\sigma'_y = \sqrt{2}\,\sigma_y$; or $\Delta\sigma_y = 0.414\,\sigma_y$, which represents a 41.4% increase. It is seen that this value agrees well with the results obtained by experiment. In a series of eight beam tests by Messrs. Thum and Wunderlich (2) an average value of 40.5% increase was obtained. The tests by the writer in both bending and eccentric tension resulted in an average increase of 42.4%, test I in eccentric tension (see Part II) was omitted from this average. Fig. 3, a plat of data by Mr. Kuntze (3), affords a graphic comparison of the values of X obtained by computation and experiment for various types of cross sections. The correlation is very good.

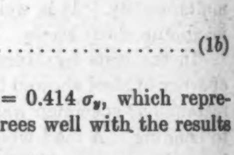


FIG. 3.—COMPARISON OF COMPUTED AND EXPERIMENTAL VALUES OF $X = \dfrac{\text{TENSION YIELD POINT}}{\text{BENDING YIELD POINT}}$

Calculation of the ultimate bending-moment resistance, M_u, on the basis of the "new theory" gives values slightly less than those given by the "old theory"; and they agree better with the results of tests as will be seen in a study made by Mr. Kuntze (3). Whether or not the "new theory" is actually correct, calculation on this basis is simplified since, after σ_y is found, the usual section modulus can be used in calculating M_u, that is

$$M_u = \sigma_y\,Z \qquad \text{(2)}$$

An account of the results obtained by the writer in some tests on bending and eccentric tension is presented in Part II.

PART II. TESTS RESULTS ON THE APPARENT RAISING OF THE YIELD POINT OF STEEL UNDER NONUNIFORM CONDITIONS OF STRESS

1. Pure Bending

These tests were made to determine inconsistencies in results by the usual tension test and those obtained under nonuniform stress. One specimen was tested in pure tension and two specimens in pure bending. Fig. 4 shows the dimensions and the arrangement of the supports and points of application of

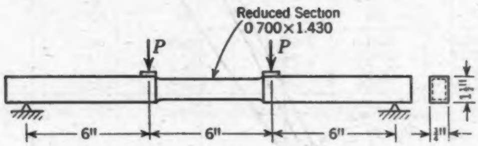

Fig. 4

the loads for the bending tests. The specimens were of cold-rolled flat bar steel 1½ in. by ¾ in., machined to 0.700 in. by 1.430 in. at the narrow section. Consequently, $A = 1.002$ sq in. and $Z = 0.239$ in.[3] A similar specimen was prepared for the standard tension test. All three specimens were annealed at 1,700° F and allowed to cool slowly in the furnace, after which the narrow section was polished so as to facilitate the observation of Lueders lines. Since 1,700° is well above the normalizing temperature the internal stresses due to cold rolling were eliminated. All three specimens were cut from the same bar.

The tension-test specimen showed an upper yield-point stress of 36,080 lb per sq in. and a lower yield point of 35,370 lb per sq in. The Lueders lines appeared immediately after the upper yield point was reached and spread quite rapidly over the entire specimen.

The specimens tested in bending were subjected to equal loads P at the third points so that the middle section was in pure bending. If the yield point in pure tension had governed the appearance of yielding in bending as evidenced by the formation of Lueders lines, these lines should have appeared at a load of 2,820 lb. Such was not the case, however. Table 1 shows the results obtained. According to the method described by Mr. Kuntze for pure bending of a rectangular cross section, the increase in the yield point should be $\Delta\sigma_y = (\sqrt{2} - 1)\sigma_y$ or about 41.4%. Considering experimental error the results of these tests agree very well with this value.

TABLE 1.—Percentage Increase in Yield Point, by Bending Test

Col. 1, specimens 1, 2, and their average.
Col. 2, Lueders line load.
Col. 3, unit stress σ in kips per square inch.
Col. 4, percentage increase beyond the tensile yield point.

Bar (1)	Load (2)	σ (3)	$\Delta\sigma_y$ (%) (4)
1	3,960	49.7	40.5
2	4,045	50.9	44.6
Average	(4,002)	(50.3)	(42.2)

As was to be expected, the Lueders lines appeared first on the upper and lower surfaces of the cross section in pure bending. They appeared almost simultaneously on these surfaces and spread quite rapidly down the sides of the specimen from the top surface, and up the sides of the specimen from the lower surface, with very little increase in the load. They reached a point

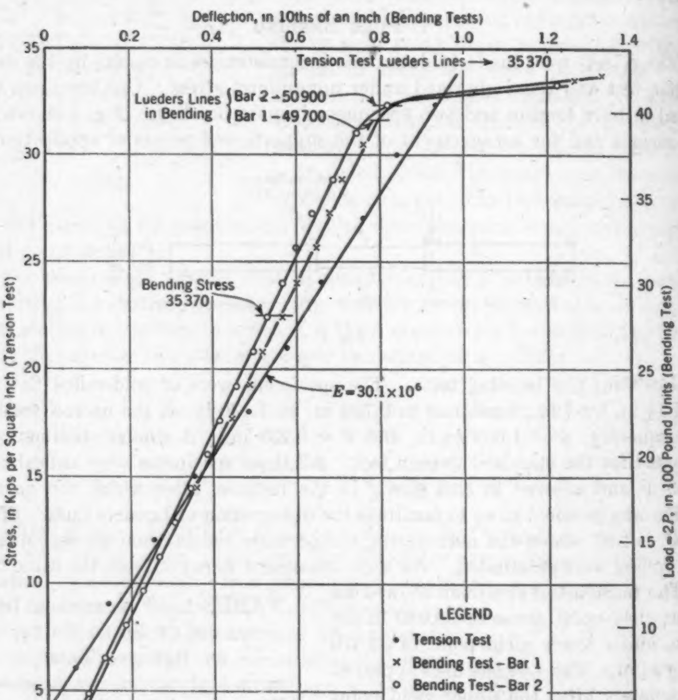

Fig. 5

about $\frac{1}{4}$ in. from the neutral axis each way. This seems to indicate that the process of yield in bending is a fairly rapid phenomenon rather than a slowly expanding region of yield.

The results of these tests are shown graphically in Fig. 5. Note that the load-deflection line appears to continue as a straight line for bending stresses far above the tension yield-point stress of 35,370 lb per sq in. Note also that

after Lueders lines have appeared the load-deflection lines tend to become horizontal, and the bending resistance is practically used up.

2. Eccentric Tension Tests

These tests were made in order to determine the effect of the nonuniform stress condition in eccentric tension on the apparent raising of the yield point

TABLE 2.—Dimensions of Specimens, Eccentric Tension Tests

Specimen	Thickness b, in Inches		Width h, in Inches		Area A, in Square Inches		Section modulus Z (in.³)
	Axial	Eccentric	Axial	Eccentric	Axial	Eccentric	
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
I	0.048	0.048	0.627	1.800	0.0301	0.0855	0.0257
II	0.1115	0.111	0.627	1.800	0.0698	0.200	0.060
III	0.234	0.233	0.628	1.800	0.147	0.429	0.126
IV	0.351	0.350	0.626	1.800	0.220	0.630	0.189

as compared to the yield point determined by axial tension. Four specimens of different thicknesses were used to discover whether the ratio of thickness to width had any effect on the results. Control tests in axial tension were made for each specimen. The steel used in these control tests was obtained from the same bars of steel, respectively, from which the eccentric specimens were obtained.

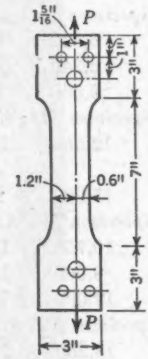

Fig. 6

The metal for these tests was selected at random from a commercial stock. Therefore, there was no reason to expect the yield point of the individual specimens to agree very closely. The steel was hot rolled. The dimensions of each specimen are presented in Table 2. The form and dimensions of the eccentric tension specimen are illustrated in Fig. 6. The eccentricity was one sixth of the width so that the stress varied from zero at one edge to twice the average at the other edge. Significant phenomena observed at various loads (in pounds) are as follows:

Load (lb)	Remarks
Specimen I, Axial.—	
1,300	Lueders lines formed near the end curves but did not spread.
1,500	Lines appeared near the center of the specimen and spread over the entire narrow section.
1,600	This was the maximum load applied.
Specimen I, Eccentric.—	
3,300	Lines first appeared at the stressed edge and spread over the length of the specimen. As the load increased, the lines gradually extended laterally toward the zero stress edge.
4,000	This was the maximum load applied.

Load (lb)	Remarks
Specimen II, Axial.—	
2,610	Upper yield point. Lueders lines began to form.
2,590	Lower yield point.
3,000	This was the maximum load applied.
Specimen II, Eccentric.—	
4,700	Lueders lines began to form near the curves at the ends of the reduced section.
5,400	Lueders lines began to form near the middle of the reduced section, at the stressed edge.
6,540	This was the maximum load applied. The formation of Lueders lines near the curved ends, under the 4,700-lb load, must have been caused by stress concentration because, after they formed, no tendency to spread was noticed until lines began to appear near the middle section of the specimen (the 5,400-lb load). Even at these points the increase was 26.5%. At the first appearance of Lueders lines they extend ½ in. or more laterally.
Specimen III, Axial.—	
6,340	Upper yield point. Lueders lines began to form.
6,240	Lower yield point.
6,550	This was the maximum load applied.
Specimen III, Eccentric.—	
12,850	Lueders lines began to form near the middle of the reduced section.
15,000	This was the maximum load applied.
Specimen IV, Axial.—	
10,750	Upper yield point. Lueders lines began to form.
9,900	Lower yield point.
12,000	This was the maximum load applied.
Specimen IV, Eccentric.—	
18,250	Lueders lines began to form at the ends of the reduced section—that is, where the end curves begin.
20,000	Lines began to form near the middle of the narrow section at the stressed edge and spread over the entire specimen.
22,500	This was the maximum load applied.

From the foregoing data it was possible to compute the percentage increase $\Delta\sigma'_y$ as shown in Table 3.

The results of these tests indicate an appreciable increase in the yield point (assuming that Lueders lines indicate the yield point) in the nonuniform state of stress as compared with the yield point resulting from axial tension; they agree quite well with the results obtained in pure bending. Each of the specimens showed an increase of more than 40% and the thinner specimens seemed to show the greatest increase. This was contrary to what was expected as it was thought that, when the axial tension yield point was reached across the thickness of the section at one edge, the Lueders lines would appear. Fig. 7

TABLE 3.—INCREASE IN YIELD-POINT STRESS BY BENDING

Specimen No.	Critical Load (Pounds)[a]		Stress (Lb per Sq In.)		Increase, $\Delta\sigma'_y$, Col. 5 over Col. 4 (%)
	Axial	Eccentric	Axial[b] σ_y	Eccentric[c] σ'_y	
(1)	(2)	(3)	(4)	(5)	(6)
I	1,500	3,300	49,900	77,200	55
II	2,590	5,400	37,100	54,000	45.5
III	6,240	12,850	42,450	60,000	41.3
IV	9,900	20,000	45,000	63,500	41.0

FIG. 7

is a photograph showing the Lueders lines on specimens II and IV, for axial and for eccentric tests. On specimens II, which are quite thin, note that the lines are predominantly horizontal whereas on specimens IV, which are relatively thick, there is a marked tendency of the lines to spread at 45° as well.

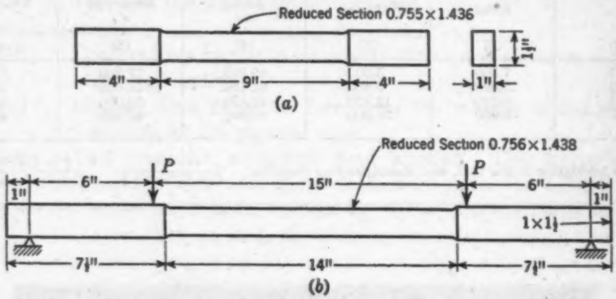

FIG. 8

This is apparently the only effect of thickness. If it is assumed that there is a straight line stress distribution up to the appearance of Lueders lines the apparent raising of the yield point is just as marked for the thin as for the thick specimens. On the three thinnest specimens the Lueders lines formed at right angles to the direction of the load although after reaching a considerable depth there was a tendency to form at 45°. On the thickest specimen the lines formed both at 90° and at 45° to the direction of the load. This seemed to be the only effect of the thickness-to-width ratio. As was shown by Messrs. Thum and Wunderlich (2) and by Mr. Kuntze (3) the shape of the cross section has a marked effect on the raising of the yield point.

The appearance of Lueders lines seems to be the first indication of physical breakdown of the internal structure of the metal. It may be open to question whether or not yield occurs before Lueders lines begin to form. Does the metal reach the plastic state in advance of the appearance of Lueders lines? Referring to Fig. 5, the load-deflection lines of bars 1 and 2 appear to continue in the same straight line far beyond the point at which the stress in the ex-

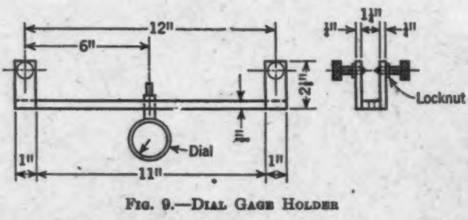

FIG. 9.—DIAL GAGE HOLDER

treme fiber has reached the tension yield point. If this is true, the beam continues to react elastically even after the tension yield point has been reached.

Check Tests.—As a check on the reliability of the foregoing tests, in support of the conclusion that the yield point is actually raised, the writer decided to

make further tests in which Lueders lines would not be observed. The writer does not contend that Lueders lines are an exact indication of yield. Since the tension stress-strain diagram shows some curvature at a stress somewhat lower than the yield point (as usually defined), some slight yielding occurs below the yield point and before Lueders lines appear.

Two rectangular specimens were tested in tension and two in bending. The dimensions of these specimens are shown in Fig. 8. All specimens were cut from the same bar of commercial mild steel. Fig. 8(*a*) gives the dimensions of the two tension specimens. Fig. 8(*b*) gives the dimensions of the bending specimens and also the arrangement of loading. This loading arrangement causes the middle 15-in. section to be subjected to pure bending. By means of the frame shown in Fig. 9, which was attached to the reduced section of the bending specimen, it was possible to read, accurately, the deflection at the mid-

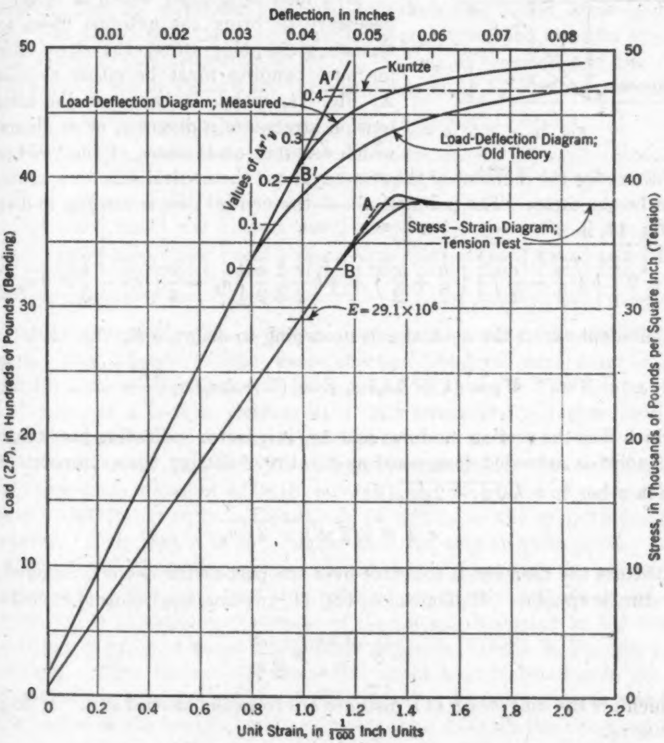

FIG. 10

point of a 12-in. section (subjected to pure bending moment) relative to the ends of that section. A dial, reading directly to 0.0001 in., was used.

The results of these tests are shown graphically in Fig. 10. The stress-strain diagrams for the tension specimens were identical except near the yield

point where two distinct curved lines appear. The yield points from direct calculation of load over area were, respectively, 37,960 lb per sq in. and 38,050 lb per sq in. The difference between these two values is not sufficient to show on the graph. The dotted lines intersecting at point A represent the idealized stress-strain diagram later assumed in calculations. In Fig. 10 is also shown the measured load-deflection diagram for the two bending specimens. The deflections for each specimen were so similar that only one curve appears.

The question now to be considered is whether or not this measured load-deflection diagram conforms with the tension stress-strain diagram (assuming that this diagram also holds for direct compression). Assume also that a plane section before bending remains plane after bending. Since no direct shear is involved this assumption is quite justified.

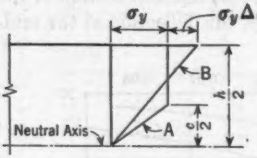

FIG. 11

If a load is applied which is larger than necessary to bring the extreme fibers to the tension yield-point stress, the stress diagram for pure bending must be either as diagram A, Fig. 11, which is based on the idealized tension stress-strain diagram, or as diagram B which assumes an increase of the yield point. In either case the moment of the stresses about the neutral axis for a given load must be the same. The moment about the neutral axis according to diagram A, Fig. 11, is

$$M_1 = 2\left[b\left(\frac{h}{2}-\frac{c}{2}\right)\tfrac{1}{2}\left(\frac{h}{2}+\frac{c}{2}\right)+\tfrac{1}{2}\,b\,\frac{c}{2}\,\frac{2}{3}\,\frac{c}{2}\right]\sigma_y = \frac{b}{4}\left(h^2-\frac{1}{3}c^2\right)\sigma_y \quad \text{(3a)}$$

The moment about the neutral axis according to diagram B, Fig. 11, is

$$M_2 = (1+\Delta\sigma_y)\,\sigma_y\,Z = (1+\Delta\sigma_y)\,\sigma_y\,\frac{b\,h^2}{6} \quad \text{(3b)}$$

in which Z is the section modulus and $\Delta\sigma_y$ is a factor indicating how much the yield point is exceeded (expressed as a ratio). Setting these moments equal to each other, $c = h\sqrt{1-2\,\Delta\sigma_y}$; or

$$c/2 = h/2\,\sqrt{1-2\,\Delta\sigma_y} \quad \text{(4)}$$

Because the moment is constant over the part of the beam considered, the curvature is circular. If diagram A, Fig. 11, governs, the radius of curvature is

$$\rho_1 = \frac{0.5\,c}{\epsilon} = \frac{c\,E}{2\,\sigma_y} \quad \text{(5a)}$$

in which ϵ is the unit strain at a distance $c/2$ from the neutral axis. If diagram B governs,

$$\rho_2 = \frac{E\,I}{M_2} = \frac{E\,I}{(1+\Delta\sigma_y)\,\sigma_y\,Z} = \frac{E\,h}{2\,(1+\Delta\sigma_y)\,\sigma_y} \quad \text{(5b)}$$

and

$$\frac{\rho_2}{\rho_1} = \frac{h}{(1+\Delta\sigma_y)\,c} = \frac{1}{(1+\Delta\sigma_y)\sqrt{1-2\,\Delta\sigma_y}} \quad \text{(6)}$$

using Eq. 4. Because of the large radius of curvature as compared with the length of the specimen involved, the ratio of the deflections is inversely proportionate to the radii of curvature, that is

$$\frac{\delta_1}{\delta_2} = \frac{1}{(1 + \Delta\sigma_y)\sqrt{1 - 2\Delta\sigma_y}} \quad \text{(7)}$$

in which δ_1 is the midpoint deflection according to diagram A and δ_2 is the same for diagram B. For as far as diagram B governs, the load-deflection line will be a straight line; but, if diagram A governs, the load-deflection line will curve toward the horizontal as the load is increased after the tension yield point has been reached in the extreme fibers.

Referring to Fig. 10, the load in bending at which the extreme fibers reach the yield point in tension is 3,300 lb as indicated by the line $\Delta\sigma_y = 0$. If diagram A, Fig. 11, governed, the load-deflection line would cease to be a straight line above this value and would diverge from the straight line for various values of $\Delta\sigma_y$ according to Eq. 7. Values of the load and the ratio of δ_1 to δ_2 are given in Table 4 for various values of $\Delta\sigma_y$. The curve resulting

TABLE 4.—VARIATION OF δ_1/δ_2

Description	Values of $\Delta\sigma_y$										
	0.00	0.05	0.10	0.15	0.20	0.25	0.30	0.35	0.40	0.45	0.50
Load	3,308	3,480	3,640	3,805	3,976	4,140	4,300	4,465	4,630	4,800	4,962
δ_1/δ_2	1.000	1.004	1.016	1.040	1.077	1.132	1.218	1.350	1.597	2.180	∞

from these tabulated values is shown in Fig. 10 marked "Load-Deflection Diagram; Old Theory." The load-deflection diagram according to Mr. Kuntze (3) is shown by the dotted line marked "Kuntze." The Kuntze "new theory" assumes a sudden yielding at a unit stress 41.4% higher than the tension yield point, for a rectangular section.

Now consider the load-deflection diagram (measured). It continues as a straight line up to a load of 4,000 lb, point B′, Fig. 10, giving an extreme fiber stress of 47,500 lb per sq in. This should be defined as the proportional limit in bending. Note that it is 25% higher than the tension yield point. Actually, this value of 47,500 lb per sq in. should be compared with the tension proportional limit. Realizing that this value is never very definite it still does not seem amiss to make an extimate of its value. Referring to the tension stress-strain diagram, a value of 33,000 lb per sq in. (point B, Fig. 10) seems about right. Then the ratio of the proportional limit in bending to the proportional limit in tension would be 47,500/33,000 = 1.44, or an increase of 44%.

For values of the load in bending greater than 4,000 lb the measured load-deflection diagram diverges from the straight line but is much closer to the straight line than to the load-deflection curve based on the "old theory." For a value of $\Delta\sigma_y = 0.30$ the divergence from the straight line according to Table 4 should be 21.8%. It is only 3%. For $\Delta\sigma_y = 0.40$ it should be 59.7% whereas it is actually only 14.5%.

Since the load-deflection diagram of Mr. Kuntze is based on the idealized stress-strain diagram, it was to be expected that the load deflection (measured) should diverge from the straight line at some point below A′ (Fig. 10) in order to conform with the fact that the actual stress-strain diagram begins to curve somewhat below point A.

Thus these latter tests, made without reference to Lueders lines, tend to confirm the fact of an increase in the yield point over that determined by the ordinary axial tension test when the stress is not uniformly distributed.

Conclusions

The data presented in this paper show that the ordinary axial tension test of mild and structural steel does not give information as to the behavior of the material under nonuniform stress conditions. The stress at which yield occurs is higher under nonuniform stress and is dependent on the kind of stress distribution and also on the form of the cross section under stress.

This fact tends to minimize the importance of stress concentrations since the stress distribution over an entire cross section, rather than the stress at an isolated point must be considered in order to determine when yielding will occur. Mr. Kuntze (3) reports that in tension tests of a flat bar with a round hole through it, the stress near the hole may reach a value from 2.3 to 2.7 times the tension yield-point stress before there is evidence of yield.

Failure due to fatigue stresses is not considered in this paper and, therefore, the paper is confined to cases of static loads or cases where the number of repetitions of loading is relatively small. Nevertheless, in tests by K. Kloppel (5) in the loading of a beam to the tension yield point in the extreme fibers, the load was repeated 700,000 times "without showing any signs of premature breakage through fatigue," and "the permanent deflections were practically zero."

DISCUSSION

F. P. Shearwood,[3] M. ASCE.—In commenting on this paper, it should be kept in mind that the true benefit of such a thesis will be realized through the promotion of investigation into the practical and useful application of the findings of the theories. The paper illustrates the fact that "yield" is a most useful and safe quality of steel and an important factor in bringing into play all resistances that oppose deformation (failure). It also indicates that overstrained fibers can be deformed slightly without endangering the structure, provided that other less strained fibers are brought into resistance. Ductility has undoubtedly been the safety valve of commercial designing in cases where poor detailing, eccentric connections, etc., would have caused failure if the elastic factor was the only deformation to be relied upon; but the ductile yield causes redistribution of the stress and so failure is avoided.

In designing or considering continuous spans, and other indeterminate structures as well as the cross bending of beams, modern practice demands that the structures be limited to the specified unit stress in their highest strained path when calculated by the elastic theory. It neglects the fact that, should this path or fiber be strained beyond its elastic limit, the other paths will then exert an increasing proportion of the required extra resistance. This proportion should be about in the ratio of the strain after and before passing the elastic limit—a fairly big ratio.

Investigation of old structures, abused structures, arc welding, badly designed structures, or other weak constructions frequently demonstrates that the yielding properties of steel must have been utilized to prevent failure. This evidence should warrant further investigation leading to the prudent use of this yielding property in the designing of indeterminate steel structures.

The manufacturing of steel and iron is made possible by this property of ductility which is constantly utilized during construction. In fact, much of the fabrication of steel would be impossible without this valuable characteristic of yielding. It is inconsistent to assume that yielding of steel is harmless during fabrication or when it relieves the excessive overstressing from faulty detailing and at the same time to prohibit counting on it when designing structures with more than one path of resistance.

It is interesting, and of much consequence, to determine the exact point where yielding will occur; however, the importance of such information lies in practical application to proportioning steel structures.

Edwin H. Gaylord,[4] Assoc. M. ASCE.—The tests described in this paper are an important contribution to the problem of the behavior to yield in pure flexure and in eccentric tension. It is worth noting that the unit bending stress at which the load deflection curve begins to deviate from the straight line bears the same ratio to the proportional limit in axial tension, as does the unit bending stress at the appearance of Lueders lines to the unit

[3] Cons. Engr., Dominion Bridge Co., Ltd., Montreal, Que., Canada.
[4] Prof. of Civ. Eng., The Ohio Univ., Athens, Ohio.

stress in axial tension at the appearance of Lueders lines (Figs. 5 and 10). This phenomenon seems to indicate that the behavior of the extreme fiber in bending, as predicted by the assumption of linear variation of stress, is the same as that of the fiber in axial tension, except for extension of the proportional limit and yield point.

The writer presents an analysis of the data in this paper on the basis of an assumption analogous to that made in the strain-energy theory for combined stresses at a point (21)(22). For a bar of unit length, the elastic strain-energy equations for axial tension and for pure bending are, respectively:

$$U_a = \frac{1}{2}\frac{P^2}{A\,E} \qquad (8a)$$

and

$$U_b = \frac{1}{2}\frac{M^2}{E\,I} \qquad (8b)$$

In Eqs. 8, let $\frac{P}{A} = \sigma_a$, the unit stress in axial tension; and $\frac{M\,c}{I} = \sigma_b$, the extreme fiber stress in bending. Then:

$$U_a = \frac{P^2}{2\,A\,E} = \left(\frac{P}{A}\right)^2 \frac{A}{2\,E} = \frac{\sigma^2_a\,A}{2\,E} \qquad (9a)$$

and

$$U_b = \frac{M^2}{2\,E\,I} = \left(\frac{M\,c}{I}\right)^2 \frac{I}{2\,c^2\,E} = \frac{\sigma^2_b\,I}{2\,c^2\,E} \qquad (9b)$$

If the unit stress at the yield point in axial tension is σ_{ay}, the yield-point stress in the extreme fiber for a rectangular section in bending is $\sqrt{2}\,\sigma_{ay}$, as computed by the method of W. Kuntze (3), and, using the relation $I/c^2 = b\,h/3$, Eq. 9*b* becomes:

$$U_b = \frac{1}{3}\frac{\sigma^2_{ay}\,b\,h}{E} \qquad (10a)$$

For a rectangular bar of the same cross section at the yield point in axial tension, Eq. 9*a* gives:

$$U_a = \frac{1}{2}\frac{\sigma^2_{ay}\,b\,h}{E} \qquad (10b)$$

If the shape of the cross section is a symmetrical diamond, the Kuntze method indicates an extreme fiber stress of precisely $2\,\sigma_{ay}$ at the yield point in bending. If b and h are taken as the width and depth, respectively, $A = b\,h/2$ and $I/c^2 = \frac{b\,h^3/48}{h^2/4} = b\,h/12$; and, from Eqs. 9,

$$U_b = \frac{1}{6}\frac{\sigma^2_{ay}\,b\,h}{E} \qquad (11a)$$

and

$$U_a = \frac{1}{4}\frac{\sigma^2_{ay}\,b\,h}{E} \qquad (11b)$$

Based on Eqs. 10 and 11, the assumption can be made that, at the yield point in pure bending, the strain energy in a given length of bar is equal to two thirds of the strain energy of a bar of the same length and cross section

at the yield point in axial tension. The yield point is defined as that point at which Lueders lines appear. Then, from Eqs. 9, if σ_{by} is the extreme fiber unit stress in bending at the yield point:

$$\frac{1}{2}\frac{\sigma^2_{by}\,I}{c^2\,E} = \frac{1}{3}\frac{\sigma^2_{ay}\,A}{E} \quad \text{(12a)}$$

and, since $I = A\,r^2$,

$$\sigma_{by} = \sqrt{\frac{2}{3}}\frac{c}{r}\sigma_{ay} = 0.816\frac{c}{r}\sigma_{ay} \quad \text{(12b)}$$

It is obvious that Eq. 12*b* will check the Kuntze method for the rectangular and diamond cross sections precisely. Table 5 gives a comparison of the

TABLE 5.—COMPARISON OF EQ. 12*b* WITH THE KUNTZE METHOD

Section	c	r	σ_{by}/σ_{ay}		$\frac{\text{Col. 4}}{\text{Col. 5}}$

36WF150	17.92	14.29	1.024	1.039	0.986
18WF47	8.95	7.30	1.001	1.041	0.961
8WF17	4.00	3.36	0.972	1.050	0.926

(*a*) R equals radius.

results of Mr. Kuntze's method and the results of Eq. 12*b* for a circular section, a tube, and a few wide-flange sections. For some of the wide-flange sections, the bending yield stress, as calculated by Eq. 12*b*, is indicated as being slightly less than the yield-point stress in axial tension. It is undoubtedly true that the two-thirds factor in Eq. 12*b* is not constant, but dependent on the shape, and that it approaches unity as r approaches c. Only in this way could the equation check the hypothetical beam in which all the material is concentrated along two lines parallel to, and equidistant from, the neutral axis; and such a section would surely be expected to yield at the yield stress for axial tension. Nevertheless, Cols. 4 and 5, Table 5, agree very well. In fact, by changing the factor 0.816 to 0.85, Eq. 12*b* will predict the bending yield, for the sections which the writer has checked, within ± 4% of the values obtained by the Kuntze method.

Eq. 12*b* provides an extremely simple method of calculating the yield stress in bending and, in so far as the two have been compared, gives substantially the same results as does the Kuntze method. Should subsequent tests establish the increase in bending yield as being reliable enough to warrant a change in design procedure, and also establish the strain-energy hypothesis, choice of a section to resist bending can be made without using Eq. 12*b* directly. If the yield stress as given by Eq. 12*b* is equated to the stress calculated from $\sigma = \frac{M\,c}{I}$,

$$\sqrt{\frac{2}{3}}\frac{I}{r} = \frac{M}{\sigma_{ay}} \quad \text{(13)}$$

In Eq. 13, the quantity $\sqrt{\frac{2}{3}}\frac{I}{r}$ is the section modulus. If a specification working stress is used in Eq. 13 instead of σ_{ay}, a uniform factor of safety with respect to yield would result for all cross sections with two axes of symmetry, regardless of shape. An extensive series of tests on both small and large sections would seem profitable, to try to establish firmly the apparent increase in the bending yield-point stress. Tests on sections which are unsymmetrical about the principal axis normal to the plane of bending would also be valuable, to determine the effect of this factor on the increase in bending-yield stress.

In extending the strain-energy equation to the case of eccentric tension, at least two assumptions are possible. One is expressed by the equation,

$$\frac{\sigma^2_b\, I}{c^2\, E} = k^2_1\left(\frac{\sigma^2_{ay}\, A}{E} - \frac{\sigma^2_a\, A}{E}\right) \qquad (14a)$$

The factor k^2_1 may be variable, but it must have the value 2/3 for $\sigma_a = 0$, to agree with Eq. 12*a*. Another possible assumption is expressed by

$$\frac{\sigma^2_b\, I}{c^2\, E} + \frac{\sigma^2_a\, A}{E} = \frac{k^2_2\, \sigma^2_{ay}\, A}{E} \qquad (14b)$$

In Eq. 14*b*, k^2_2 is definitely variable, since it must have the value 2/3 for $\sigma_a = 0$, and the value unity for $\sigma_b = 0$.

To obtain an expression for the maximum yield stress, the relation,

$$\frac{\sigma_b}{\sigma_a} = \frac{M\, c/I}{P/A} = \frac{e\, c}{r^2} \qquad (15a)$$

can be used to eliminate σ_b from Eq. 14*a*; thus:

$$\left(\frac{e}{r}\right)^2 \sigma^2_a + k^2_1\, \sigma^2_a = k^2_1\, \sigma^2_{ay} \qquad (15b)$$

from which

$$\sigma_a = \frac{k_1\, \sigma_{ay}}{\sqrt{k^2_1 + (e/r)^2}} \qquad (16a)$$

Similarly, from Eq. 14*b*,

$$\sigma_a = \frac{k_2\, \sigma_{ay}}{\sqrt{1 + (e/r)^2}} \qquad (16b)$$

The maximum stress σ_{my} is given by

$$\sigma_{my} = \sigma_a + \sigma_b = \sigma_a\,(1 + e\, c/r^2) \qquad (17)$$

and, therefore, from Eqs. 16:

$$\sigma_{my} = k_1 \frac{1 + e\, c/r^2}{\sqrt{k^2_1 + (e/r)^2}}\, \sigma_{ay} = \frac{1 + e\, c/r^2}{\sqrt{1 + (1/k^2_1)(e/r)^2}}\, \sigma_{ay} \qquad (18a)$$

and

$$\sigma_{my} = k_2 \frac{1 + e\, c/r^2}{\sqrt{1 + (e/r)^2}}\, \sigma_{ay} \qquad (18b)$$

For the specimens in Table 2, $e = 0.3$ in.; c/r^2 ($= 6/h$ for a rectangular section) $= 6/1.800 = 10/3$; and $r^2 = h^2/12 = 0.27$. Assuming an increase in yield stress of about 41%, or, say, $\sigma_{my} = \sqrt{2}\,\sigma_{ay}$, as is indicated for specimens III and IV of Table 3, and, substituting these values in Eqs. 16, $k^2{}_1 = 1/3$ and $k^2{}_2 = 2/3$.

Since $k^2{}_1$ has the values 2/3 for pure bending and 1/3 for the eccentric tension specimens, it seems reasonable to assume that it will approach zero with e. This variation can be expressed very simply by the equation,

$$k^2{}_1 = \frac{2}{3}\,\frac{a\,x}{a\,x + 1} \qquad \text{(19a)}$$

in which the constant a depends on the choice of the independent variable x. The variation of $k^2{}_1$ might be assumed to be with e, or with the dimensionless quantities e/r, e/h, $e\,c/r^2$, etc. It seems appropriate, however, to assume the variation to be with $e\,c/r^2$, since this quantity is the ratio of σ_b to σ_a. With this assumption, Eq. 19a reduces to

$$k^2{}_1 = \frac{2}{3}\,\frac{e\,c/r^2}{e\,c/r^2 + 1} \qquad \text{(19b)}$$

in which $a = 1$ was calculated on the assumption that $k^2{}_1 = 1/3$ when $e\,c/r^2 = 1$ (the values of these variables for the specimens of Table 3). The simplicity of Eq. 19b is encouraging, and the relation seems even more plausible when $e\,c/r^2$ is replaced by its equivalent σ_b/σ_a. This substitution leads to

$$k^2{}_1 = \frac{2}{3}\,\frac{\sigma_b}{\sigma_a + \sigma_b} \qquad \text{(19c)}$$

Since the value of $k^2{}_2$ is the same for the specimens of Table 3 as it is for pure bending, and yet must approach unity as e approaches zero, it is more difficult to assume a variation of $k^2{}_2$ without further data.

In seeking a possible explanation for the larger increase in yield stress for specimens I and II of Table 3, it might be assumed that there was an accidental eccentricity across the thickness of the specimen, since a constant eccentricity would have a greater effect on the thinner specimens. Eq. 18a is easily extended for eccentricities in two directions, and results in:

$$\sigma_{my} = \frac{1 + (e\,c/r^2)_1 + (e\,c/r^2)_2}{\sqrt{1 + (1/k^2{}_1)[(e/r)^2{}_1 + (e/r)^2{}_2]}}\,\sigma_{ay} \qquad \text{(20)}$$

The value of $k^2{}_1$ can be assumed to be given by the equation

$$k^2{}_1 = \frac{2}{3}\,\frac{(e\,c/r^2)_1 + (e\,c/r^2)_2}{(e\,c/r^2)_1 + (e\,c/r^2)_2 + 1} \qquad \text{(21a)}$$

or

$$k^2{}_1 = \frac{2}{3}\,\frac{\sigma_{b_1} + \sigma_{b_2}}{\sigma_a + \sigma_{b_1} + \sigma_{b_2}} \qquad \text{(21b)}$$

In Eqs. 20 and 21, the subscripts denote the principal axes of the bar.

Assuming that there is an accidental eccentricity of 0.001 in. in the direction of the thickness for each specimen of Table 3, Eqs. 20 and 21a yield: For

specimen I—

$$\sigma_{my} = 1.54\ \sigma_{ay} \qquad \text{(22a)}$$

for specimen II—

$$\sigma_{my} = 1.47\ \sigma_{ay} \qquad \text{(22b)}$$

for specimen III—

$$\sigma_{my} = 1.44\ \sigma_{ay} \qquad \text{(22c)}$$

and, for specimen IV—

$$\sigma_{my} = 1.43\ \sigma_{ay} \qquad \text{(22d)}$$

The agreement with the increases shown in Table 3, Col. 6, is surprisingly good. Perhaps Mr. Peterson will state in his closing discussion whether such an accidental eccentricity might have existed.

It will be of interest to investigate Eq. 18a for maximum or minimum values. Differentiating the equation with respect to e, and remembering that k^2_1 is also a function of e, with $\frac{d(k^2_1)}{de}$ to be obtained from Eq. 19b; a maximum or a minimum for the value of σ_{my} is found to occur for the value of e given by

$$e = \frac{4\,c}{3} - \frac{r^2}{c} \qquad \text{(23)}$$

For a rectangular section, Eq. 23 gives $e = h/2$. Then $k^2_1 = 1/2$ and $\sigma_{my} = (4/\sqrt{7})\ \sigma_{ay} = 1.51\ \sigma_{ay}$. This is evidently a maximum. The result is perhaps disappointing, as one might expect the increase in yield to be greatest for pure bending. However, considering that Mr. Peterson's tests show the same increase for eccentric tension with $e = h/6$ as for pure bending ($e \rightarrow \infty$) and that there can be no increase for $e = 0$, the existence of a maximum value seems plausible. For a circular section, Eq. 23 gives $e = 13\,R/12$. Then $k^2_1 = 13/24$ and $\sigma_{my} = 1.71\ \sigma_{ay}$. For an 18WF47 the maximum value occurs for $e = 5.98$ in. and is $1.15\ \sigma_{ay}$.

The increase in yield stress for eccentric tension could be determined by another method. It is common practice in aeronautical structural engineering to use so-called stress-ratio curves for combined stresses (23)(24). The specification of the American Institute of Steel Construction for combined axial and bending stress (25), expressed by the inequality $f_a/F_a + f_b/F_b < 1$, is an example. Although there are insufficient data from which to determine stress-ratio equations for the problem in Mr. Peterson's paper, it is interesting to observe that, for a rectangular section, the equation:

$$\frac{\sigma_b}{\sigma_{by}} = 1 - \left(\frac{\sigma_a}{\sigma_{ay}}\right)^2 \qquad \text{(24)}$$

checks specimens III and IV of Table 3. For specimen IV, $\frac{\sigma_a}{\sigma_{ay}} = \frac{31{,}750}{45{,}000}$ $= 0.706$. Substituting this value in Eq. 24, $\frac{\sigma_b}{\sigma_{by}} = 0.498$. The actual value of $\frac{\sigma_b}{\sigma_{by}}$ from Table 3 is $\frac{31{,}750}{45{,}000\,\sqrt{2}} = 0.499$.

The equations developed in this discussion are admittedly speculative, and are based on incomplete data. However, granting the possibility of the accidental eccentricity of 0.001 in. previously discussed, the results seem sufficiently good to justify further verification and development.

L. J. Mensch,[5] M. ASCE.—The related phenomena of plasticity, ductility, time yield, elastic failure, and fatigue are of great interest to manufacturers of products made from high and low yield-point steel, aluminum and its alloys, copper, gold and silver and other metals, plastics, and especially those of wood, cast iron, and reinforced concrete. The aforementioned phenomena lead to serious deviations from the behavior of materials as visualized by Hooke's law which is the foundation of the modern theory of elasticity.

The problems created by these deviations have been the subject of extensive and costly research during the last two hundred years by large users of the various materials. The first important series of tests known to the writer was made by the French government around 1750 on timber, followed about 50 years later by more thorough tests by the British Admiralty (26).

In the latter tests, Thomas Barlow subjected a great number of full-sized beams as used in ships to uniform loads (with cannon balls) and noted deflections and ultimate loads, when the beams were simply supported. Then he fixed similar sized beams by cast-iron shoes in heavy masonry walls and loaded them to failure. According to the theory of elasticity, the fixed beams should have carried a load 50% greater than the simply-supported beams; actually, without question or doubt, they carried 100% more. In modern terminology it would be stated that failure occurred under a bending moment of $w\,L^2/16$. Beams fixed at one end only failed under a bending moment of $w\,L^2/10.8$. Mr. Barlow also tested beams of triangular sections, both with the edge up and the edge down, simply supported and fixed, and found very serious deviations from the results as taught by the theory of elasticity. He discovered similar discrepancies when testing beams of metals and glass, and further referred to tests by Thomas Young (Young's modulus of elasticity) on cast iron, where even greater deviations occurred. Mr. Barlow boldly asserted that the theory of elasticity assumed properties of materials not to be found in nature and led to underestimating the real strength of beams.

Teachers of the theory of elasticity did not pay much attention to Mr. Barlow and the most important series of tests which were ever made up to that time, and one famous work on the theory of elasticity (27) refers to the speculations of Mr. Barlow as the "nadir" of English thought on applied mechanics.

In the nineteenth century the fact that the theory of elasticity underestimated the strength of materials in most cases was the subject of reports by the laboratories of Hodgekinson in Manchester, England; by Sir Thomas Fairbairn also of Manchester; by David Kirkaldy and Son of London, England; by Professor Tresca of Paris, France, and by his pupil A. Considere; and by A. Kick of Prague, Czechoslovakia. No attention was paid by the teachers of the theory of elasticity to all these reports, since the teachers were too much intrigued by the elegance of their methods and too much encouraged by the

[5] Civ. Engr. and Contr., Chicago, Ill.

success of their pupils in the construction of bridges and halls of unprecedented spans. It is, of course, true that the theory of elasticity leads to safe results; but, as Mr. Barlow and others showed, more economical designs may be obtained by considering the deviations of the materials from behavior like that specified by Hooke's law under high stresses.

This phase of the strength of materials has been treated in papers and discussions before the Society in the last 75 years. Although practical engineers greatly benefited by these papers, teachers did not. In December, 1914, the writer published a working theory of the strength of reinforced concrete beams based on conditions near the ultimate load (28)(29). A similar theory for steel structures and other materials was published in 1918 (30). Not much attention was paid to these and other papers by the writer on this subject; but, when the German engineers in the early 1930's found that no work could go ahead in that impoverished land unless fewer materials were used than formerly, a furious campaign was started in German literature because of a supposed discovery that a theory based on conditions of ultimate load would justify higher stresses on materials of construction.

The author of this paper derived his inspiration from these overseas sources and imitated their crude tests (afflicted with an error of about 20% due to friction, as can be noted by comparison with the tests made by the Special Committee of the Society on Column Research (31), at Madison, Wis.).

Nothing new is offered in this paper and it may be of value only to call the attention of teachers to the insufficiency of the theory of elasticity to describe the strength of materials accurately.

George Winter,[6] M. ASCE.—The question raised in this paper is of considerable interest in connection with modern tendencies toward what is variously called "limit design," "ultimate design," or "plastic design" (32). The application of this method to statically determinate and indeterminate problems of flexure is essentially predicated on the "old theory" of plastic stress distribution as given in Fig. 1. Problems of column buckling beyond the elastic range are also analyzed fundamentally by the same concept with good experimental confirmation (33). If the author's opinion, that this type of stress distribution does not actually occur, were confirmed by sufficient evidence, substantial revision of present ideas on ultimate design of steel structures would become necessary.

The problem is difficult to approach experimentally, chiefly because, beyond the yield point, the ordinary kind of strain measurements can no longer be translated into stress. Even if the strain distribution were investigated carefully, therefore, no conclusion could be reached on the absolute magnitude of the stresses in the "overstrained" parts of the beam.

The difficulty can be overcome to some extent by X-ray stress measurements. This method measures changes in distances of lattice planes in the crystals, but is not affected by relative shifts of various parts of the crystals due to "sliding-yielding." Therefore, it measures that part of the strain which is proportional to stress. The accuracy of this method, however, is generally of

[6] Associate Prof. of Civ. Eng., Cornell Univ., Ithaca, N. Y.

the order of from 5% to 10% of the yield point of mild steels. It has not attained the same degree of dependability as strain measurements, therefore, although effects of the order of 40% of the yield point, as indicated in the paper, are easily detected by this method.

In addition to such X-ray measurements the actual stress distribution can be inferred by indirect methods, such as the occurrence of Lueders lines, permanent distortion, magnitude of curvature and deflection, and similar secondary effects.

That the situation, fundamentally, is not so simple as usually assumed can be recognized from the following consideration: For steels in the elastic range Poisson's ratio is from about 0.25 to 0.30. On the other hand, in the plastic range Poisson's ratio should be that of a liquid—that is, 0.5. Consequently, at the transition from the elastic to the plastic range, the lateral deformation would have to increase suddenly and discontinuously by from 60% to 100% of its maximum elastic value. In other words, the cross section of a rectangular beam stressed partly into the plastic range should be of the shape shown (exaggerated) in Fig. 12(*b*). Such a shape can develop only if the shear resistance in the outer parts of a-a is completely overcome. Actually, a shape more like that of Fig. 12(*c*) must be expected. It is clear that this shape causes shear

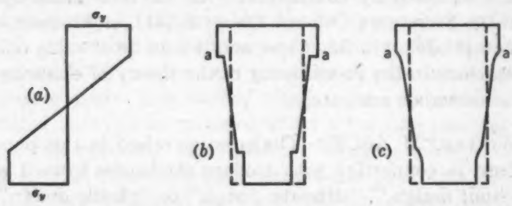

FIG. 12.—DISTRIBUTION OF LONGITUDINAL STRESS AND OF LATERAL STRAIN IN BEAMS STRESSED BEYOND THE YIELD POINT

stresses at and around section a-a such that at least part of the beam above a-a is subject to lateral compression, and part of the beam below section a-a is subject to lateral tension, in addition to the primary, longitudinal compression stress. At and near the supposed boundary of the elastic zone a two-dimensional state of stress, instead of the assumed uniaxial condition, is obtained. Assuming the yield condition to be defined by the distortion energy theory, these lateral stresses cannot fail to affect the yield point of the material in that zone.

From this consideration alone it is evident that the "old theory" can be expected to represent only a reasonable approximation to the actual condition. In addition, Fig. 12 suggests another possible experimental approach for investigation of this problem, namely—the determination of Poisson's ratio by test. It is relatively simple to make simultaneous longitudinal and transverse strain measurements on the top surface of beams of any cross section; for example, by means of electric-resistance gage rosettes. If properly evaluated, the stage at which Poisson's ratio increases from its elastic value and, finally,

reaches 0.5 (most likely) would give at least some indication of the actual condition of the metal—plastic or elastic.

A review of existing evidence, alongside the author's interesting tests, is rather perplexing; but it shows, at least, that the situation is not so simple as indicated in the paper. In the following survey of available information, the writer purposely omitted investigations based on the appearance of Lueders lines as evidence of yielding. These lines seem to be a satisfactory indication of the occurrence of strains in the specimen (beam) of magnitude equal to that which, at the yield point, occurs in a tension specimen. However, in the case of nonuniform stress distribution, the strains in "overstressed" zones adjacent to parts that are stressed in the elastic range are necessarily of the order of magnitude of elastic strains. It is doubtful whether macroscopic Lueders lines can be detected when yield strains are of such small amount, although it is likely that slip bands in individual crystals could be observed in such zones by microscopic inspection.

In an extensive investigation (34) E. Volterra obtained interesting experimental evidence on the behavior of a great number of "overstressed" steel beams. Although the report of this work is somewhat sketchy and contains minor errors (34*a*) it presents broad evidence that W. Kuntze's and W. Prager's (35) ideas are not confirmed by test. (Messrs. Kuntze and Prager have held that there is a sharply increased yield point in the "overstressed" parts of a beam; that there is purely elastic behavior far beyond the tensile yield-point stress; and that, subsequently, there is a sudden breakdown of elasticity in the

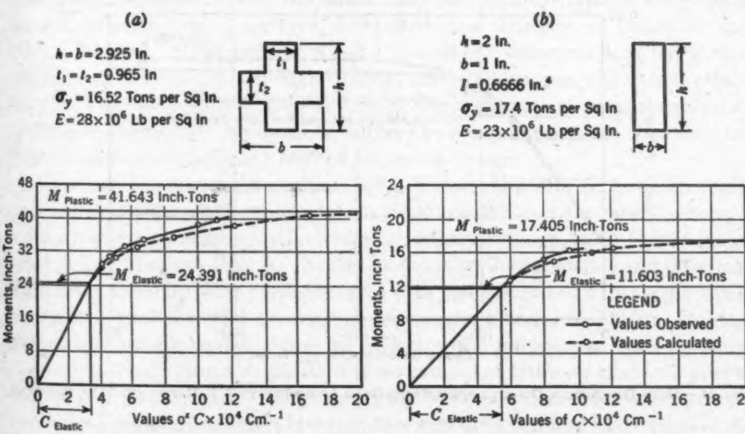

FIG. 13.—LOAD-CURVATURE DIAGRAMS FOR TWO STEEL BEAMS ACCORDING TO E. VOLTERRA

entire cross section.) On the other hand, Mr. Volterra's tests also present evidence that, in the "elasto-plastic range" (that is, at loads larger than those causing tensile yield-point stress in the outer fiber, but below the ultimate), the curvatures and deflections are smaller than those predicted by the "old theory."

Both these facts are well illustrated by two curvature-bending-moment diagrams (Fig. 13) taken from the Volterra paper. Mr. Volterra attributes the difference between measured and computed curvature to the effect of strain-hardening, whereas, in a discussion of that paper J. F. Baker, Assoc. M. ASCE, (34a), holds the upper yield point to be responsible for that difference, a factor which is generally neglected in the "old theory." In the writer's opinion the phenomenon depicted in Fig. 12 is likely to represent at least a contributing factor to this limitation of deformations to values below those expected from the "old theory."

Similar results were obtained by Professor Baker and J. W. Roderick in a very important investigation on welded rigid frames (36). Fig. 14, a load-deflection diagram from this investigation, shows rather close agreement between experimental values and those computed by the "old theory," again exhibiting a somewhat sharper curvature of the load-deflection curve than predicted theoretically.

Whereas measurements of deflections, curvatures, and observations of Lueders lines give only indirect evidence of the actual stress distribution in a beam—X-ray measurements, within their limits of accuracy, enable the investigator to determine the magnitude of stress directly, in the elastic and in the plastic range. In this connection F. Bollenrath and F. Schiedt (37) observed (see Table 6) that in the period from 1932 to 1938 successive investigators found less and less difference between yield points in bending and in simple tension.

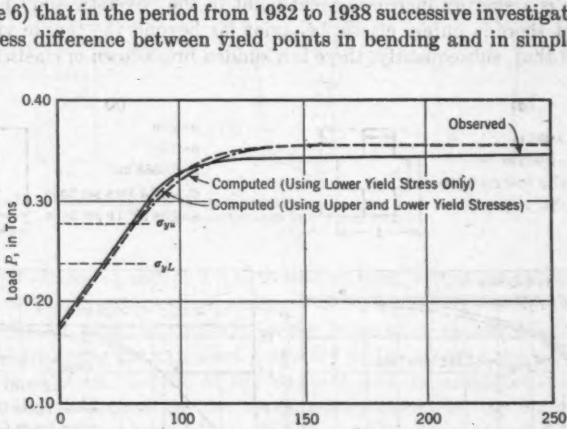

FIG. 14.—LOAD-DEFLECTION DIAGRAM FOR A STEEL BEAM ACCORDING TO J. F. BAKER AND J. W. RODERICK

These tests relate to rectangular sections, although the last of these investigations was extended to triangular and other shapes. Messrs. Bollenrath and Schiedt stated their conclusion as follows (37a): "Independent of the shape of the cross-section no increase of the yield point does occur in bending as compared with that determined from a tension test."

Similar conclusions are reported in papers recently published in the United States by J. T. Norton, D. Rosenthal, and S. B. Maloof (38)(39). In the first of these investigations (38) X-ray stress measurements were made in notch-bend tests—that is, on specimens that have steeper stress gradients than ordinary, prismatic beams and, consequently, in which the supposed increase in yield point should be larger than in such beams. However, in the words of Messrs. Norton, Rosenthal, and Maloof (38*a*) "* * * the X-rays reveal no increase of yield point as a result of notching or steep stress gradient."

TABLE 6.—COMPARISON OF PERCENTAGE INCREASES IN YIELD-POINT STRESS

Investigators	Year	Increase	Criterion
A. Thum and F. Wunderlich (2)	1932	35 to 40	Lueders lines
H. Moeller and J. Barbers (40)	1934	40	X-ray
E. Siebel and F. H. Vieregge (16)	1934	28	Beam deflection
H. Moeller and J. Barbers (41)	1935	13	X-ray
F. Rinagl (42)(43)	1936	0	Residual strains
F. Bollenrath and E. Schiedt (37)	1938	0	X-ray

It cannot be stated that these few quotations shed any definite or final light on the actual process of yielding in nonuniformly stressed members. A much more extensive review of available evidence than can be discussed in this brief contribution convinced the writer that the actual details of the process depend, to some extent, on type, treatment, and structure of the steel, and other influences. That yielding is not a process of continuous flow, but that it occurs in discontinuous, although minute, layers also appears (44) well established. The dimensions of these layers, as compared with those of the member or those of the part of the member, subject to nonuniform stress, also may influence the over-all behavior beyond the elastic range.

However, the structural engineer is little concerned with these details. In deciding the rather vital question of practical reliability of the newly proposed methods of limit design, plastic design, or ultimate design, he is chiefly interested in final results—that is, whether or not carrying capacities and deformations determined by these methods agree with test results. In this respect it is noteworthy that the "old theory," as well as the theories of Messrs. Kuntze, Prager, and others, agrees closely in reflecting the influence of cross-sectional shape on ultimate moment, and that these computed ultimate moments are extensively verified by test. Also noteworthy is the fact that deflections and curvatures measured by different investigators were always found to be either equal to, or somewhat smaller than predicted by, the "old theory." Hence, this very simple and practical theory seems to be well confirmed with regard to ultimate strength, but errs slightly on the conservative side with respect to deformations beyond the elastic limit. In the field of statically indeterminate structures, where this design method is particularly appropriate, the degree of agreement

of test results with values computed by the "old theory," for seven-portal model steel frames (45), is evident from the following:

Portal No.	Failure Load, in Tons: Computed	Failure Load, in Tons: Observed
F.3	1.54	1.60
F.4	1.45	1.64
F.5	1.54	1.62
F.6	3.08	2.98
F.8	2.49	2.79
F.9	1.58	1.64
F.10	1.65	1.75

With one exception, discrepancies do not exceed 6%; in the one case of lesser agreement (F.8), the "old theory" errs on the conservative side by about 11%.

Despite the fact, therefore, that the details of the yielding process are probably not so simple as frequently assumed, it is this writer's opinion that the "old theory," by present evidence, represents a simple and reliable tool for structural analysis.

Acknowledgment.—Some of the quotations cited in this discussion were brought to the writer's attention by N. M. Newmark, and Bruce G. Johnston, Members, ASCE.

O. SIDEBOTTOM,[7] ESQ., AND T. J. DOLAN,[8] ESQ.—Structural designers usually have assumed that the material in a ductile metal member subjected to uniaxial stress starts to yield (or attains a small measurable plastic deformation) at a given stress, regardless of the existence of a stress gradient on the cross section of the member. In recent years, however, the results of several investigators (see for instance, J. L. M. Morrison (46), G. Cook (47), Fujio Nakanishi (48), and G. Brewer (49)) and the tests reported by the author have been interpreted as showing that yielding is suppressed in the presence of a stress gradient and hence that an "elastic" peak stress can be built up which is greater than the yield point developed by the material under a uniform stress.

The finding of the author (see "Conclusions") that "The stress at which yield occurs is higher under nonuniform stress * * *" than that found from axial tensile tests, in which the stress is uniform, does not agree with the conclusions reached in studies in 1946 by D. Morkovin and O. Sidebottom (50), and by J. T. Norton, D. Rosenthal, and S. B. Maloof (38). It seems desirable, therefore, that a review be made of the fundamental structural actions involved in a beam to clarify some of the divergent conclusions of various investigators. The writers feel that the conclusions of the author create false impressions which, if not reinterpreted, may lead to unsafe design practices. The material presented in this discussion is based on the work of Messrs. Morkovin and

[7] Special Research Associate in Theoretical and Applied Mechanics, Univ. of Illinois, Urbana, Ill.
[8] Research Prof. of Theoretical and Applied Mechanics, Univ. of Illinois, Urbana, Ill.

Sidebottom whose study included a re-examination of the data of several previous investigators.

The reported changes in yield point for a given metal under different test conditions, involving stress gradients in uniaxial stress, may be attributed to two factors: (a) Difficulties in detecting the load at which yielding started in the most stressed fibers, resulting in erroneous interpretation of the test data; and (b) the varying stress levels at which the upper yield-point phenomenon may be exhibited by certain mild steels under different test conditions. The following discussion will deal mainly with a study of item (b) since the writers believe the material in the members tested by Mr. Peterson exhibited an upper yield point. However, item (a) will be considered first in order to facilitate the explanation of item (b).

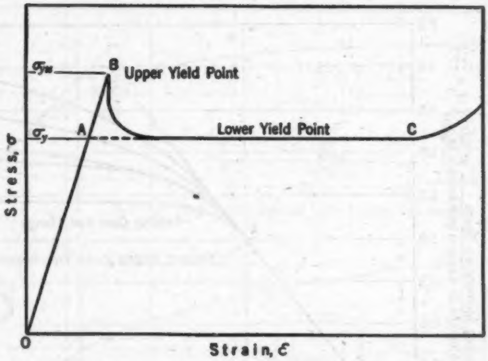

FIG. 15.—STRESS-STRAIN DIAGRAMS FOR TENSION SPECIMENS

First, examine the resisting moments that would be developed by a beam if each fiber exhibited exactly the same stress-strain relationship as that determined for a tension (or compression) specimen. By assuming that, in a beam, plane sections remain plane, and the tensile and compressive stress-strain diagrams of a material are identical and similar to curve OAC in Fig. 15, it is possible to develop mathemathical equations based on equilibrium conditions relating the bending moment in the beam to the strains, ϵ, developed in the extreme fibers for various cross-sectional shapes. The curves shown in Fig. 16 have been so derived (50), and have been plotted in terms of the dimensionless ratios M/M_y and ϵ/ϵ_y to facilitate comparison for the five cross sections illustrated. In this discussion the symbols M_y, σ_y, and ϵ_y will designate the bending moment, stress, and strain, respectively, corresponding to the lower yield point of the material; M and ϵ represent the bending moment in the test part and the strain in the extreme fiber, respectively, developing at any given stage of the test.

As the relative volume of material in the extreme fibers is decreased by modifying the shape of the beam (see Fig. 16), there is a tendency for the departure from the initial straight line to become less abrupt. This leads to an illusion that the proportional limit has been raised. Actually, however, all curves begin to depart from the straight line when the ratio $\dfrac{M}{M_y} = 1$ is exceeded. Although all curves may represent identical material, the bending moment at

which the deviation from linearity becomes a definite measurable amount (as evidenced also by distortion of the member as a whole) is a function of the shape of the beam. Fundamentally, the resisting moment developed by a beam and plotted in a moment-strain curve represents an integrated sum of

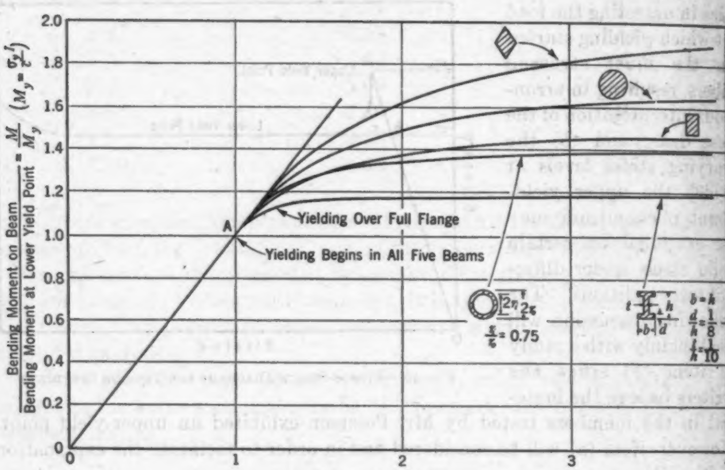

FIG. 16.—THEORETICAL MOMENT-STRAIN DIAGRAMS FOR METAL WITH A DEFINITE YIELD POINT, σ_y (STRESS-STRAIN DIAGRAM SIMILAR TO CURVE OAC IN FIG. 15)

the resisting moments developed by all fibers of the member. Thus, although yielding in a beam starts in the outer fibers at the same stress, the potential load-carrying capacity of fibers beneath the surface makes it much more difficult to detect initial yielding experimentally than is the case in a simple tension member.

Comparisons of experimental moment-strain data for rectangular beams obtained by Messrs. Morkovin and Sidebottom (50) with theoretical curves of the type shown in Fig. 16, are presented in Fig. 17. In Fig. 17(*b*) good agreement is seen to exist between the moment-strain diagram predicted by the "old theory" and the actual test data for two beams made of an annealed high-carbon steel. In analyzing the data shown in Fig. 17(*a*), it was found that for two of the mild-steel beams initial yielding began at the lower yield point as determined from tensile tests; whereas, the third mild-steel beam (shown by solid circles) exhibited an upper yield point approximately 10% greater than the tensile (lower) yield point. As plastic action progressed, subsequent yielding of the mild-steel beams occurred at a stress equal to the lower yield point. (Analyses of these data in terms of stress were facilitated by use of equations developed by H. Herbert (51).) Thus, for cases in which an upper

yield point was not exhibited, the stress gradient occurring in a beam did not raise the yield point of the material. For materials with a high upper yield point the theoretical curves of Fig. 16 must be modified to provide for this phenomenon.

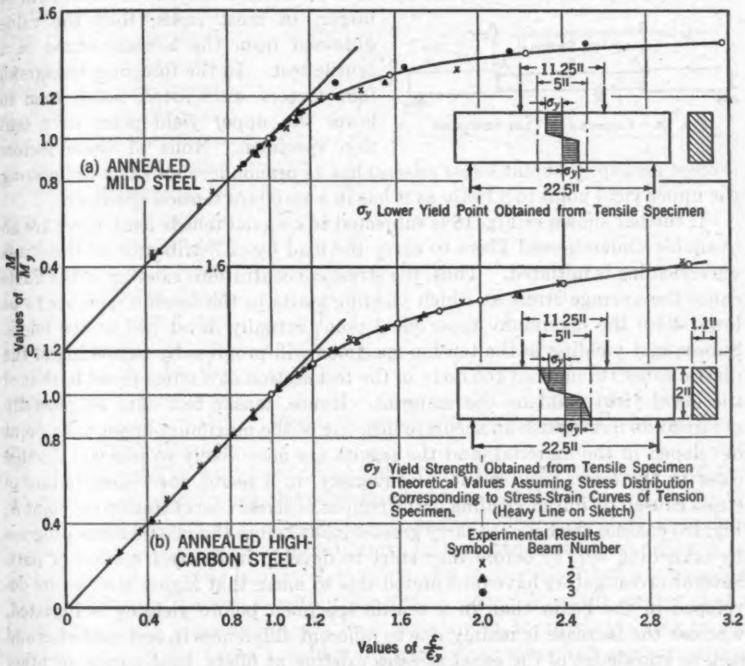

FIG. 17.—COMPARISON OF THEORETICAL AND EXPERIMENTAL MOMENT-STRAIN DIAGRAMS FOR RECTANGULAR BEAMS

The occurrence of a high upper yield point in carefully conducted tensile tests is a phenomenon long associated with mild steel and is a factor which, if present, will modify the behavior of a beam in the early stages of yielding. If special precautions are taken in tensile tests, the stress-strain diagram of the material may be of the shape OBC as shown in Fig. 15, in which an upper yield point, σ_{yu}, is exhibited. The magnitude of the upper yield point is extremely variable and unpredictable depending upon such factors as (*a*) the rigidity of the testing machines; (*b*) the alinement of the specimen in the grips; (*c*) the radius of fillets on the specimen; and (*d*) inherent stress raisers such as surface roughness, residual stresses, or discontinuities in the material. If the effects of these variables are minimized successfully, the magnitude of the upper yield point may be considerably greater than that of the lower yield point, σ_y. For instance, G. Cook (47) has obtained values for upper yield point as large as 1.56 σ_y.

If a mild-steel tension specimen can be tested under such favorable conditions that an upper yield point will be exhibited, it is reasonable to assume that the material in the most stressed fibers of a mild-steel beam, tested under similar conditions, will exhibit an upper yield point. Furthermore, the magnitude of the upper yield point exhibited by the most stressed fibers of the beam will be larger, in most cases, than the value obtained from the average stress in a tensile test. In the foregoing paragraph four factors were listed which tend to lower the upper yield point in a tension specimen. None of these factors (except perhaps inherent stress raisers) has as pronounced an effect in lowering the upper yield point in a beam as it has in a standard tension specimen.

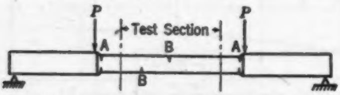

Fig. 18.—Yielding in Test Specimen

If the bar shown in Fig. 18 is subjected to an axial tensile load, there are no available understressed fibers to carry the load by redistribution of the stress once yielding is initiated. Thus, the stress concentrations existing at the fillets cause the average stress at which yielding starts in the tension member to be lower than the maximum upper yield point actually developed at the fillets. Subsequent yielding in the tension specimen will progress by branching of the plastic zones throughout the body of the test section at a stress equal to that of the lower yield point on the material. Hence, tensile test data as generally obtained do not furnish an accurate measure of the maximum upper yield point developed in the material, and the results are more likely to indicate a value close to the lower yield point. Conversely, in a beam, the redistribution of stress caused by initial yielding in the regions of stress concentration (at point A, Fig. 18) enables the beam to carry greater loads before the plastic zones progress by branching out, or before they start to develop in the test section or part. Several investigators have interpreted this to mean that higher stresses are developed in the beam than in a tensile specimen before yielding is initiated, whereas the increase is mainly due to inherent differences in test condition and lack of knowledge of the exact stresses existing at fillets, load points, or other stress raisers.

The effect of an upper yield point on the behavior of a beam can best be shown by considering the moment-strain diagrams for a rectangular beam shown in Fig. 19. If the inherent stress concentrations are of sufficient magnitude so that none of the material in the most stressed fibers of the beam finds it possible to exhibit an upper yield point, initial yielding will begin at the bending moment M_y corresponding to the lower yield point σ_y $\left(\frac{M}{M_y} = 1\right.$ as shown at point A in Fig. 19) and the moment-strain diagram will follow the theoretical curve OADB which is the same as that shown in Fig. 16. On the other hand, if the inherent stress concentrations are sufficiently small the moment-strain diagram will remain linear until the stress in the most stressed fibers reaches the upper yield point of the material. For instance, if the upper yield point is equal to 1.3 σ_y, initial yielding will start at a bending moment of $\frac{M}{M_y} = 1.3$ as shown at point C in Fig. 19. Unlike the tensile stress-strain diagram in which

there is a sudden drop at the beginning of yielding from an upper yield point to the lower yield point, the moment-strain diagram shows no drop when initial yielding occurs at the upper yield point of $1.3\,\sigma_y$ although the stress in the most stressed fibers of the beam in the yielded region drops to a value equal to the lower yield point. In Fig. 11, if the author's $\sigma_y + \sigma_y\,\Delta\sigma'_y$ is replaced by the upper yield point, σ_{yu}, the stress distribution may be visualized as changing from that shown as B to the type shown as A; the yielded zone penetrates into the beam, thereby forcing the understressed fibers to carry more load and thus increasing the resisting moment to the value of the applied moment. The shape of the moment-strain diagram after initial yielding will depend upon the magnitude and distribution of the inherent stress raisers along the most stressed fibers of the beam.

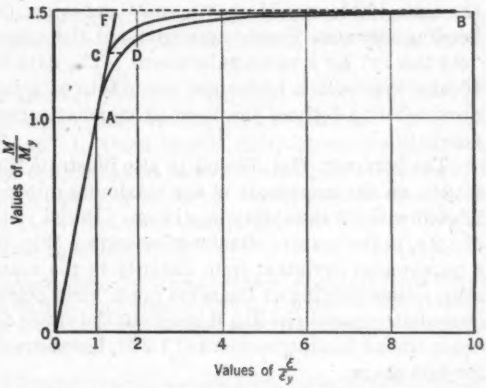

FIG. 19.—MOMENT-STRAIN DIAGRAMS FOR RECTANGULAR BEAMS

The original yielding in a beam usually appears heterogeneously in wedge-shaped zones in regions of localized stress such as at the fillets at point A in Fig. 18. As the load is increased, yielding at a higher load (but at the same stress) will occur in zones B within the test section. Since the strains in the beam are usually measured over a long gage length, localized yielding in the test section may not cause a sudden increase in the measured average strain. Thus, the moment-strain diagram shown in Fig. 19 departs gradually from a straight line at point C. As the applied moment is increased to some value greater than $1.3\,M_y$, the plastic wedges penetrate to greater depth, thereby increasing the resisting moment; the maximum stress at a section some distance from the plastic region increases correspondingly to a value greater than $1.3\,\sigma_y$ or until the upper yield point of the material in that part of the beam is reached. The moment-strain diagram for the beam will follow some relationship such as curve OCB in Fig. 19. In any case the moment-strain diagram will be bounded by the curves OCDB and OFB. The line FB at the bending moment of $\frac{M}{M_y} = 1.5$ is the horizontal asymptote to the theoretical moment-strain diagram and may be considered as the limiting moment for a rectangular beam in which the upper yield point is less than $1.5\,\sigma_y$. This same magnitude for limiting bending moment for a rectangular beam with a definite yield point is also derived by S. Timoshenko (52).

The curves in Figs. 16 and 19 are a development of what the author refers to as the "old theory," as contrasted to the "new theory" attributed to W.

Kuntze (which is not strictly a theory but an approximate empirical relationship). The author's discussions of ultimate resisting moment, M_u, in connection with these two theories, seem irrelevant since (as shown by Fig. 16 and the author's test data) initial yielding of a beam occurs (and large plastic deformations are developed) long before the ultimate bending moment is reached. In the tests of Messrs. Morkovin and Sidebottom (see Fig. 17(*a*)), the limiting bending moments closely approximated the value of 1.5 M_y predicted by the "old theory" for a rectangular beam. The data for the author's beam in Fig. 10 also approach a horizontal asymptote at a limiting bending moment approximately 1.5 times the bending moment corresponding to the lower yield point.

The curves in Figs. 16 and 19 also illustrate the effect of the shape of cross section on the magnitude of the maximum upper yield point that may be exhibited without instability in a beam. Initial yielding at an upper yield point of 1.2 σ_y in the beam of circular cross section (Fig. 16) probably would not cause a pronounced deviation from linearity in the moment-strain diagram. However, initial yielding at the same upper yield point in the I-beam would cause immediate general yielding throughout the entire depth and a breakdown of the beam, since a bending moment of 1.2 M_y lies above the limiting resisting moment for that shape.

The author's tensile specimen shown in Fig. 8(*a*) would not be adequate to determine the existence of a high upper yield point, although there is some evidence in Fig. 10 that an upper yield point occurred. The writers believe, therefore, that for the moment-strain diagram in Fig. 10 the upper yield point of the material was approximately 20% greater than the lower yield point, and only a value of the lower yield point was obtained from the tensile test. Similarly, in connection with the data shown in Fig. 5 the author states that the Lueders lines "* * * spread quite rapidly down the sides of the specimen * * * with very little increase in the load." This is an indication in itself that an unstable condition existed in which a high upper yield point was developed. Once yielding was initiated in the test section at the upper yield point, the stress on the extreme fiber dropped to the lower yield point and it was necessary for the plastic zone to progress deeply before the resisting moment balanced the unchanged bending moment. Lueders lines would generally develop slowly as loads were increased if the material in the beam did not exhibit an upper yield point.

The appearance of Lueders lines on the surface of a beam is not a sensitive criterion of initial yielding since it involves observation of plastic flow in a considerable part of a member. For beams (particularly those having cross sections with a minimum of material on the extreme fibers such as the circular and rhombic sections in Fig. 16), the small volume of metal subjected to the peak stress makes it doubtful whether strain markings would become visible until yielding had progressed to an appreciable depth below the surface fibers.

The author's reference to the fatigue test by K. Kloppel (5), in which a beam withstood a large number of cycles of stress equal to the yield point, should not be interpreted as evidence that the yield point is raised in a bend test. No correlation exists between values of endurance limit and yield

strength; hence, there would be no reason to suspect that a change in endurance limit would accompany an increase in elastic strength (even if it did occur in a bend test). In fact, in axial tension fatigue test W. L. Collins, Assoc. M. ASCE, and T. J. Dolan (53) found that for five mild steels (subjected to stress cycles varying from zero to a maximum) the endurance limits were about the same as, or somewhat higher than, their yield points. Thus, one would also expect beams made of these same metals to withstand large numbers of cycles of a stress equal to the yield point without evidence of fracture even though some plastic yielding may occur.

In a study of the stresses developed around a notch in a beam subjected to pure bending (38), X-ray diffraction patterns were used to determine the stress at which yielding was initiated. In these tests a sharp stress gradient was present—resulting in a stress concentration factor of about 2½ at the notch; any effects of delayed yielding resulting in higher elastic stresses should be even more pronounced under these conditions than in the tests reported by the author. However, Mr. Norton concludes that:

> "* * * the stress concentration and the stress gradient resulting from bending have no effect on the initiation of plastic flow in the immediate vicinity of the notch. There the state of stress is uni-axial and plastic flow sets in at the yield stress for pure tension."

For many applications of beams made of ductile steel, considerable yielding of the outer fibers can occur without causing excessive curvature or deflection of the member; hence, for some uses the investigators may infer that the beam is not structurally damaged as a whole. Certain beams may resist loads greater than those required to start yielding in the extreme fibers. It should be recognized that the increased strength is not the result of "higher elastic stresses" but rather that, because of the redistribution of stress, the understressed part can offer greater resistance to the load without permitting sufficient plastic distortion to the member as a whole, to constitute appreciable structural damage. The curves in Fig. 16 indicate the relative extent to which beams of various shapes may be overloaded (stressed beyond the yield point) before appreciable damage is apparent by their relative deviations from a linear load-strain relationship. The plastic deformations of the metal in the extreme fibers corresponding to these small deviations from linearity are rather large, however, as indicated roughly by the percentage by which the ratio e/e_y exceeds unity. This fact might require serious consideration in certain applications where danger of instability because of localized buckling may be aggravated by the plastic deformation of the most stressed fibers.

In conclusion, the basic behavior of flexural members as visualized by the writers may be summarized as follows:

(*a*) The materials that do not exhibit an upper yield point, the actual stress necessary to cause initial yielding of the most stressed fibers of a member subjected to a nonuniform stress distribution (such as that which occurs in a beam) is the same as that required to cause yielding under a uniform stress as obtained in a standard tensile test specimen.

(*b*) For materials exhibiting an upper yield point, the stress gradient that occurs in a beam makes it possible to obtain, before yielding occurs, a computed

stress somewhat larger than the yield point that is ordinarily determined as the average stress in a tension specimen. This is true since the magnitude of the upper yield point as computed from the tension test is markedly decreased by unfavorable test conditions, whereas these test conditions do not have as pronounced an effect in decreasing the apparent upper yield point in a beam.

(c) The nonuniform distribution of stress that occurs in a beam enables the member to resist static loads considerably greater than those required to start yielding of the extreme fibers. As indicated in Fig. 16, the shape of the cross section of the beam will determine the extent to which plastic deformation of the extreme fibers may occur before structural damage is evidenced by appreciable distortion of the member as a whole.

J. F. Baker,[9] Assoc. M. ASCE, and J. W. Roderick,[10] Esq.—The main contention in this paper is that the upper yield stress for mild steel subjected to nonuniform stress distributions is much higher than that for an axially loaded tension specimen. Mr. Peterson has conducted tests in pure bending and eccentric tension in which the first signs of yielding, as indicated by the appearance of Lueders lines, represent stresses much in excess of the upper yield stress recorded in the usual tension test. This result is contrary to the conclusions reached by A. Robertson (54), G. Cook (55), H. Quinney (56), and J. L. M. Morrison (46), all of whom have shown that, in a tension test on annealed mild steel, where adequate precautions are taken to insure axial loading and where the specimen is tested in a machine designed to record upper and lower yield points, the upper yield stress observed is frequently more than 40% greater than the lower value—showing good agreement with the results of tests in pure bending. As confirmation, the diagram shown in Fig. 20 for a specimen of black mild steel was obtained on a Quinney autographic testing machine (56) in the Engineering Laboratory at Cambridge, England. The steel had received no particular heat treatment and was in the condition "as received"; but despite this the upper yield point was 44% higher than the lower value.

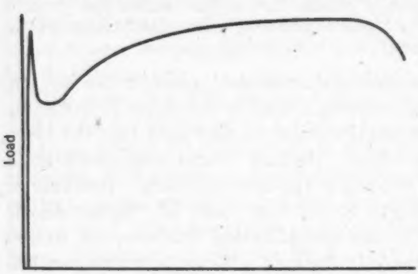

Fig. 20

However, in testing a number of tension specimens cut from any carefully heat treated bar, it will usually be found that, whereas the lower yield stresses are remarkably constant, the upper values will often vary considerably, with no evidence of it at all in some specimens. As Mr. Morrison (46) has shown, however, by using a number of extensometers around the circumference of the tension specimen, even the slightest eccentricity can mask the true value of

[9] Prof. of Mech. Science, Univ. of Cambridge, Eng. Laboratory, Cambridge, England.
[10] Asst. Director of Research, Univ. of Cambridge, Cambridge, England.

the upper yield stress. When it is realized that these eccentricities can arise not only from the mechanical shortcomings of the loading gear but also from slight variations in properties across the section of the specimen, inconsistent values of upper yield stress as recorded by over-all extension are not unexpected.

It would appear from the stress-strain diagrams in Fig. 10 that no special precautions were taken to insure axial loading in the tension test and also, since no reference is made to the type of testing machine employed, that the lower yield point was presumably obtained by rebalancing the normal lever type machine. If this were the case, it is very doubtful whether either the upper or lower yield points recorded represent the true properties of the material. The load-deflection curve for the beam test is compared with curves based on what are described as the "old theory" and the "new theory" of plastic failure, neither of which give good agreement with the beam test results. In England the former theory is now generally accepted, although where the material has an upper yield point the stress distribution for a partially plastic section of a member subjected to bending is taken to be of the form shown in Fig. 21 as opposed to that given in Fig. 1(*d*). The distribution in Fig. 21 is that established by Messrs. Robertson and Cook (54). The "new theory" referred to by the author is that stated by W. Kuntze (3) which, while it gives reasonable results in isolated cases, cannot be claimed to have any true fundamental basis. One cannot but agree with the criticism of this and other theories offered by F. Rinagl (57):

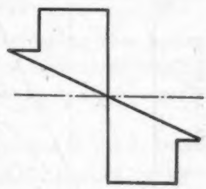

FIG. 21

> "Kuntze's theory, whereby yielding in the extreme fibres is supposed to set in only when the tensile yield limit has been attained in a certain layer—the so called centre of resistance—in the interior of the beam, cannot be accepted either. The 'centre of resistance' is a purely geometrical illusion and has no physical significance. The approximate coincidence with the results of Thum and Wunderlich's tests is only incidental and vanishes as soon as the tests are properly interpreted."

Most continental writers think of W. Prager's theory (12), which assumes that failure of a member subjected to pure bending is instantaneous upon the attainment of the upper yield stress at the extreme fiber, as the "new theory."

The writers have made considerable use of the "old theory" in studying the behavior of rigid welded steel frames tested to collapse (36)(45)(58)(59). At the beginning of this investigation tests were made on beams to verify the theory; but, although the results obtained were satisfactory, it was realized that better agreement between the yield points in tension and bending might have been obtained if more attention had been paid to rate of loading. Another series of beam tests is in progress taking due account of this factor, and a typical load deflection curve is shown in Fig. 22. When the upper yield stress is neglected as in the version of the "old theory" referred to by Mr. Peterson, there is considerable difference between the observed and calculated load deflection curves. On the other hand, using the stress distribution of Fig. 21 and an

upper yield stress corresponding to the load at which the observed load deflection curve deviates from the straight line, exceedingly good agreement is obtained. The yield stresses determined from the beam test were: Lower yield

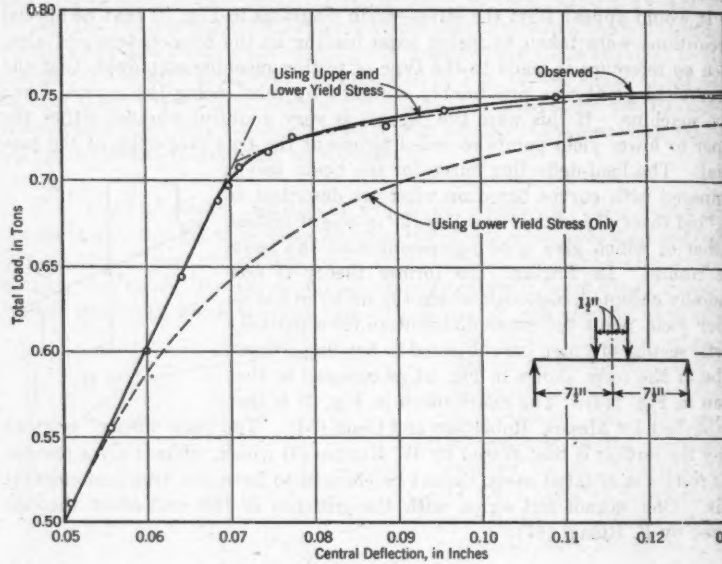

Fig. 22

stress, 13.46 tons per sq in. and upper yield stress, 19.05 tons per sq in. The average lower yield stress from a number of tension tests was 13.84 tons per sq in.

R. K. Bernhard,[11] M. ASCE.—The "effect of stress distribution on yield points" described mainly from the point of view of the material itself is presented in this paper. It might be of interest to treat the subject more dynamically (60), discussing the change of equilibrium between specimen and testing machine or the effect of the natural frequency of test machines on the accuracy of indication in high-speed tests with respect to the determination of yield points. (The writer has contributed to this subject twice before (61)(62).)

In high-speed testing of essentially the same material, different results may be obtained depending upon whether a massive or a light testing machine is used. Furthermore, the stress-strain diagrams of certain materials indicate near the yield point peculiar forms, which in some cases may not be dependent upon the qualities of the tested material alone.

Static System.—Any testing machine with a hydraulic cylinder may be considered as a system composed of masses and springs. Masses constitute the

[11] Prof. of Eng. Mechanics, Rutgers Univ., New Brunswick, N. J.

frame of the machine (the crosshead, etc.) whereas springs with a definite elastic constant represent the test specimen and the hydraulic medium. At any moment there must be equilibrium between the summation of the elastic forces of the springs and the load on the ram of the machine.

In the case of a testing machine having a low elastic constant, a very small decrease of load will result with the increase of strain; a high elastic constant, on the other hand, will result in a considerable decrease in load with increase of strain. When plastic flow ceases, equilibrium between the two elastic forces (specimen and pressure medium) may be restored and the point of equilibrium again rises as soon as the pressure pump starts to force new liquid into the cylinder. It must be borne in mind, however, that, with decreasing tension in the specimen, the plastic flow will also cease.

Any rapid flow gradually changes into some kind of creeping flow before equilibrium is finally achieved. Hence, in certain cases of high-speed testing such drop in the load-deformation diagram, due to plastic flow, may be independent of the quality of the tested materials.

Dynamic System.—The plastic flow or any pressure changes in the cylinder may take place very suddenly and the indicating device of the testing machine must follow immediately these rapid changes in both coordinates—that is, load and deformation. It is well known that as soon as rapid changes come into consideration the accuracy of any indicating device depends on the natural period of the entire vibrating system.

Any fluctuations during the test having a frequency of more than one tenth of the frequency of the machine will cause incorrect indications, assuming, for simplicity, that only vibrations of a sine form with a small damping factor come into consideration. This indicates, also, that different values for the upper and lower yield points, independent of the quality of the tested material and due to rapid changes of plastic flow near these yield points, may be found in certain cases of high-speed testing.

Effect Upon Yield-Point Determinations.—The surplus in tension at the upper yield point is a type of delayed phenomenon. Once plastic flow of the material in the specimen has started, the further shape of the diagram depends, at least to a certain amount, upon the character of the test machine. If the elastic constant of the test machine is low, any lower yield point will be suppressed, as the elongation of the test specimen produced by plastic flow means no decrease in tension for the testing machine itself. A very high elastic constant of the testing machine, however, will produce the well-known "leaping effect" fluctuations.

A similar result will be produced if the test specimen is long and has a low elastic constant, thus causing a heavy drop in the diagram. Consequently, a very short and rigid specimen may indicate no lower yield point at all.

Summary.—In the light of the foregoing comment the conclusions are reached that the upper and lower yield points are also associated with the characteristics of the testing machine and, to a certain degree, are independent of the quality of the material, and that in specific cases of high-speed testing the form of the specimen may be secondary.

F. G. ERIC PETERSON,[12] Assoc. M. ASCE.—As stated by Mr. Shearwood, it is true that the value of the thesis presented "* * * will be realized through the promotion of investigation into the practical and useful application of the findings * * *."

The general formula (Eq. 12*b*) developed by Professor Gaylord, which gives a relation between the tension yield point and the bending yield point for various shapes of cross section, is quite ingenious and appears to give quite accurate results. It should be observed that, in shapes where a large proportion of the area of a cross section is far from the neutral axis (for example, wide-flange beams), the effect is quite small, whereas in cross sections with a large proportion of the area close to the neutral axis (rectangular, cylindrical, diamond shape, etc.) the bending yield point is appreciably greater than the tension yield point. The accidental eccentricity of 0.001 in. mentioned by Professor Gaylord may have existed. It would be difficult to avoid such a small eccentricity.

In the presentation of this paper the writer has not concerned himself with the behavior of the metal after the plastic state has been reached. In other words, he has visualized the final designed structure as acting elastically throughout (after using a suitable factor of safety) without being tied to a definite maximum stress. The relative dimensions of the structure have a definite bearing on the final maximum stress that will result. One structure may have a maximum stress of 30,000 lb per sq in., whereas another may have a maximum stress of 24,000 lb per sq in.; both may have the same factor of safety (N) as defined by the ratio of the ultimate failure load to the working load:

$$N = \frac{L_u}{L_w} \qquad (25)$$

Various structures investigated by the writer, using a factor of safety of $N = 2$, had final working stresses varying from about 22,000 lb per sq in. to about 30,000 lb per sq in.; but such stresses were always appreciably below even the tension yield point.

As a consequence of the study of limit design, the American Institute of Steel Construction has adopted a specification allowing a 20% increase in stress for continuous beams. Although this is probably safe, it is not logical, since, as mentioned herein, a given factor of safety based on ultimate failure loads does not result in the same final maximum stress for different structures.

Mr. Mensch's statement that for fixed beams with uniform load "* * * it would be stated that failure occurred under a bending moment of $w\,L^2/16$ * * *" is logical. This merely means that once the end cross sections have reached their ultimate resisting moments the beam acts as a simple beam until the center cross section has reached the same ultimate resisting moment. The end moment plus the center moment must equal $1/8\, w\, l^2$.

[12] Civ. Engr., Oakland, Calif.

As stated by Professor Winter, "The problem is difficult to approach experimentally, chiefly because * * * strain measurements can no longer be translated into stress." However, consider the load-deflection diagram of a beam in bending: The first part of that diagram for steel is straight (OB′, Fig. 10) and no other stress distribution than that shown in Fig. 2(*b*) can possibly be justified—that is, a straight-line stress distribution must exist.

Professor Winter states that in a "* * * cross section of a rectangular beam stressed partly into the plastic range * * * a shape more like that of Fig. 12(*c*) must be expected." The writer agrees with this statement but wishes to emphasize that this shape must be accompanied by the appearance of deformation wedges or Lueders lines. Professor Winter also states:

> "It is doubtful whether macroscopic Lueders lines can be detected when yield strains are of such small amount, although it is likely that slip bands in individual crystals could be observed in such zones by microscopic inspection."

In this connection it should be noted that the appearance of Lueders lines is not a gradual process but that they appear quite suddenly—to an appreciable depth at once, afterward expanding in a series of jumps as reported by C. F. Kollbrunner (44). Thus, the writer concludes that the process of initial yield is immediately apparent through the appearance of macroscopic Lueders lines.

Although the writer is not very familiar with the X-ray method of stress measurement, it is commonly agreed that it is not very accurate (possibly 10% in error). What seems more important in the present discussion is that this method sheds no light on the phenomenon of the upper yield point. It may be that the results obtained by the writer and others are directly associated with the existence of an upper yield point—that is, the upper yield point is the controlling factor when the stress is nonuniform and no fibers show any evidence of yield until the extreme fiber has reached the upper yield point.

Referring to Fig. 21 by Messrs. Baker and Roderick, it is quite evident that no yield would occur in any fiber until the extreme fiber reached the upper yield point. Thus, the writer is quite ready to agree with Messrs. Baker and Roderick that the lower yield point is not necessarily raised but that the yield is governed by the upper yield point. Fig. 22 proves this contention. It is possible that the value of the upper yield point is affected by the shape of the cross section being tested.

An important question presents itself to the writer. In the usual commercial tension test the yield point that is reported is the lower yield point. Should this value be used in design, particularly where nonuniform stress is to result? If this lower yield point is the one that is always supplied by the commercial testing laboratories, it does not seem much amiss to refer to a "raised yield point" in bending or other nonuniform stress; or, perhaps, it should be given another designation. The usual testing machine allows the load to decrease because of the yielding of the specimen (especially in machines of a high elastic constant, as suggested by Professor Bernhard), thus exhibiting a lower yield point. Under field conditions of loading, the load is not decreased as the structure yields. It appears to the writer that it would be better if commercial

testing machines were of a type that would not allow the load to decrease since (in general) this would conform more closely to the conditions which a designed structure undergoes in actual use.

The testing machine used by the writer in his tests was a 60,000-lb mechanical pendulum machine with a direct-reading dial indicator. The speed of testing for bending was about 0.02 in. per min, whereas for the tension tests it was well under 0.01 in. per min.

The writer deeply appreciates the time and effort expended by various writers in contributing discussions on this paper.

Paper No. 2326

STRENGTH OF BEAMS AS DETERMINED BY LATERAL BUCKLING

By Karl de Vries,[1] M. ASCE

With Discussion by Messrs. George Winter, David B. Hall, Theodore R. Higgins, Neil Van Eenam, H. N. Hill, H. D. Hussey, H. G. Brameld, Edwin H. Gaylord, Oliver G. Julian, and Karl de Vries.

Synopsis

All usual specifications for the design of beams provide for reducing the allowable unit stress of the compression flange as the unsupported span length increases, to guard against lateral buckling. Such provisions, for the sake of simplicity, relate this reduction only to the ratio of unsupported beam length to flange width, thus neglecting the obvious influence of (a) the horizontal moment of inertia of the compression flange; and (b) the restraint afforded by the tension flange, which decreases as the depth of the beam increases.

By an extension and an evaluation of the treatment of this problem given by S. Timoshenko,[2] more nearly rational formulas are developed. Typical formulas are proposed for inclusion in specifications, and additional formulas for special investigations are derived and their application is described.

Professor Timoshenko's basic formulas have been accepted without repeating their derivations. He has also tabulated certain values[3] for beam strengths, which are practically identical with the corresponding values of this paper; but a greater range of beam strengths is given in this paper than is presented by Professor Timoshenko. In referring to the Timoshenko formulas, some repetition is unavoidable. Since Professor Timoshenko has not shown the steps for computing the beam strengths and since they will be of interest for the reader who wishes to check the work done here, they are given in Appendix I with the necessary condensation.

Notation.—The letter symbols in this paper are defined where they first appear, in the text or illustrations, and are assembled alphabetically, for con-

Note.—Published in September, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

PART I. SIMPLE BEAMS

Concentrated Load at Center

It is assumed that the ends of the simple beam shown in Fig. 1 can rotate freely with respect to the x-axis and the y-axis, but that rotation with respect to the z-axis is prevented. In calculating the critical value of the load P, Fig. 1, Professor Timoshenko assumes that a small lateral buckling has occurred and, from the differential equations of equilibrium, determines the magnitude of the smallest load required to keep the beam in this slightly buckled form:[4,5]

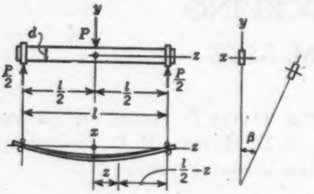

Fig. 1.—Concentrated Load at Center

$$\frac{P^2}{4\,B}\int_0^{l/2} \beta^2\left(\frac{l}{2} - z\right)^2 dz = C \int_0^{l/2}\left(\frac{d\beta}{dz}\right)^2 dz + \frac{B\,d^2}{4}\int_0^{l/2}\left(\frac{d^2\beta}{dz^2}\right)^2 dz \ldots\ldots(1)$$

Eq. 1 expresses the relationship between a concentrated load P applied at the centroid of the beam at midspan; and β, the angular deflection of the beam at any point at a distance z from midspan, in terms of two constants B and C which in turn depend on the properties of the beam. The values of these constants are found as follows:[6] B is the transverse flexural rigidity of the beam, and is equal to $E\,I_y$; C is its torsional rigidity and is equal to $\frac{E\,I_y\,d^2}{4\,a^2}$; E is the modulus of elasticity; I_y is the moment of inertia about the y-axis; and a is a torsional bending constant, values of which, for beams, are listed in manuals.[7]

It is necessary to introduce a correction term in Eq. 1 to allow for the effect of loading not at the centroid but at the top or bottom flange. This correction is $+\frac{P\,d}{4}\,\beta^2_o$ for top flange loading and $-\frac{P\,d}{4}\,\beta^2_o$ for bottom flange loading, in which β_o is the angle of twist of the beam at its center line.

With this modification, substituting the foregoing constants, Eq. 1 yields the basic formula:

$$\frac{P^2}{4\,E\,I_y}\int_0^{l/2} \beta^2\left(\frac{l}{2} - z\right)^2 dz \pm \frac{P\,d}{4}\,\beta^2_o - \frac{E\,I_y}{4}\,\frac{l^2}{a^2}\,\frac{d^2}{l^2}\int_0^{l/2}\left(\frac{d\beta}{dz}\right)^2 dz - \frac{E\,I_y}{4}\,d^2\int_0^{l/2}\left(\frac{d^2\beta}{dz^2}\right)^2 dz = 0 \ldots\ldots\ldots(2)$$

---

[4] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1936, p. 251, Fig. 146.

[5] *Ibid.*, p. 266, Eq. (*e*).

[6] *Ibid.*, pp. 240–258.

[7] "Bethlehem Manual of Steel Construction," *Catalogue S-47*, Bethlehem Steel Co., Bethlehem, Pa., 1934, p. 285, Table II.

Eq. 2 is a quadratic equation with respect to P, which can readily be solved into:

$$P = \frac{E\,I_y\,d}{2}$$

$$\times \frac{\mp \beta^2{}_o + \sqrt{\beta^4{}_o + 4 \int_0^{l/2} \beta^2 \left(\frac{l}{2} - z\right)^2 dz \left[\frac{l^2}{a^2}\frac{1}{l^2}\int_0^{l/2}\left(\frac{d\beta}{dz}\right)^2 dz + \int_0^{l/2}\left(\frac{d^2\beta}{dz^2}\right)^2 dz\right]}}{\int_0^{l/2} \beta^2 \left(\frac{l}{2} - z\right)^2 dz} \quad (3)$$

The least value of P, as determined by Eq. 3, is the critical load under which beam failure by flange buckling may be expected for these loading conditions. For a concentrated load applied at the top flange, $-\beta^2{}_o$ is used; applied at the bottom flange, $+\beta^2{}_o$ is used; and, applied at the centroid, since the correction factor $\pm \frac{P\,d}{4}\beta^2{}_o$ disappears, $\beta^2{}_o$ and $\beta^4{}_o$ are omitted. Eq. 3 is not readily soluble; and, to reduce it to a more usable form, the unit stress in the beam for critical load (f) is determined as explained in Appendix I. This unit stress is expressed as:

$$f = \frac{I_y\,d^2}{I_x\,a^2} E \frac{a^2}{l^2} k \quad (4)$$

For any beam of given length the values in Eq. 4 are constant, with the exception of the factor k which will vary for different loading conditions. The values of k are as shown in Table 1(a).

TABLE 1.—VALUES OF k (SEE EQS. 21, 36, 43, AND 50, RESPECTIVELY) FOR USE IN SOLVING EQ. 4

UNIFORMLY DISTRIBUTED LOAD

In a manner similar to that described under the heading, "Concentrated Load at Center," values of f, the critical unit stress, for a load uniformly dis-

tributed on the beam, may be determined. The equation for f is identical with Eq. 4, but the values of k for values of l/a from 2 to 14 are not the same as those for a beam with concentrated load (see Table 1(b)).

Critical Stress for Rolled Beams

A comparison of the k-factors in Tables 1(a) and 1(b) indicates that a uniformly distributed load applied at the top flange gives the lowest critical stress; and, since this loading also represents the most usual case, or nearly so, it alone has been used in the following study. Critical stresses for uniformly distributed load applied at the top flange were computed for all "wide-flange" (WF) sections from 36 in. to 10 in. deep, which ordinarily are classified as beams, and also for all "light beams" 12 in. and 10 in. deep—a total of 132 beams.[8] First, the $\frac{I_y\, d^2}{I_x\, a^2}$-factors of Eq. 4 were computed for each beam, and then, using the k-values of Table 1, Col. 5, with their corresponding values of $E\,\frac{a^2}{l^2}$, the critical stresses could be tabulated, omitting, however, any case in which the resulting critical stress would exceed 60,000 lb per sq in. and any case in which l/b (b being the width of the beam flange) would exceed 100. The complete tabulation of all the beams is filed with the Engineering Societies Library in New York, N. Y. The tabulation for five 14-in. sections is given in Table 2(a), Cols. 2 to 6, and is typical of the work.

In computing the values shown in Table 2, it is assumed that in Eq. 4 the modulus of elasticity $E = 30{,}000{,}000$ lb per sq in.; and that the values of a and $10{,}000\,\frac{I_y\, d^2}{I_x\, a^2}$ are as follows:

14-in. WF	a (in.)	$10{,}000\,\frac{I_y\, d^2}{I_x\, a^2}$
87 lb	104.0	65.54
78 lb	81.86	71.71
61 lb	74.32	58.59
43 lb	69.04	41.27
34 lb	64.28	29.79

For the section 14WF43, and a beam length of $5\,a = 5 \times 69.04$ in. $= 345.2$ in., for example, the critical stress is $\frac{41.27}{10{,}000} \times 30{,}000{,}000 \times \frac{1}{25} \times 4.121 = 20{,}410$ lb per sq in.

Entries in Table 2 below the horizontal line represent beams that would be excluded from use under the frequently found arbitrary restriction that l/b shall not exceed 40, yet these beams are found in the present analysis to possess considerable capacity.

To be able to express the critical stresses in terms of readily obtained variables (that is, the properties of the beam sections shown in handbooks), trials of various combinations of the variables that contribute most to the strength of

beams were made. Finally, it was found that, if the critical stress, as ordinate, were plotted against the dimension ratio—

$$\frac{l\,d}{b\,t} \qquad (5)$$

—as abscissa, the resulting group of points would fall in such a pattern that a curve expressing the relationship could readily be plotted. Values of d, b, and t for rolled sections are tabulated in standard handbooks.

For each of the 132 beams, therefore, the ratio $\frac{l\,d}{b\,t}$ was computed. First the quantity $\frac{a\,d}{b\,t}$ was computed from the handbook values of these four factors, and then this value was multiplied by values of l/a from 2 to 14, to give a value of $\frac{l\,d}{b\,t}$ for each value of l/a.

A part of the resulting tabulation embracing only the five sections selected for Table 2, is given in Table 3. Only those $\frac{l\,d}{b\,t}$-values are shown for which critical stresses are given in Table 2. The horizontal dividing lines in the two tables are the same.

TABLE 3.—Ratio $\frac{l\,d}{b\,t}$, for the Beams in Table 2

l/a	14 WF 87	14 WF 78	14 WF 61	14 WF 43	14 WF 34
$\frac{a\,d}{b\,t}$	146.0	133.6	160.8	223.6	294.3
2	....	....	....	....	589
3	....	....	482	671	883
4	584	534	643	894	1,177

13	1,898	1,737	2,090	....	....
14	2,044	1,870	....	....	....

The observations in Tables 2 and 3 for uniformly distributed load were then plotted in Fig. 2; values of $\frac{l\,d}{b\,t}$ were plotted as abscissas and the corresponding critical stresses f were plotted as ordinates. Round dots represent the five 14-in. sections, of the other points, × represents entries for all other beam sections for which l/b is less than 40; and +, those for which l/b is 40 or more. Not every entry can be shown, as in some instances they superimpose. It is obvious that the grouping of entries gives a good pattern and that a curve for a practical formula can easily be obtained from it. The formula for critical stress (Eq. 4) has the modulus of elasticity, E, as one of its variables, but there

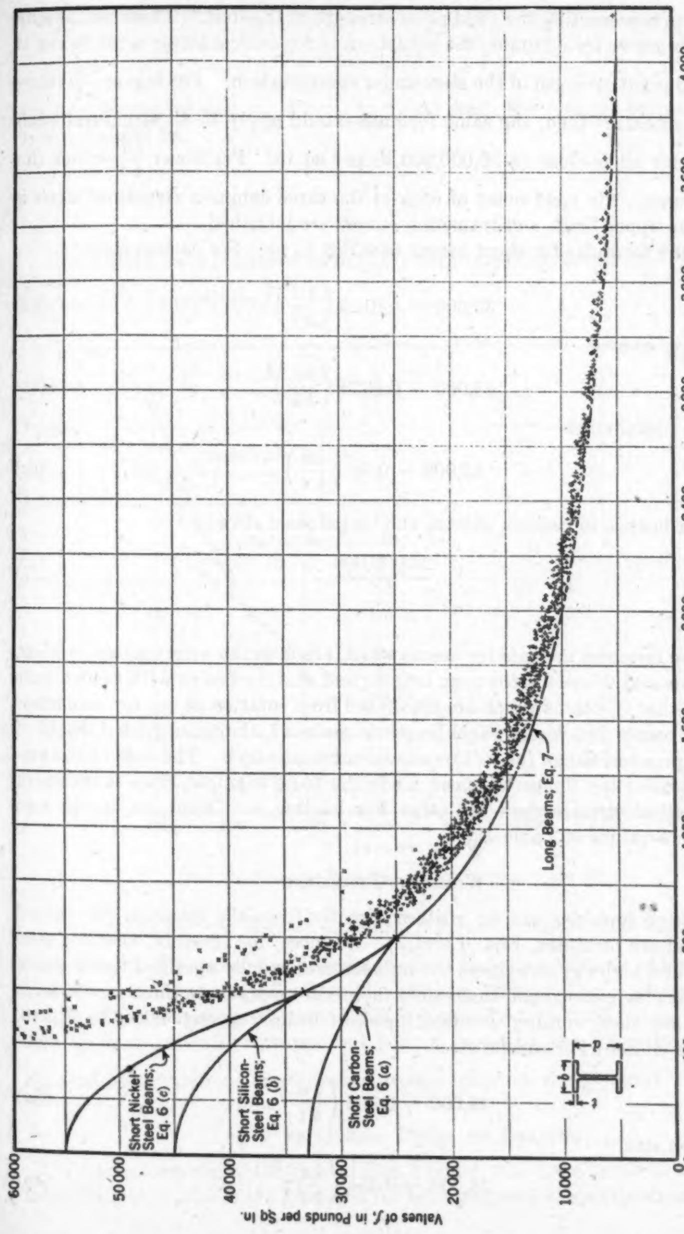

FIG. 2.—CRITICAL STRESSES COMPUTED FOR A SIMPLE BEAM, WITH A UNIFORMLY DISTRIBUTED LOAD AT THE TOP FLANGE, AND CURVES FOR THE FAILURE FORMULAS EQS. 6 AND 7

is no term representing the yield point strength of the steel. Therefore, as with the Euler curve for columns, the actual curve for critical stress must be cut at the yield point strength of the steel under consideration. For higher $\frac{l\,d}{b\,t}$-values (for long beams) then, the same formula should apply to all structural steels since E for all is close to 30,000,000 lb per sq in. For lower $\frac{l\,d}{b\,t}$-values (for short beams), the yield point of each of the three common structural steels is made the upper limit, and transition curves are inscribed.

Failure formulas for short beams (see Fig. 2) are: For carbon steel—

$$33{,}000 - 0.0125\left(\frac{l\,d}{b\,t}\right)^2 \qquad (6a)$$

for silicon steel—

$$45{,}000 - 0.0324\left(\frac{l\,d}{b\,t}\right)^2 \qquad (6b)$$

and, for nickel steel—

$$55{,}000 - 0.06\left(\frac{l\,d}{b\,t}\right)^2 \qquad (6c)$$

For long beams, in carbon, silicon, and nickel steel alike:

$$\frac{20{,}000{,}000}{\frac{l\,d}{b\,t}} \qquad (7)$$

These formulas are safe for beams which are laterally unsupported between their ends and where l is the span length; and also for beams with two or more panels—that is, beams which are prevented from rotation at one or more intermediate points and whose panel length is used as l, the unsupported length of the compression flange (as will be shown subsequently). The case of the uniformly loaded top flange has been made the basic example, since it results in lower critical stresses than the other five loading conditions, as can be seen from the k-values of Table 1.

Working Formulas

Working formulas can be written directly from the formulas for critical stress (failure formulas, Eqs. 6 and 7). Suppose, for instance, that for steel railway and highway structures the unit stresses usually specified for beams of zero length be retained and that safety factors comparable to those now in force are applied, then working formulas for short beams, corresponding to Eqs. 6, might be chosen: For carbon steel—

$$18{,}000 - 0.006\left(\frac{l\,d}{b\,t}\right)^2 \qquad (8a)$$

for silicon steel—

$$24{,}000 - 0.014\left(\frac{l\,d}{b\,t}\right)^2 \qquad (8b)$$

and, for nickel steel—

$$30{,}000 - 0.024\left(\frac{l\,d}{b\,t}\right)^2 \quad \text{(8c)}$$

For long beams, of carbon, silicon, or nickel steel, the formula corresponding to Eq. 7 might be:

$$\frac{12{,}000{,}000}{\dfrac{l\,d}{b\,t}} \quad \text{(9)}$$

Eqs. 8 and 9 have been plotted in Fig. 3 with transition points at $\frac{l\,d}{b\,t}$ = 1,000, 700, and 500, respectively.

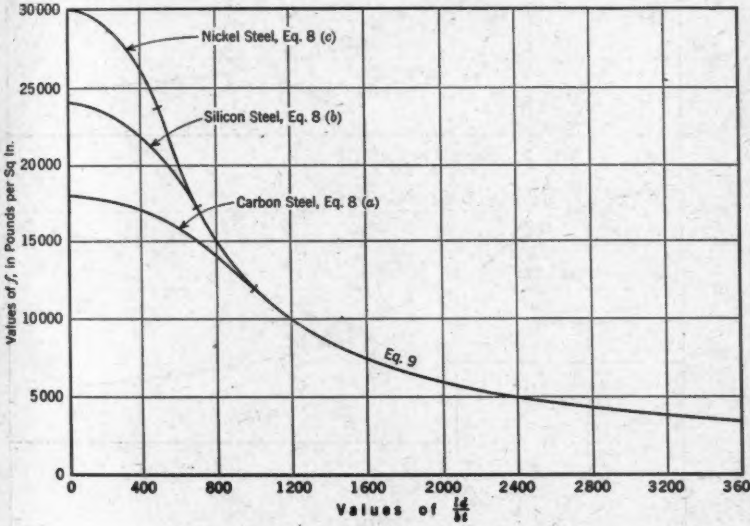

FIG. 3.—PROPOSED WORKING FORMULAS (EQS. 8 AND 9)

To simplify the use of these formulas, it is recommended that the $\frac{d}{b\,t}$-values be listed with the properties of beam sections in future editions of handbooks. Handbook tabulations of allowable stresses, giving "unit stresses" and "ratios" for converting allowable loads on laterally supported beams to allowable loads on laterally unsupported beams, based on the l/b-ratio, could be replaced by tabulations of allowable stresses based on the $\frac{l\,d}{b\,t}$-ratio.

THE FIVE OTHER TYPES OF LOADING

Working formulas of the type of Eqs. 8 and 9, which are based on the failure formulas Eqs. 6 and 7, are proposed for incorporation in specifications. They

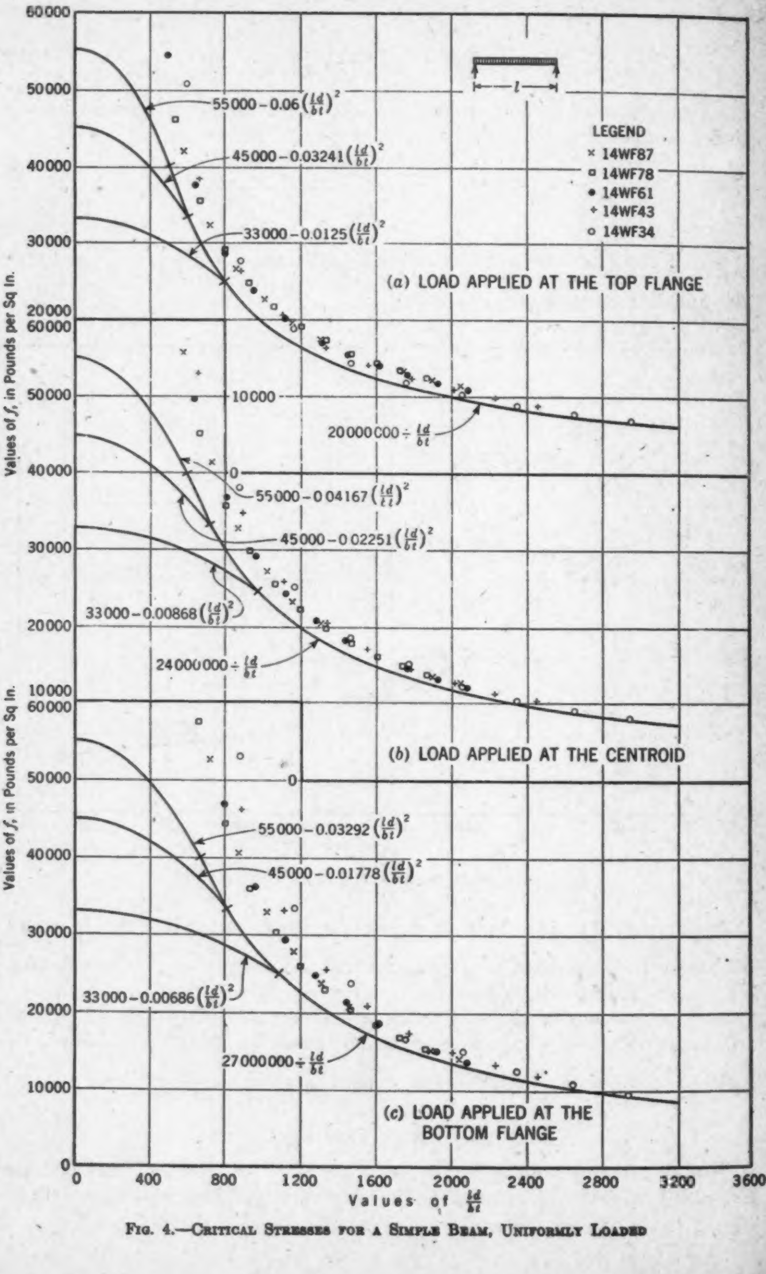

FIG. 4.—CRITICAL STRESSES FOR A SIMPLE BEAM, UNIFORMLY LOADED

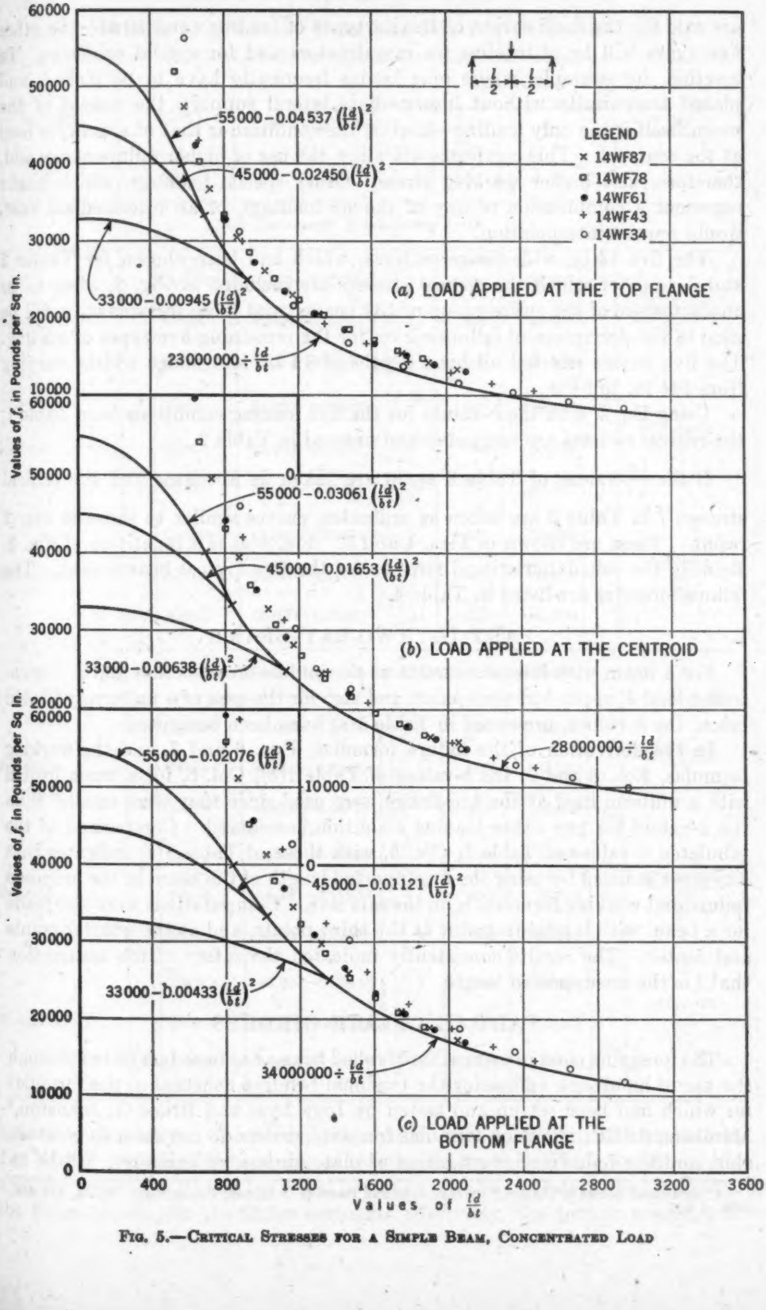

Fig. 5.—Critical Stresses for a Simple Beam, Concentrated Load

are safe for the most severe of the six types of loading considered—the other five types will be of interest for investigators and for special problems. In erection, for example, where long beams frequently have to be picked, and placed temporarily without intermediate lateral support, the weight of the beam itself is the only loading—that is, the condition is that of a uniform load at the centroid. This condition will allow the use of higher failure stress and, therefore, also higher working stress. Other special loadings, which might represent a combination of any of the six loadings, or an intermediate case, would require interpolation.

The five 14-in. wide-flange sections, which had been chosen for Tables 2 and 3, and for which the critical stresses are included in Fig. 2, seem to be characteristic of the entire group of 132 beams; and these sections only will be used in the derivation of failure curves for the remaining five types of loading. The five beams selected all have depths of 14 in. and flange widths varying from $14\frac{1}{2}$ in. to $6\frac{3}{4}$ in.

Using Eq. 4 with the k-values for the five loading conditions from Table 1, the critical stresses are computed and entered in Table 2.

If the $\frac{l\,d}{b\,t}$-values of Table 3 again are taken as abscissas and the critical stresses f in Table 2 are taken as ordinates, curves similar to those in Fig. 2 result. These are shown in Figs. 4 and 5. Fig. 4(*a*) is a repetition of Fig. 2, showing the calculated critical stresses for the five typical beams used. The failure formulas are listed in Table 4.

PART II. TWO-BAY BEAMS

For a beam with lateral restraint at the middle cross section and a concentrated load P applied at that point, and also for the case of a uniformly loaded beam, the k-values, presented in Table 1(*c*) have been computed.

In the derivation of the failure formulas, Eqs. 6 and 7, and the working formulas, Eqs. 8 and 9, the k-values of Table 1(*b*), Col. 5, for a beam loaded with a uniform load at the top flange were used since they were smaller than the k-values for any other loading condition considered. Comparison of the tabulated k-values of Table 1, Col. 5, with those of Table 1(*c*) indicates that any error induced by using the unsupported length of the beam in the proposed failure and working formulas is on the safe side. Computations were also made for a beam with lateral restraint at the third points, and at the quarter points and center. The results consistently indicated the safety of the assumption that l is the unsupported length.

PART III. PLATE GIRDERS

The foregoing close investigation of rolled beams has been facilitated through the use of handbook values for the torsional bending constant a, the formulas for which had been set up and tested by Inge Lyse and Bruce G. Johnston,[9] Members, ASCE. Torsion formulas for plate girders do not seem to be available, and the following investigation of plate girders, of necessity, will be an

[9] "Structural Beams in Torsion," by Inge Lyse and Bruce G. Johnston, *Transactions*, ASCE, Vol. 101, 1936, p. 857.

TABLE 4.—FAILURE FORMULAS FOR SIMPLE BEAMS

Load at:	Steel	Short beams (see Figs. 4 and 5)	Transition		Long beams (see Figs. 4 and 5)
			$\frac{l\,d}{b\,t}$	f	
(1)	(2)	(3)	(4)	(5)	(6)
(a) Uniformly Distributed Load					
Top flange	Carbon	$33{,}000-0.01250\left(\frac{l\,d}{b\,t}\right)^2$	800	25,000	$\frac{20{,}000{,}000}{\frac{l\,d}{b\,t}}$

Bottom flange	Carbon	$33{,}000-0.00686\left(\frac{l\,d}{b\,t}\right)^2$	1,080	25,000	$\frac{27{,}000{,}000}{\frac{l\,d}{b\,t}}$
	Silicon	$45{,}000-0.01778\left(\frac{l\,d}{b\,t}\right)^2$	810	33,333	
	Nickel	$55{,}000-0.03292\left(\frac{l\,d}{b\,t}\right)^2$	675	40,000	
(b) Concentrated Load at the Center of the Span					
Top flange	Carbon	$33{,}000-0.00945\left(\frac{l\,d}{b\,t}\right)^2$	920	25,000	$\frac{23{,}000{,}000}{\frac{l\,d}{b\,t}}$
	Silicon	$45{,}000-0.02450\left(\frac{l\,d}{b\,t}\right)^2$	690	33,333	
	Nickel	$55{,}000-0.04537\left(\frac{l\,d}{b\,t}\right)^2$	575	40,000	
Centroid	Carbon	$33{,}000-0.00638\left(\frac{l\,d}{b\,t}\right)^2$	1,120	25,000	$\frac{28{,}000{,}000}{\frac{l\,d}{b\,t}}$
	Silicon	$45{,}000-0.01653\left(\frac{l\,d}{b\,t}\right)^2$	840	33,333	
	Nickel	$55{,}000-0.03061\left(\frac{l\,d}{b\,t}\right)^2$	700	40,000	
Bottom flange	Carbon	$33{,}000-0.00433\left(\frac{l\,d}{b\,t}\right)^2$	1,360	25,000	$\frac{34{,}000{,}000}{\frac{l\,d}{b\,t}}$
	Silicon	$45{,}000-0.01121\left(\frac{l\,d}{b\,t}\right)^2$	1,020	33,333	
	Nickel	$55{,}000-0.02076\left(\frac{l\,d}{b\,t}\right)^2$	850	40,000	

approximation only. Consider a plate girder with a section such as that in Fig. 6(*a*), for which the moments of inertia are given in Table 5. Assuming that the torsional formulas for rolled beams apply also to plate girders, and that the flange rivets join the flange segments effectively, the torsion constant K

can be computed thus:[10]

$$
\begin{aligned}
2 \times 0.333 \times 13 \times 3^3 &= 234.0 \\
2 \times 0.333 \times 5.25 \times 2.5^3 &= 54.7 \\
8 \times 0.333 \times 3.5 \times 1^3 &= 9.3 \\
8 \times 0.333 \times 1.75 \times 1^3 &= 4.7 \\
1 \times 0.333 \times 88 \times 0.5^3 &= 3.7 \\
2 \times 0.109 \times 2.15 &= 46.9 \\
16 \times 0.10504 \times 1^4 &= -1.7 \\
\hline
\text{Torsion constant } K \text{ (in.}^4\text{)} &= 351.6
\end{aligned}
$$

TABLE 5.—MOMENT OF INERTIA, PLATE GIRDER IN FIG. 6(*a*)

Section shapes	Number of pieces	Dimensions (inches)	Moment of Inertia (In.⁴)	
			I_x	I_y

Inner cover plates..........	Two	20 by 1	103,026	1,333
Angles....................	Four	8 by 8 by 1	137,906	768
Web.......................	One	100 by ½	41,667	1
Total................	....	....	389,725	3,435

In a report published in 1941, Ingvald E. Madsen, Jun. ASCE, assumes[11] that the torsional constant of a riveted girder should be one third of the K-value for an identical solid section, because of rivet slip. If this assumption were used in the foregoing computation, it would reduce the K-value of a solid section (which has been computed separately and found to be 428 in.⁴) to 142.7 in.⁴, and is thus considerably less than the foregoing value of 351.6 in.⁴ The writer believes that the effect of rivet slip on the small specimens tested by Mr. Madsen is much greater than on full-size plate girders, and he has therefore rejected Mr. Madsen's assumption in favor of the foregoing computations.

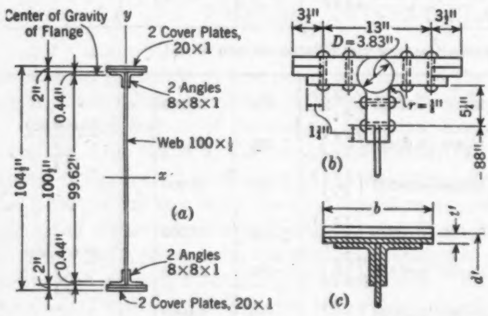

FIG. 6

To determine the torsional bending constant a, the formula—[12]

$$a = 0.806\, d_e \sqrt{\frac{I_y}{K}} \qquad (10)$$

[10] "Structural Beams in Torsion," by Inge Lyse and Bruce G. Johnston, *Transactions*, ASCE, Vol. 101, 1936, p. 865, Eq. 21.

[11] "Report of Crane Girder Tests," by I. Madsen, *Iron and Steel Engineer*, November, 1941, Section 4, p. 68.

[12] "Structural Beams in Torsion," by Inge Lyse and Bruce G. Johnston, *Transactions*, ASCE, Vol. 101, 1936, p. 869.

—gives $a = 0.806 \times 99.62 \times \sqrt{\dfrac{3{,}435}{351.6}} = 251.0$ in. and the value of $10{,}000 \dfrac{I_y\, d^2}{I_x\, a^2}$ is $10{,}000 \times \dfrac{3{,}435 \times 104.5^2}{389{,}725 \times 251.0^2} = 15.28$. In Eq. 10, d_e is the depth of the plate girder between flange centroids.

Since the proposed specification formulas Eqs. 8 and 9 involve the thickness of the flange, t, an equivalent thickness of the flange must be evaluated in the case of plate girders. For rolled beams, t is tabulated in handbooks, but can also be expressed by the formula:

$$t = \frac{6\, I_y}{b^3} \qquad \text{(11)}$$

If b is assumed to be the maximum flange width of the plate girder, Eq. 11 could be used to determine the equivalent average flange thickness of the plate girder of Fig. 6, for which, then, $t = \dfrac{6 \times 3{,}435}{20^3} = 2.576$ in., and the ratio $\dfrac{a\,d}{b\,t} = \dfrac{251.0 \times 104.5}{20 \times 2.576} = 509.1$.

Table 6(a) has been compiled from these values. In Table 6, Col. 2 gives the failure stresses of the plate girder up to $\dfrac{l}{b} = \dfrac{l}{a} \times \dfrac{a}{b} = \dfrac{8 \times 251.0}{20} = 100.4$, for a uniformly distributed load applied at the top flange computed as for Table 2(a); Col. 3, the $\dfrac{l\,d}{b\,t}$-ratio derived from the $\dfrac{a\,d}{b\,t}$-values; Col. 4, the values of the failure curve of Eq. 7; and Col. 5, the ratio of failure stress to failure curve. Table 6(a) shows that the failure stresses of Eq. 7 will be exceeded for $\dfrac{l\,d}{b\,t}$-ratios greater than about 2,000, or a laterally unsupported girder length of $l = \dfrac{l\,d}{b\,t} \times \dfrac{b\,t}{d} = 2{,}000 \dfrac{20 \times 2.576}{104.5} = 986$ in., or 82.2 ft.

This small overstress for long lengths seems to be immaterial; but, since close investigations and tests are not available, it is proposed to use, instead of Eq. 11, the following formula for the computations of average flange thicknesses of plate girders:

$$t = \frac{5\, I_y}{b^3} \qquad \text{(12)}$$

in which I_y is the moment of inertia of the girder about the y-axis; and b is the maximum flange width. Table 6(b) has been prepared to show the results of using Eq. 12 instead of Eq. 11. If the compression flange of a plate girder is different from the tension flange, twice the moment of inertia of the compression flange about the y-axis should be used as I_y in Eq. 12.

Long plate girders usually have cover plates of various lengths, and an average moment of inertia I_y of the girder will have to be computed to express its lateral stiffness. If the cover plates are computed to follow a parabolic moment diagram, with a minimum total cover plate thickness of t (min) at the ends, and a maximum total cover plate thickness t (max) in the middle, then

the effective average thickness t' (Fig. 6(c)) will be

$$t' = t(\min) + \tfrac{2}{3}\,[t(\max) - t(\min)] \qquad (13)$$

This effective average flange thickness t' will have to be used for determining I_y in Eq. 12; and, with the effective depth d' (Fig. 6(c)), the $\frac{l\,d}{b\,t}$-ratio can be established.

TABLE 6.—COMPARISON OF FAILURE STRESS WITH THE FAILURE CURVE FOR THE PLATE GIRDER IN FIG. 6(a), USING DIFFERENT EQUIVALENT FLANGE THICKNESSES, t

$\frac{l}{a}$	Failure stress, f	(a) $t = 6\,I_y/b^3$ (Eq. 11)			(b) $t = 5\,I_y/b^3$ (Eq. 12)		
		$\frac{l\,d}{b\,t}$	$\frac{20{,}000{,}000}{\frac{l\,d}{b\,t}}$	$\frac{\text{Col. 2}}{\text{Col. 4}}$	$\frac{l\,d}{b\,t}$	$\frac{20{,}000{,}000}{\frac{l\,d}{b\,t}}$	$\frac{\text{Col. 2}}{\text{Col. 7}}$
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
2	26,000	1,018	19,650	1.323	1,222	16,370	1.588
3	14,200	1,527	13,100	1.084	1,832	10,920	1.300
4	9,800	2,036	9,820	0.998	2,443	8,190	1.197
5	7,560	2,546	7,860	0.962	3,054	6,550	1.154
6	6,200	3,055	6,550	0.947	3,665	5,460	1.136
7	5,290	3,564	5,610	0.943	4,276	4,680	1.130
8	4,630	4,073	4,910	0.943	4,886	4,090	1.132

The computation of the effective average flange thickness would not be necessary for conditions which are generally encountered. Such a computation applies and is of consequence only for long unsupported lengths—as, for example, for the investigation of erection stresses of plate girders temporarily unsupported laterally. It should be noted that the average flange thickness of Eq. 12 should be used for all compound sections, such as cover-plated rolled beams, since a condition results which is similar to that in the plate girder which has been investigated.

PART IV. CONCLUSION

By investigating the strength of steel beams in lateral buckling, it has been shown that the critical stresses of rolled beams can be grouped to follow a good pattern (Fig. 2) and that working formulas can be derived from them. Working formulas (Eqs. 8 and 9) are proposed for inclusion in specifications. For plate girders and other compound sections it is proposed that the same formulas be used with l equal to the unsupported length of the compression flange, d equal to the depth of the section, b equal to the maximum compression flange width, and an average compression flange thickness (see Eq. 12) of $t = 5\,I_y/b^3$. Additional failure formulas for special loading conditions are derived and the treatment of long plate girders is discussed.

For all computations it is assumed that the beams at their supports are held in vertical positions. Beams with eccentrically applied loads are torsional problems and have not been included in this paper.

Commonly used beam sections and plate girders have been discussed. Channels, zees, angles, and other unsymmetrical sections are seldom used as

long beams, and it is proposed to allow the same unit stress for them as for symmetrical sections. The deviation of stresses of the proposed formulas from those of other beam formulas is negligible for short beams, and these unsymmetrical sections do not deserve special consideration.

ACKNOWLEDGMENT

The writer wishes to express his appreciation to Jonathan Jones and W. H. Jameson, Members, ASCE, for their assistance in preparing this paper.

APPENDIX I—DERIVATION OF k-VALUES

SIMPLE BEAMS; CONCENTRATED LOAD AT CENTER

The solution of Eq. 3 involves the evaluation of quantities of the angle of twist β. This can most readily be done by expressing β as a series:[13]

$$\beta = a_1 \cos \frac{\pi z}{l} + a_3 \cos \frac{3 \pi z}{l} + \cdots \qquad (14)$$

Only the first two terms of the series are of sufficient magnitude to be of importance. Introducing $y = \frac{a_3}{a_1}$, the following values are obtained:

$$\beta^2_o = a^2_1 (1 + y)^2 \qquad (15a)$$

$$\int_0^{l/2} \beta^2 \left(\frac{l}{2} - z\right)^2 dz = a^2_1 l^3 \frac{1}{8} \left(\frac{1}{6} y^2 + \frac{1}{9 \pi^2} y^2 + \frac{5}{2 \pi^2} y + \frac{1}{6} + \frac{1}{\pi^2}\right) \qquad (15b)$$

$$\int_0^{l/2} \left(\frac{d\beta}{dz}\right)^2 dz = a^2_1 \frac{1}{l} \frac{\pi^2}{4} (1 + 9 y^2) \qquad (15c)$$

and

$$\int_0^{l/2} \left(\frac{d^2\beta}{dz^2}\right)^2 dz = a^2_1 \frac{1}{l^3} \frac{\pi^4}{4} (1 + 81 y^2) \qquad (15d)$$

Substituting Eqs. 15 in Eq. 3:

$$P = \frac{4 E I_y d}{l^3} \left\{ \mp (1 + y)^2 + \sqrt{(1 + y)^4 + \frac{\pi^2}{8} \left[\frac{y^2}{6} + \frac{y^2}{9 \pi^2} + \frac{5 y}{2 \pi^2} + \frac{1}{6} + \frac{1}{\pi^2}\right] \times \left[\frac{l^2}{a^2} (1 + 9 y^2) + \pi^2 (1 + 81 y^2)\right]} \right\} \div \left[\frac{y^2}{6} + \frac{y^2}{9 \pi^2} + \frac{5y}{2 \pi^2} + \frac{1}{6} + \frac{1}{\pi^2}\right] \qquad (16)$$

[13] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1936, p. 266, Eq. (f).

Eq. 16 will now be transformed into an equation in unit stress f, such that:

$$f = \frac{P\,l}{4} \times \frac{d}{2\,I_x} \qquad \text{(17)}$$

for any beam, in which I_x is the moment of inertia about the x-axis. If Eq. 17 is written:

$$f = \frac{I_y\,d^2}{I_x\,a^2}\,E\,\frac{a^2}{l^2}\,\frac{1}{2}\,\frac{P\,l^3}{4\,E\,I_y\,d} \qquad \text{(18)}$$

and, if also the substitution—

$$A = \frac{1}{6}\,y^3 + \frac{1}{9\,\pi^2}\,y^2 + \frac{5}{2\,\pi^2}\,y + \frac{1}{6} + \frac{1}{\pi^2} \qquad \text{(19)}$$

—is made, the unit stress becomes

$$f = \frac{I_y\,d^2}{I_x\,a^2}\,E\,\frac{a^2}{l^2}\,\frac{1}{2\,A}$$

$$\times \left\{ \mp (1+y)^2 + \sqrt{(1+y)^4 + \frac{\pi^2}{8}\,A\left[\frac{l^2}{a^2}(1+9\,y^2) + \pi^2(1+81\,y^2)\right]}\right\} \qquad \text{(20)}$$

or in its general form, Eq. 4, in which k varies because of the introduction of $\frac{P\,d}{4}\,\beta^2_o$ in Eq. 2. For a concentrated load applied, respectively: At the top flange—

$$k = \frac{1}{2\,A}\left\{ -(1+y)^2 + \sqrt{(1+y)^4 + \frac{\pi^2}{8}\,A\left[\frac{l^2}{a^2}(1+9\,y^2) + \pi^2(1+81\,y^2)\right]}\right\} \qquad \text{(21a)}$$

at the centroid—

$$k = \frac{\pi}{4\,A}\sqrt{\frac{A}{2}\left[\frac{l^2}{a^2}(1+9\,y^2) + \pi^2(1+81\,y^2)\right]} \qquad \text{(21b)}$$

and, at the bottom flange—

$$k = \frac{1}{2\,A}\left\{ (1+y)^2 + \sqrt{(1+y)^4 + \frac{\pi^2}{8}\,A\left[\frac{l^2}{a^2}(1+9\,y^2) + \pi^2(1+81\,y^2)\right]}\right\} \qquad \text{(21c)}$$

The unit stress determined from Eq. 4 is a variable depending on the value of k. Since the basic problem is to determine the least value of f which will cause the beam to buckle (that is, "the critical stress"), it is necessary to determine, for each of a series of possible ratios l/a the value of y that will make the value of k a minimum. These critical values of y have been computed, and are given in Table 7(a). The corresponding computed values of k for these critical values of y have been tabulated in Table 1(a).

Simple Beams; Uniformly Distributed Load

Assuming a uniformly distributed load of w per linear unit, as in Fig. 7(a), equations similar to those for concentrated load can be set up. For work done by the external forces, assumed to be applied at the centroid, a method anal-

ogous to that used by Professor Timoshenko[14] can be used. Consider an element of the longitudinal axis at point D and consider the cross section mn at that point fixed. Then, because of bending of this element in the (ξ, ζ)-plane,

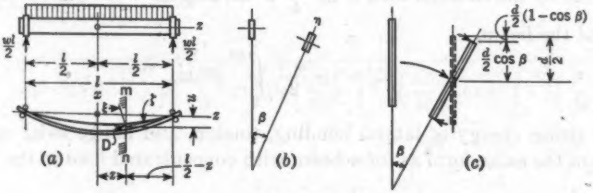

Fig. 7

the end of the beam, where the reaction ($= w\,l/2$) is applied, describes an infinitely small arc,

$$ds = \frac{d^2u}{dz^2}\left(\frac{l}{2} - z\right) dz \qquad (22a)$$

in the (ξ, ζ)-plane, the vertical component of which is

$$ds_v = \beta\,\frac{d^2u}{dz^2}\left(\frac{l}{2} - z\right) dz \qquad (22b)$$

[14] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1936, p. 253.

In Eqs. 22, u is the deflection of any element. The uniform load between point D and the right-hand end of the beam can be considered concentrated at its center of gravity, at a distance $\frac{1}{2}(l/2 - z)$ from point D, and the vertical component of movement, due to the bending of the element at point D, is

$$ds_D = \beta \frac{d^2u}{dz^2} \frac{1}{2} \left(\frac{l}{2} - z \right) dz \quad \text{(22c)}$$

The work done by the external forces to the right of point D, due to bending of the element at point D caused by beam buckling, is

$$V_D = \frac{w\,l}{2} \beta \frac{d^2u}{dz^2} \left(\frac{l}{2} - z \right) dz - w \left(\frac{l}{2} - z \right) \beta \frac{d^2u}{dz^2} \frac{1}{2} \left(\frac{l}{2} - z \right) dz$$

$$= \frac{w}{2} \beta \frac{d^2u}{dz^2} \left(\frac{l^2}{4} - z^2 \right) dz \quad \text{(23)}$$

and the work done on the full length of the beam is twice the summation of these forces from 0 to $l/2$:

$$V_1 = w \int_0^{l/2} \beta \frac{d^2u}{dz^2} \left(\frac{l^2}{4} - z^2 \right) dz \quad \text{(24)}$$

If the load is applied at the top or bottom flanges, instead of along the centroid of the beam, the external work done by the load is increased or decreased by the movement of the flanges caused by the beam rotation.[15] Considering the beam of Fig. 7(a) as a simple beam between its reactions, an element at the point of load application at the top or the bottom of the beam (Fig. 7(c)) is either lowered or raised a distance $\frac{d}{2}(1 - \cos \beta)$ or approximately $\frac{d}{4} \beta^2$. The work done by the element then is $\pm \frac{w\,d}{4} \beta^2\, dz$, and the work done along the full length of the beam,

$$V_2 = \pm \frac{w\,d}{2} \int_0^{l/2} \beta^2\, dz \quad \text{(25)}$$

The strain energy of lateral bending, torsion, and flange twist can be expressed in the same form as for a beam with concentrated load in the middle,[16] thus:

$$w \int_0^{l/2} \beta \frac{d^2u}{dz^2} \left(\frac{l^2}{4} - z^2 \right) dz \pm \frac{w\,d}{2} \int_0^{l/2} \beta^2\, dz$$

$$= B \int_0^{l/2} \left(\frac{d^2u}{dz^2} \right)^2 dz + C \int_0^{l/2} \left(\frac{d\beta}{dz} \right)^2 dz + \frac{B\,d^2}{4} \int_0^{l/2} \left(\frac{d^2\beta}{dz^2} \right)^2 dz \quad \text{(26)}$$

Equations corresponding to those for a concentrated load, given by Professor Timoshenko[17] can be written for a uniformly distributed load, for which the

[15] "The Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1936, p. 254.

[16] *Ibid.*, p. 266, Eq. (d).

[17] *Ibid.*, p. 251.

vertical moment is

$$M_z = -\frac{w\,l}{2}\left(\frac{l}{2} - z\right) + \frac{w}{2}\left(\frac{l}{2} - z\right)^2 = -\frac{w}{2}\left(\frac{l^2}{4} - z^2\right) \quad \ldots\ldots (27a)$$

This moment, projected to the η-axis, is

$$M_\eta = \frac{w}{2}\left(\frac{l^2}{4} - z^2\right)\beta \quad \ldots\ldots (27b)$$

and the differential equation for the buckled beam is

$$B\,\frac{d^2u}{dz^2} = \frac{w}{2}\left(\frac{l^2}{4} - z^2\right)\beta \quad \ldots\ldots (27c)$$

Using the value of $\frac{d^2u}{dz^2}$ of Eq. 27c, the equation for uniformly distributed load, corresponding to Eq. 2, will be:

$$\frac{w^2}{4\,E\,I_y}\int_0^{l/2} \beta^2 \left(\frac{l^2}{4} - z^2\right)^2 dz \pm \frac{w\,d}{2}\int_0^{l/2} \beta^2\,dz - \frac{E\,I_y}{4}\frac{l^2}{a^2}\frac{d^2}{l^2}\int_0^{l/2}\left(\frac{d\beta}{dz}\right)^2 dz - \frac{E\,I_y}{4}\,d^2\int_0^{l/2}\left(\frac{d^2\beta}{dz^2}\right)^2 dz = 0 \quad \ldots (28)$$

This equation may be solved for the loading $w\,l$:

$$w\,l = E\,I_y\,dl\left\{\mp\int_0^{l/2}\beta^2\,dz + \sqrt{\int_0^{l/2}(\beta^2\,dz)^2 + \int_0^{l/2}\beta^2\left(\frac{l^2}{4} - z^2\right)^2 dz\left[\frac{l^2}{a^2}\frac{1}{l^2}\int_0^{l/2}\left(\frac{d\beta}{dz}\right)^2 dz + \int_0^{l/2}\left(\frac{d^2\beta}{dz^2}\right)^2 dz^2\right]}\right\} \div \left[\int_0^{l/2}\beta^2\left(\frac{l^2}{4} - z^2\right)^2 dz\right] \quad \ldots (29)$$

With the same definitions for β and y as for concentrated load and the additional solutions for the integrals—

$$\int_0^{l/2}\beta^2\,dz = a^2{}_1\,\frac{l}{4}\,(1 + y^2) \quad \ldots\ldots (30a)$$

and

$$\int_0^{l/2}\beta^2\left(\frac{l^2}{4} - z^2\right)^2 dz = a^2{}_1\,l^5\,\frac{1}{8}\left(\frac{1}{15}\,y^2 + \frac{1}{27\,\pi^4}\,y^2 + \frac{45}{8\,\pi^4}\,y + \frac{1}{15} + \frac{3}{\pi^4}\right) \quad \ldots (30b)$$

—the loading may be expressed thus:

$$w\,l = \frac{2\,E\,I_y\,d}{l^3}\Bigg\{\mp(1+y^2)$$

$$+\sqrt{(1+y^2)^2+\frac{\pi^2}{2}\left[\frac{y^2}{15}+\frac{y^2}{27\,\pi^4}+\frac{45\,y}{8\,\pi^4}+\frac{1}{15}+\frac{3}{\pi^4}\right]}$$

$$\overline{\times\left[\frac{l^2}{a^2}(1+9\,y^2)+\pi^2(1+81\,y^2)\right]}\Bigg\}\div\left[\frac{y^2}{15}+\frac{y^2}{27\,\pi^4}\right.$$

$$\left.+\frac{45\,y}{8\,\pi^4}+\frac{1}{15}+\frac{3}{\pi^4}\right]\ldots\text{(31)}$$

Eq. 31 may be transformed into an equation in unit stress f, by a process similar to that used in the case of concentrated load (Eq. 17):

$$f = \frac{w\,l^2}{8}\times\frac{d}{2\,I_x}\ldots\ldots\ldots\ldots\text{(32)}$$

or

$$f = \frac{I_y\,d^2}{I_x\,a^2}\,E\,\frac{a^2}{l^2}\,\frac{1}{8}\,\frac{w\,l\,l^3}{2\,E\,I_y\,d}\ldots\ldots\ldots\ldots\text{(33)}$$

and, with the substitution—

$$A = \frac{1}{15}\,y^2+\frac{1}{27\,\pi^4}\,y^2+\frac{45}{8\,\pi^4}\,y+\frac{1}{15}+\frac{3}{\pi^4}\ldots\ldots\ldots\ldots\text{(34)}$$

—the unit stress becomes (compare Eq. 20):

$$f = \frac{I_y\,d^2}{I_x\,a^2}\,E\,\frac{a^2}{l^2}\,\frac{1}{8\,A}\Bigg\{\mp(1+y^2)$$

$$+\sqrt{(1+y^2)^2+\frac{\pi^2}{2}\,A\left[\frac{l^2}{a^2}(1+9\,y^2)+\pi^2(1+81\,y^2)\right]}\Bigg\}\ldots\text{(35)}$$

Eq. 35 has the general form of Eq. 4. Values of k are, for a uniformly distributed load applied, respectively: At the top flange,

$$k = \frac{1}{8\,A}\Bigg\{-(1+y^2)$$

$$+\sqrt{(1+y^2)^2+\frac{\pi^2}{2}\,A\left[\frac{l^2}{a^2}(1+9\,y^2)+\pi^2(1+81\,y^2)\right]}\Bigg\}\ldots\text{(36a)}$$

at the centroid,

$$k = \frac{\pi}{8\,A}\sqrt{\frac{A}{2}\left[\frac{l^2}{a^2}(1+9\,y^2)+\pi^2(1+81\,y^2)\right]}\ldots\ldots\ldots\text{(36b)}$$

and, at the bottom flange,

$$k = \frac{1}{8\,A}\left\{ (1 + y^2) + \sqrt{(1 + y^2)^2 + \frac{\pi^2}{2}\,A\left[\frac{l^2}{a^2}(1 + 9\,y^2) + \pi^2\,(1 + 81\,y^2)\right]}\right\} \quad \text{....(36c)}$$

To determine the least value of f in Eq. 4, the critical values of y for a given ratio of l/a have been computed, and are listed in Table 7(*b*). The corresponding computed values of k for these critical values of y are given in Table 1(*b*).

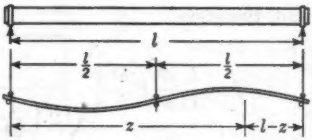

Fig. 8

Two-Bay Beams; Concentrated Load at Center

For a beam with lateral restraint at the middle cross section and with a load P applied at that point (Fig. 8), an equation similar to Eq. 2 can be written:

$$\frac{P^2}{4\,E\,I_y}\int_{l/2}^{l}\beta^2\,(l - z)^2\,dz - \frac{E\,I_y}{8}\,\frac{l^2}{a^2}\,\frac{d^2}{l^2}\int_0^l\left(\frac{d\beta}{dz}\right)^2 dz - \frac{E\,I_y}{8}\,d^2\int_0^l\left(\frac{d^2\beta}{dz^2}\right)^2 dz = 0 \quad \text{....(37)}$$

Note that the term in Eq. 2, which takes into account the external work done by the load P due to twisting of the middle cross section, disappears for Eq. 37. Solved for P, Eq. 37 gives

$$P = E\,I_y\,d\,\sqrt{\frac{\dfrac{l^2}{a^2}\,\dfrac{1}{l^2}\displaystyle\int_0^l\left(\frac{d\beta}{dz}\right)^2 dz + \int_0^l\left(\frac{d^2\beta}{dz^2}\right)^2 dz}{2\displaystyle\int_{l/2}^{l}\beta^2\,(l - z)^2\,dz}} \quad \text{........(38)}$$

in which

$$\beta = a_2 \sin\frac{2\,\pi\,z}{l} + a_4 \sin\frac{4\,\pi\,z}{l} \quad \text{................(39a)}$$

and

$$y = \frac{a_4}{a_2} \quad \text{..........................(39b)}$$

The integrals in Eq. 38 are solved thus:

$$\int_0^l\left(\frac{d\beta}{dz}\right)^2 dz = a_2^2\,\frac{1}{l}\,2\,\pi^2\,(1 + 4\,y^2) \quad \text{.............(40a)}$$

$$\int_0^l\left(\frac{d^2\beta}{dz^2}\right)^2 dz = a_2^2\,\frac{1}{l^3}\,8\,\pi^4\,(1 + 16\,y^2) \quad \text{.............(40b)}$$

and

$$\int_{l/2}^{l} \beta^2 (l - z)^2 \, dz = a^2{}_2 \, l^3 \frac{1}{2}\left(\frac{1}{24} y^2 - \frac{5}{64 \pi^2} y^2 - \frac{4}{9 \pi^2} y + \frac{1}{24} - \frac{1}{16 \pi^2}\right) \ldots (40c)$$

which values, in Eq. 38, yield:

$$P = \frac{E I_y d}{l^2} 2 \pi \sqrt{\frac{\frac{l^2}{a^2}(1 + 4 y^2) + 4 \pi^2 (1 + 16 y^2)}{2\left(\frac{1}{24} y^2 - \frac{5}{64 \pi^2} y^2 - \frac{4}{9 \pi^2} y + \frac{1}{24} - \frac{1}{16 \pi^2}\right)}} \ldots (41)$$

and, therefore,

$$f = \frac{I_y d^2}{I_x a^2} E \frac{a^2}{l^2} \frac{\pi}{4} \sqrt{\frac{\frac{l^2}{a^2}(1 + 4 y^2) + 4 \pi^2 (1 + 16 y^2)}{2\left(\frac{1}{24} y^2 - \frac{5}{64 \pi^2} y^2 - \frac{4}{9 \pi^2} y + \frac{1}{24} - \frac{1}{16 \pi^2}\right)}} \ldots (42)$$

To express the unit stress, f, in terms of the unsupported length of the beam instead of the full length of the beam, as in Eq. 42, l in Eq. 42 should be multiplied by 2. The value of f is then expressed by Eq. 4 in which

$$k = \frac{\pi}{8} \sqrt{\frac{\frac{l^2}{a^2}(1 + 4 y^2) + \pi^2 (1 + 16 y^2)}{2\left(\frac{1}{24} y^2 - \frac{5}{64 \pi^2} y^2 - \frac{4}{9 \pi^2} y + \frac{1}{24} - \frac{1}{16 \pi^2}\right)}} \ldots\ldots (43)$$

in which l equals the unsupported, or half, length of beam. The critical values of y and of k as determined by Eq. 43 have been computed and are tabulated in Tables 7(c) and 1(c).

Two-Bay Beams; Uniformly Distributed Load

In the case of a uniformly loaded beam with lateral restraint at the middle cross section (Fig. 8), by the method previously used for the laterally unsupported beam, an equation similar to Eq. 28 can be written:

$$\frac{w^2}{8 E I_y} \int_0^l \beta^2 z^2 (l - z)^2 \, dz \pm \frac{w d}{4} \int_0^l \beta^2 \, dz$$

$$- \frac{E I_y}{8} \frac{l^2 d^2}{a^2 l^2} \int_0^l \left(\frac{d\beta}{dz}\right)^2 dz - \frac{E I_y}{8} d^2 \int_0^l \left(\frac{d^2\beta}{dz^2}\right)^2 dz = 0 \ldots (44)$$

Eq. 44 may be solved for the loading $w\,l$:

$$w\,l = E I_y \, d l \left\{ \mp \int_0^l \beta^2 \, dz \right.$$

$$\left. + \sqrt{\int_0^l (\beta^2 \, dz)^2 + \int_0^l \beta^2 z^2 (l - z)^2 \, dz \left[\frac{l^2}{a^2} \frac{1}{l^2} \int_0^l \left(\frac{d\beta}{dz}\right)^2 dz + \int_0^l \left(\frac{d^2\beta}{dz^2}\right)^2 dz\right]} \right\}$$

$$\div \left[\int_0^l \beta^2 z^2 (l - z)^2 \, dz\right] \ldots (45)$$

With solutions for integrals, not solved before:

$$\int_0^l \beta^2\, dz = a^2{}_2\, l\, \tfrac{1}{2}\,(1 + y^2) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (46a)$$

and

$$\int_0^l \beta^2 z^2 (l - z)^2\, dz = a^2{}_2\, l^5 \frac{1}{8}\left(\frac{2}{15} y^2 - \frac{1}{2\,\pi^2} y^2 + \frac{63}{128\,\pi^4} y^2 - \frac{320}{27\,\pi^4} y + \frac{2}{15} + \frac{3}{8\,\pi^4}\right) \ldots (46b)$$

Eq. 45 becomes

$$w\,l = \frac{4\,E\,I_y\,d}{l^3}\left\{ \mp (1 + y^2) + \sqrt{(1 + y^2)^2 + \pi^2 \left[\frac{2\,y^2}{15} - \frac{y^2}{2\,\pi^2} + \frac{63\,y^2}{128\,\pi^4} - \frac{320\,y}{27\,\pi^4} + \frac{2}{15} + \frac{3}{8\,\pi^4}\right] \times \left[\frac{l^2}{a^2}(1 + 4\,y^2) + 4\,\pi^2 (1 + 16\,y^2)\right]}\right\} \div \left[\frac{2\,y^2}{15} - \frac{y^2}{2\,\pi^2} + \frac{63\,y^2}{128\,\pi^4} - \frac{320\,y}{27\,\pi^4} + \frac{2}{15} + \frac{3}{8\,\pi^4}\right] \ldots (47)$$

and, with—

$$A = \frac{2}{15} y^2 - \frac{1}{2\,\pi^2} y^2 + \frac{63}{128\,\pi^4} y^2 - \frac{320}{27\,\pi^4} y + \frac{2}{15} + \frac{3}{8\,\pi^4} \ldots\ldots (48)$$

—the formula for stress becomes:

$$f = \frac{I_y\,d^2}{I_x\,a^2} E \frac{a^2}{l^2} \frac{1}{4\,A}\left\{ \mp (1 + y^2) + \sqrt{(1 + y^2)^2 + \pi^2 A \left[\frac{l^2}{a^2}(1 + 4\,y^2) + 4\,\pi^2 (1 + 16\,y^2)\right]}\right\} \ldots (49)$$

If each l in Eq. 49 is multiplied by 2, to express the unit stress, f, in terms of the unsupported length instead of the full length of the beam, as was done for the concentrated load (Eq. 42), then the value of f for uniformly distributed load is expressed by Eq. 4 in which, with the load at the top flange,

$$k = \frac{1}{16\,A}\left\{ - (1 + y^2) + \sqrt{(1 + y^2)^2 + 4\,\pi^2 A \left[\frac{l^2}{a^2}(1 + 4\,y^2) + \pi^2 (1 + 16\,y^2)\right]}\right\} \ldots (50a)$$

at the centroid,

$$k = \frac{\pi}{8\,A}\sqrt{A\left[\frac{l^2}{a^2}(1 + 4\,y^2) + \pi^2\,(1 + 16\,y^2)\right]}\qquad\text{(50b)}$$

and, at the bottom flange,

$$k = \frac{1}{16\,A}\left\{(1 + y^2) + \sqrt{(1 + y^2)^2 + 4\,\pi^2\,A\left[\frac{l^2}{a^2}(1 + 4\,y^2) + \pi^2\,(1 + 16\,y^2)\right]}\right\}\qquad\text{(50c)}$$

The critical values of y and the corresponding values of k have been computed and are given in Tables 7(c) and 1(c).

APPENDIX II. NOTATION

The following letter symbols, used in the paper and in its discussions, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials (ASA—Z10a—1932), prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932. As nearly as possible, consistent with standard practice, they also follow the nomenclature used by Professor Timoshenko:[2]

A = a substitution factor; for simple beams with a concentrated load at the center, A is defined by Eq. 19; for simple beams with a uniformly distributed load, A is defined by Eq. 34; and, for a two-bay beam with a uniformly distributed load, A is defined by Eq. 48;

a = a torsional bending constant; also where defined, a_1, a_2, a_3, a_4 = maximum ordinates of sine curves (Eqs. 14 and 39);

B = transverse flexural rigidity of a beam = $E\,I_y$;

b = width of compression flange of beam or girder;

C = torsional rigidity of beam = $E\,I_y\,d^2/(4\,a^2)$;

D = diameter of an inscribed circle in a flange section;

d = depth of a beam or girder:

  d' = effective depth of a plate girder (see Fig. 6);

  d_c = depth of a plate girder between flange centroids;

E = modulus of elasticity;

f = unit stress;

I = moment of inertia about an axis denoted by an appropriate subscript;

K = a torsion constant;

k = a substitution factor; for concentrated loads on a simple beam, k is defined by Eqs. 21; for uniformly distributed loads on a simple beam, k is defined by Eqs. 36; for a concentrated load on a two-bay beam k is defined by Eq. 43; and, for uniformly distributed loads on a two-bay beam, k is defined by Eqs. 50;

l = length; in general, l denotes "the laterally unsupported length of the compression flange," with exceptions as described in the text;

M = moment, with subscripts indicating the plane of reference;

P = a concentrated load;

r = radius; r_f = fillet radius;

s = length along any arc; ds = an increment of s, with appropriate subscript;

t = thickness of compression flange:

t' = effective average thickness of cover plates (Eq. 14);

t(max) = maximum cover-plate thickness;

t(min) = minimum cover-plate thickness;

u = deflection of any element;

V = work, with subscripts as defined in the text;

w = load per unit length of span;

x = a coordinate;

y = a coordinate; also, where defined, $y = \dfrac{a_3}{a_1}$ and $y = \dfrac{a_4}{a_2}$;

z = a coordinate;

β = angular deflection of a beam at any point; β_o = angle of twist of the beam at its center line;

ζ = a coordinate in the (ξ, ζ, η)-system;

η = a coordinate in the (ξ, ζ, η)-system; and

ξ = a coordinate in the (ξ, ζ, η)-system.

DISCUSSION

George Winter,[18] M. ASCE.—It has been shown repeatedly and convincingly that the generally accepted slenderness ratio for unsupported beams, l/b, is by no means a real criterion for their lateral strength.[19] The great merit of this paper is that the author has succeeded in developing a sufficiently simple set of formulas for inclusion in design specifications, all depending on the compact parameter $\frac{l\,d}{b\,t}$. These formulas (Eqs. 6 to 8), however, are not as general as may appear from the paper, and sometimes they result in greatly misleading and uneconomical values. Furthermore, no rational justification is given in the paper for this particular parameter, except that it happens to fit rather satisfactorily the stress magnitudes obtained from the exact formulas.

It is the intent of this discussion to show in a rigorous manner: (*a*) Why it is this particular parameter and no other which gives satisfactory results for the author's beams; and (*b*) the limitations of the proposed formulas. Finally, for beams to which Mr. de Vries' equations are found not to be applicable, another simple formula is proposed to supplement those given in the paper.

Expressions for critical loads and stresses of unsupported beams have been published before. In particular, the writer,[20] in collaboration with the late Lt. R. K. Schrader,[21] Jun. ASCE, published in 1941 a set of expressions for critical loads and moments, which not only covers Mr. de Vries' cases but is more general and also deals with additional types of loading. The only difference in Mr. de Vries' treatment is that he accounts for the second term in the Fourier expansion of the elastic curve, whereas the writer was satisfied with the first term. The negligible influence of this second term can be noted not only in the close agreement of the values in both papers, but also in the fact that the values for y in Table 7 are all rather small as compared with unity.

In a subsequent paper the writer gave the following formula for the buckling stress of such beams:

$$f = \frac{E\,\pi^2}{2\left(\frac{l}{d}\right)^2}\sqrt{\left(\frac{I_y}{2\,I_x}\right)^2 + \frac{K\,I_y}{2(1+\nu)\,I^2_x}\left(\frac{l}{\pi\,d}\right)^2}\;\ldots\ldots\ldots(51)$$

in which ν is Poisson's ratio and K is the torsional constant of the beams.[22] He also showed that Eq. 51, derived for pure bending, can be applied satisfactorily to most practical cases of transverse loading[23]—a finding which is identical with Mr. de Vries' analysis of various loading conditions.

The reason for, and the limitations of, the author's parameter, $\frac{l\,d}{b\,t}$, can be derived rigorously from Eq. 51. The buckling stress depends on the two quan-

[22] "Strength of Slender Beams," by George Winter, *Transactions*, ASCE, Vol. 109, 1944, p. 1334, Eq. 41.

[23] *Ibid.*, pp. 1339 and 1340.

tities appearing under the radical. It so happens, however, that for most rolled and built-up sections the first term is negligibly small as compared with the second. For example, for the three I-beams (24I120, 3I5.7, and 12I55), with $l/d = 30$, the values of these two terms are, respectively, 0.00020 and 0.0037, 0.0085 and 0.068, and 0.00073 and 0.009. Therefore, in a practical design formula, the first term in Eq. 51 is negligible for such beams, particularly since both are included under the radical. Neglecting this term, the following simplification can be introduced:

In view of the usual shape of rolled and built-up I-beams, the web contributes very little to I_x, I_y, and K. Consequently, the following approximate expressions can be used for these three quantities—

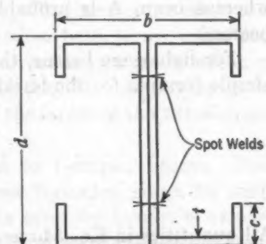
$$I_x = 2\,b\,t\left(\frac{d}{2}\right)^2; \quad I_y = \frac{2\,t\,b^3}{12}; \quad \text{and} \quad K = \tfrac{2}{3}\,b\,t^3 \ldots\ldots\ldots (52)$$

Substitution of these values in Eq. 51, with the first term under the radical equal to zero, results in

$$f = \frac{19{,}500{,}000}{\dfrac{l\,d}{b\,t}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (53)$$

Eq. 53 differs from Eq. 7 by only 2.5%.

It is thereby established that Mr. de Vries' approximate formula is rigorously justified provided that the first term under the radical in Eq. 51 is negligible as compared with the second term. This condition will be true for all beams whose flange thickness is not too small as compared to the width (to about $b/t = 20$). For beams with still thinner flanges the torsional constant K (which is proportional to t^3) decreases rapidly to such an extent that the second of these two terms approaches the order of magnitude of the first. For example (to consider an extreme case) for 6WF15.5, with $l = 20$ ft, the magnitude of these two terms, in order, is 0.030 and 0.071. Although the first term is still seen to be smaller than the second, it is no longer of negligible magnitude. Indeed, the buckling stress from Eq. 51, for $l = 20$ ft, is 27,000 lb per sq in., whereas Eq. 7 results in only 21,800 lb per sq in. Beams of this character, however, are used infrequently except for relatively small structures with light loading.



Beam	t	d	b	c
A	0.075	6.0	5.0	0.75
B	0.050	8.0	3.0	0.60

FIG. 9—LIGHT-GAGE STEEL BEAMS

However, for structures of this kind new types of sections are coming into increasingly widespread use. Such members are fabricated from sheet steel by cold-forming and, usually, by spot-welding.[24] Sections of this type are manufactured at present by a number of specialized firms in that field and, in the near future, will be-

[24] "Light-Gage Steel for Peacetime Building," by Milton Male, *Engineering News-Record*, October 18, 1945, p. 525.

come available commercially on a wide scale. Sheet steel I-beams are frequently made up from two C-channels spot-welded back to back as shown in Fig. 9. In such beams the thickness-width ratio of the flange is ordinarily of the order of b/t = from 25 to 100. It must be expected, therefore, that in such beams the first of the two terms in Eq. 51 is no longer of negligible magnitude. Indeed, for the two beams whose dimensions are given in Fig. 9, with $l/d = 30$, the values of the two terms, in order, are 0.019 and 0.0034 and 0.00049 and 0.00018. The situation here is the reverse of that found for rolled sections; and, consequently, Eq. 7, if applied to these beams, must result in stresses which err very much on the low (conservative) side.

Since the simple parameter $\frac{l\,d}{b\,t}$ cannot be used for such light-gage I-beams, it will naturally be asked how lateral strength should be determined in the design of sections of this kind. For this purpose Eq. 51 can be used as it is. Most designers, however, will consider it too cumbersome for everyday use. To arrive at a sufficiently simple expression, essentially the same kind of simplification can be used as was employed for rolled sections. It will be noted from the foregoing data that, for light-gage beams, the first term under the radical in Eq. 51 is several times larger than the second. It appears, therefore, that a formula which discards this second term, gives a result not too different from the accurate value of Eq. 51.

(The situation for beam A (Fig. 9) is much more favorable in this respect than that for beam B. However, sections of such extreme shape as beam B will scarcely be suitable for beams, since the low ratio of b/d makes such use very uneconomical. Beam B was chosen as an extreme case to show the maximum discrepancies to be expected from the formula that follows, whereas beam A is probably rather close to average dimension of practical beams.)

For light-gage beams, then, if the second term of Eq. 51 is discarded, the simple formula for the buckling stress is obtained:

$$f = \frac{74{,}000{,}000}{\left(\frac{l}{d}\right)^2} \frac{I_y}{I_x} \qquad \text{(54a)}$$

All quantities in Eq. 54a are those usually tabulated for commercial sections.

For the two beams in Fig. 9, for $l/d = 30$, the following values of the buckling stress are obtained:

Eq.	Beam A	Beam B
51	24,600	4,300
7	6,900	1,900
54	22,500.	3,700

It is clear that the author's values cannot be used for such light-gage beams. The writer's values, although somewhat conservative, can be considered accurate enough for design use.

In the "Specifications for the Design Of Light Gage Structural Members"[25] of the American Iron and Steel Institute, Eq. 54*a* was used to develop design requirements for nonbraced light-gage beams. For purposes of simplification, Eq. 54*a* can also be written in the following form:

$$f = \frac{74{,}000{,}000}{\left(\frac{l}{d}\right)^2}\left(\frac{r_y}{r_x}\right)^2 = \frac{74{,}000{,}000}{\left(\frac{l}{r_y}\right)^2}\left(\frac{d}{r_x}\right)^2 \ldots\ldots\ldots\ldots (54b)$$

in which r_x and r_y are the radii of inertia of the section. It was found that for light-gage beams of economical dimensions the ratio d/r_x is almost constant and equal to 2.5 or slightly above that value. By substituting this value for d/r_x in Eq. 54*b*, the following, extremely simple formula for the buckling stress of light-gage beams of the type of Fig. 1 is obtained:

$$f = \frac{463{,}000{,}000}{\left(\frac{l}{r_y}\right)^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (54c)$$

It is Eq. 54*c*, with a suitable factor of safety, which was used in the specifications of the American Iron and Steel Institute.

Although general indications concerning the range of applicability of these two formulas have been discussed herein, doubt may sometimes arise as to which of the two to use. In such a case it is a safe and somewhat conservative procedure to compute the buckling stresses by both approximate formulas (Eqs. 7 and 54) and to use the larger of the two values. The stress so obtained will always err on the conservative side, but by not more than about 30%. Indeed, both formulas give values which are always smaller than the exact stress (Eq. 51) since they neglect positive terms. The maximum error can easily be established for the worst case—that is, when both terms under the square root are equal. In that case either formula results in a stress which is $\sqrt{0.5}$, or 0.707, times the exact stress determined by Eq. 51. Any other ratio of these two terms, therefore, will cause the error of the larger of the two stresses to be less than 30%.

Both these investigations are strictly limited to I-shaped beams. Box beams or U-beams should not be designed by these formulas, since, for such beams, the equations give values that are often in error by hundreds of percentage points. Such members must be analyzed by substantially different methods. Current design specifications are rather vague in this respect and the author would have done well to indicate a clear limitation to I-beams in the title.

These remarks are in no way intended to detract from the value of this paper which, at long last, gives a usable formula for standard types of beams. On the contrary, the writer, despite his development of relatively simple rigorous equations, did not reduce them to their simplest possible approximate form. The author, on the other hand, although handicapped by his somewhat unnecessarily complex mathematics, developed a usable formula by persistent trial and error.

[25] "Specifications for the Design of Light Gage Structural Members," A.I.S.I., April, 1946.

These comments, therefore, are merely intended to show the rigorous basis of the author's formulas, and to supplement his fundamental Eq. 7 by an equally simple one (Eq. 54*a*), which is valid for sections to which Mr. de Vries' formulas cannot be applied.

(In the numerical data presented in this discussion, the torsional constants were computed by the approximate formula:

$$K = (\tfrac{1}{3})\, \Sigma w_n\, t^3_n \qquad (55)$$

in which w_n and t_n are, respectively, the widths and thicknesses of the component rectangles of the section. Slide-rule accuracy was held to be sufficient for these merely illustrative figures.)

DAVID B. HALL,[26] Assoc. M. ASCE.—Some of the beams analyzed in this paper have fairly high ratios of I_y to I_x. Since the formulas of the paper are all derived on the assumption that this ratio is negligibly small, the question arises as to the amount of error introduced. It turns out, however, that, in practice, these beams can never buckle within the elastic range. Hence an increase in stability which, in an elastic structure could permit a considerable increase in the buckling load, would increase the load only slightly in this case. As an illustration, the 14WF87 beam, with a 14.5-in. flange may be considered. Referring to Table 2, it is observed that the lowest value of l/a for which the critical stress f was small enough to be recorded was 4. Since the value of a is 104 in., this would give a length of 4×104, or 416 in., which is approximately thirty times the depth of the beam. To prevent excessive deflection, the maximum length permitted in practically any type of structure would be considerably less than this. It may thus be concluded that questions of refinement of the theoretical buckling equations in this region are subordinate to the broader problem of plastic buckling, which the writer is not prepared to discuss.

The academic problem of such a beam, long enough to buckle in the elastic range (about 700 in. for a 14×14.5 beam) may still be of interest. The modified buckling load depends on the ratio I_y/I_x and also upon a relation between the torsional stiffness (including torsion bending) and I_x, but for a long I-beam the latter relation is of negligible importance. For any type of loading applied along the centroid of the beam the approximate correct buckling load can then be found by multiplying the buckling load that was previously found by the methods of the paper, by a factor,

$$F = \frac{1}{\sqrt{1 - \frac{I_y}{I_x}}} \qquad (56)$$

For the 14WF87 beam $F = 1.25$. Eq. 56 is easily obtained by considerations of energy. Assuming any section rotated through an angle β, and acted on by a moment M about the x-axis, the moments about the two principal axes of the section are $M \cos \beta$ and $M \sin \beta$, and the components of the curvature

[26] Stress Analyst, The Glenn L. Martin Co., Baltimore, Md.

in the (yz)-plane are $\frac{M}{E\,I_x}\cos^2\beta$ and $\frac{M}{E\,I_y}\sin^2\beta$. Since $\cos^2\beta = 1 - \sin^2\beta$,

$$\text{The total curvature of an element} = \frac{M}{E\,I_x} + \frac{M}{E\,I_y}(1 - I_y/I_x)\sin^2\beta \quad (57)$$

The first term in Eq. 57 represents the curvature in the stable state, and the second represents the additional curvature in the buckled state. In this latter term $\sin^2\beta$ may be replaced by β^2, and it is found that the expression $\frac{1 - I_y/I_x}{E\,I_y}$ takes the place of $\frac{1}{E\,I_y}$ in expressions for both internal and external energy, and ultimately comes out in the form of Eq. 56.

A second question concerns the selection of loading and end support conditions. Several conditions have been treated in the paper. One interesting and very simple case (that of a simple beam acted on by pure end couples) was omitted.

A common type of bridge structure consists of a pair of main carrying beams or girders braced together by floor beams. The weight of the floor and moving traffic is delivered to the main beams at the floor-beam connections. Thus a single panel of such a beam corresponds very closely to the ideal beam. The condition of simply supported ends follows from the freedom of alternate panels to buckle in opposite directions, although it is modified somewhat by the restraint offered by the floor beams and bracing.

Beams in which principal loads are applied between supporting points will ordinarily present a more complicated problem than that treated in the paper, since structures of this kind (for example, a crane runway beam) would almost certainly be subject to lateral as well as vertical loading.

The case of a simple beam acted on by end couples is easier to treat than any of those considered in the paper. The coefficient k in Eq. 4 can be computed directly instead of by trial.[27] A few typical values are:

l/a	k
1	2.92
2	3.41
10	8.2

Comparison with values in Table 1 indicates that this condition is about eight tenths as severe as the case of a beam uniformly loaded along the top flange, when l/a is 1 and that it is practically identical to it when l/a is 10. It would appear logical to choose this as the standard loading condition, treating the other cases as special.

In the paper, the case of a long girder picked up at the ends during erection was cited as an example of the case of a simply supported beam loaded along the center line. Such a beam, supported by ordinary slings, is prevented from rotating about a point in the vicinity of the top flange only by its own weight, and presents an entirely different problem. For equilibrium in the slightly

[27] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1936, p. 261, Eq. 159.

buckled state, the product of the height from center of load to the eye of the sling by the end rotation β must be equal to the average lateral deflection. An equilibrium solution, however, would be difficult except in the case where the torsional rigidity of the beam is assumed infinite. In this case the angle β is constant throughout the length of the beam. The lateral load is $w\,\beta$. The average lateral deflection, obtained by integrating the deflection curve, is found to be $\dfrac{w\,l^4\,\beta}{120\,E\,I_y}$. The height from load to the eye of sling may be conservatively taken as $d/2$, making the offset $\dfrac{\beta\,d}{2}$. Then:

$$\frac{w\,l^4\,\beta}{120\,E\,I_y} = \frac{\beta\,d}{2} \qquad \text{(58a)}$$

and

$$\frac{w\,l^4}{E\,I_y\,d} = 60 \qquad \text{(58b)}$$

By properly combining Eqs. 58*b*, 32, and 4, there follows the relation,

$$k = 3.75 \qquad \text{(58c)}$$

which represents a limiting value approached by k as l/a increases indefinitely. This value of k contrasts strongly with the indefinitely increasing value of k in Table 1, for cases in which end rotation is prevented.

An approximate solution can be obtained by the energy method. An equation very similar to Eq. 28 may be derived, replacing the term from Eq. 25 (for lowering a load distributed along a flange) by the expression,

$$V_2 = -\frac{\beta^2_{z=0.5l}}{2}\,w\,l\,\frac{d}{2} \qquad \text{(59)}$$

to represent the work done in raising the entire load when the ends rotate. The new equation becomes:

$$\frac{w^2}{4\,E\,I_y}\int_0^{l/2} \beta^2\left(\frac{l^2}{4} - z^2\right)dz - \frac{w\,l\,d}{4}\beta^2_{z=0.5l} - \frac{E\,I_y}{4}\,\frac{l^2}{a^2}\,\frac{d^2}{l^2}\int_0^{l/2}\left(\frac{d\beta}{dz}\right)^2 dz$$
$$- \frac{E\,I_y}{4}\,d^2\int_0^{l/2}\left(\frac{d^2\beta}{dz^2}\right)^2 dz = 0 \qquad \text{(60)}$$

A reasonably satisfactory representation of β as a function of z should be:

$$\beta = a_0 + a_1\cos\frac{\pi\,z}{l} = a_0\left(1 + m\cos\frac{\pi\,z}{l}\right) \qquad \text{(61)}$$

Substitution of Eq. 61 and its derivatives in Eq. 60 yields:

$$\frac{w^2\,l^5}{4\,E\,I_y}\left[\frac{1}{60} + m\left(-\frac{4}{\pi^3} + \frac{48}{\pi^5}\right) + m^2\left(\frac{1}{120} + \frac{3}{8\,\pi^4}\right)\right]$$
$$- \frac{w\,l\,d}{4} - \frac{E\,I_y}{4}\,\frac{l^2}{a^2}\,\frac{d^2}{l^2}\,\frac{m^2\,\pi^2}{4\,l} - \frac{E\,I_y}{4}\,d^2\,\frac{m^2\,\pi^4}{4\,l^3} = 0 \qquad \text{(62)}$$

Let:

$$\frac{w\,l^4}{E\,I_y\,d} = X \qquad \text{(63)}$$

Then Eq. 62 reduces to:

$$X^2\left[\frac{1}{60}+m\left(-\frac{4}{\pi^3}+\frac{48}{\pi^5}\right)+m^2\left(\frac{1}{120}+\frac{3}{8\,\pi^4}\right)\right]$$
$$-X-\frac{\pi^2\,m^2}{4}\left(\frac{l^2}{a^2}+\pi^2\right)=0\ldots\ldots\ldots\ldots\ldots\ldots(64)$$

Eq. 64 has been solved approximately for a few typical values of l/a, with the following results:

l/a	X	k
2	17.85	1.12
8	27.2	1.70
∞	60	3.75

The last line, it will be noted, checks with Eqs. 58*b* and 58*c*.

This analysis shows that the handling of a long flexible girder during erection is likely to require special consideration, and also indicates that one possible way to strengthen such a girder is by devising a special lifting rig with a high center of rotation.

THEODORE R. HIGGINS,[28] M. ASCE.—The author is to be complimented for his method of attack, which consisted, first, of solving the problem as rationally as practicable in view of the mathematical complexities and, second, in transforming the results into simple functions of published beam properties. There is obvious logic in a formula which considers, in addition to the length and width of the beam as embraced in formulas used heretofore, also the thickness of the flanges (which makes for lateral stability) and the beam depth (which militates against it). It is equally obvious that the four quantities, l, d, b, and t, appear in the author's formula in the numerator and denominator, respectively, as they properly should to express their influence upon lateral and torsional stability. The form of the author's formula is, accordingly, logical.

It is interesting to note, from the quantitative standpoint, that this formula operates to reduce the rated capacity of deep or narrow beams and to increase the rated capacity of shallow beams, as compared to their capacity when rated by previous specification formulas involving only l and b.

Although the case for Eq. 7, pertaining to long laterally unsupported beams, has convincingly been developed by the author, both analytically and statistically, the supporting argument for Eqs. 6*a*, 6*b*, and 6*c* is lacking. These equations are presented merely as affording "transition curves" with yield point stress as their upper limits. The analogy between the Euler curve for long columns, and Eq. 7, as applied to long laterally unsupported beams, is readily apparent. It does not follow directly, however, that a curve for short beams needs to simulate that for short columns as given by the secant formula.

As will be perceived by dividing 20,000,000 by 600, the critical bending stress in a beam having a $\frac{l\,d}{b\,t}$-value of 600 is not less than 33,333 lb per sq in.,

[28] Director of Eng., Am. Inst. of Steel Constr., New York, N. Y.

even under the most severe of the six different types of loading considered. Thus, the usefulness of a further reduction, amounting to $0.0125 \times (600)^2 = 4{,}500$ lb per sq in., is not apparent in applying the results of the analysis to design problems.

From a practical standpoint, it is highly desirable to limit the use of variable working stresses—which impose an added burden on the designer—as much as possible, consistent with sound practices.

For these reasons the American Institute of Steel Construction (A.I.S.C.) Committee on Specifications has seen fit, in revising the Standard Specifications,[29] to recommend the use of Eq. 9 for all values of $\frac{l\,d}{b\,t}$ greater than 600, the point where the equation affords a working stress of 20,000 lb per sq in. For values of $\frac{l\,d}{b\,t}$ less than 600, the basic 20,000 lb per sq in. bending stress governs.

On this basis, for most rolled wide flange beams there is a rather substantial length up to which no reduction in capacity need be made because of the lack of lateral support. For instance, for a beam 36 in. deep by 16½ in. wide at 300 lb per lin ft, this length is 38 ft. Accordingly, in the Fifth (1946) Edition of the A.I.S.C. manual on "Steel Construction" in the tables of safe loads on beams, the constant value $\frac{d}{b\,t}$, and the length (L_u) up to which the absence of lateral support does not reduce the allowable load, are given for each beam size. For any given beam, the only variable in Eq. 9 is the factor l and, when $l > L_u$,

$$f = \frac{20{,}000\,L_u}{l} \qquad (65)$$

Although Eq. 9 determines the allowable unit stress once the beam has been selected, it requires (as did the previous l/b formula) the selection of a trial beam. To avoid this step, since three beam dimensions affect the allowable stress instead of one, the A.I.S.C. manual now provides four new charts from which proper beams can be selected without any "cut and try." The charts are so arranged that, entering on the left with the desired bending moment and at the bottom with the unsupported span length, and proceeding across and up, respectively, to the intersection point thus found, the curves for all beams which satisfy the new formula lie above and to the right of this point.

In applying Eq. 9 to beams where the $\frac{l\,d}{b\,t}$-value requires a reduction from the 20,000 lb per sq in. basic working stress, investigation of vertical deflection for all ordinary conditions is unnecessary. As the laterally unsupported span length increases, the reduction in allowable unit stress operates to an extent such that the vertical deflection will always be within the usual limits prescribed for a fully loaded, fully supported beam of the same span.

[29] "Specification for the Design, Fabrication and Erection of Structural Steel for Buildings," A.I.S.C., New York, N. Y., 1946.

The author has wisely called attention to the fact that the working formula (Eq. 9) is safe for the most severe of the six types of loading considered, and that in investigating special problems the designer would do well to consider the expressions derived for the other five conditions. For the ordinary run of work a single rule, safe for all conditions of loading, will suffice and will not prove wasteful of material. In studies of this kind, however, there is a natural tendency to lose sight of the information pertaining to special cases; and to ascribe to the single recommendation, intended to cover the general case, a sanctity not intended by the originator. These same considerations would suggest that the user of Eq. 9, in attacking problems involving unusual profiles, would do well to study carefully the discussion of some of these problems contained in the paper.

NEIL VAN EENAM,[30] M. ASCE.—Two separate phases of the problem of lateral buckling of beams and girders are treated in this paper. In the first part, additional values of the factor k are derived for various types and conditions of loading which supplement the factors m derived by Professor Timoshenko.[2] The derivation of these additional factors k, which can readily be converted to the Timoshenko factors m, is a valuable contribution. This part of the paper will be appreciated by those who prefer original sources for data on the solution of this type of problem. It is unfortunate, however, that for braced beams of two bays, the symbol l denotes the full length of the beam between end supports in Fig. 8 and in Eqs. 42 and 49, whereas in Table 1 the symbol l denotes the unsupported length of the compression flange, which in this case is one half of the full length of the beam. This may lead to some confusion.

Simplified formulas, both for critical stresses and for working stresses, are proposed in the second part of the paper. These formulas employ the dimension ratio $\frac{l\,d}{b\,t}$. In Figs. 10 and 11, results obtained by these simplified formulas are compared with those obtained by more exact methods. An analysis of the principal source of variation in results follows the comparison.

Curves ABCD of Figs. 10 and 11, representing the more exact values for the type of loading shown, were computed according to Professor Timoshenko's method.[31] However, identical results would have been obtained by using Eq. 4 of the paper. The torsion constants K entering into the more exact formulas may be accurately determined for rolled beams.[9] In riveted plate girders, there may be considerable slip between the various parts comprising the section, and there is uncertainty as to the proper reduction to be made on this account. The tests made by I. E. Madsen,[11] Jun. ASCE, appear to give the best data available, and it was decided to follow his recommendation that

[30] Highway Bridge Engr., U. S. Public Roads Administration, Washington, D. C.

[31] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1936, p. 268, Eq. 164, and p. 278.

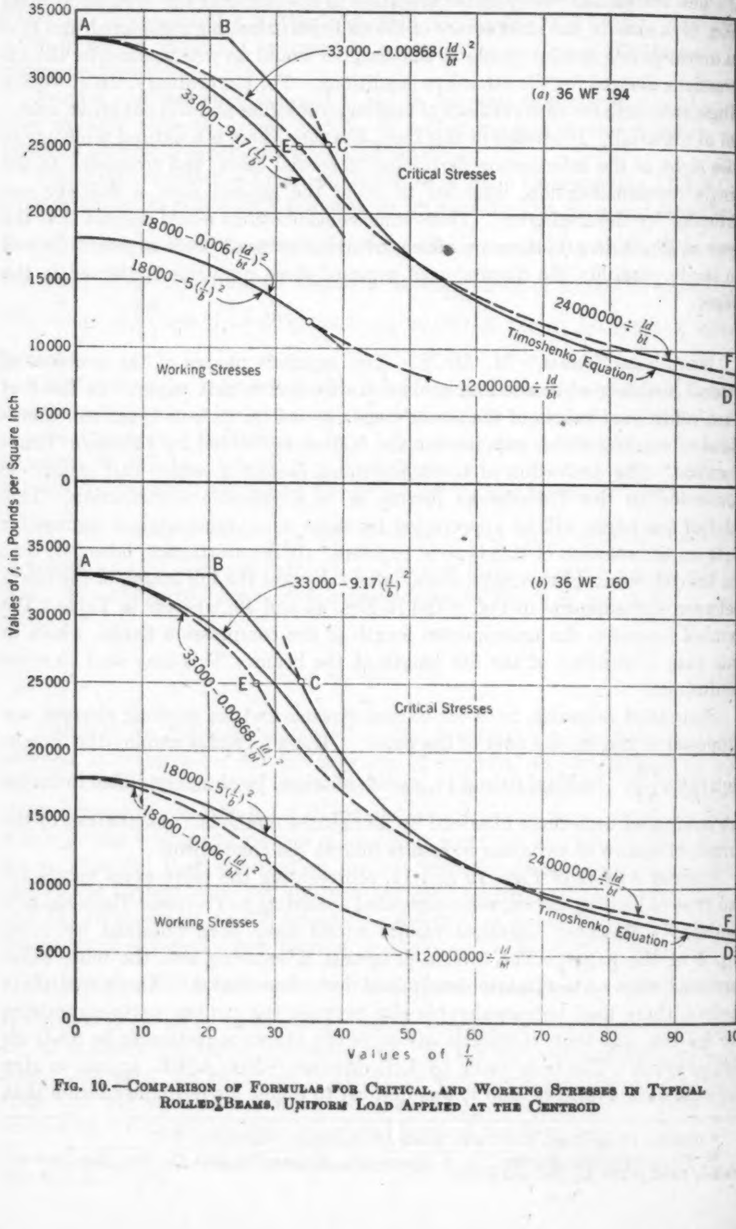


FIG. 10.—COMPARISON OF FORMULAS FOR CRITICAL, AND WORKING STRESSES IN TYPICAL ROLLED I BEAMS, UNIFORM LOAD APPLIED AT THE CENTROID

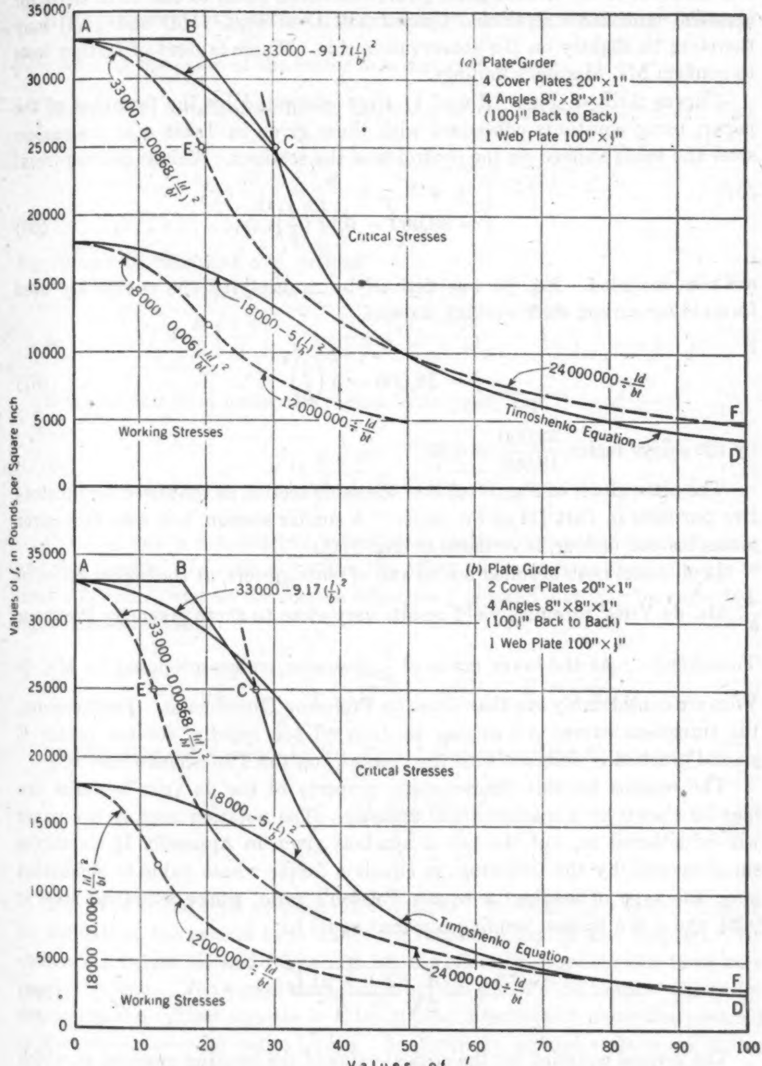

Fig. 11.—Comparison of Formulas for Critical and Working Stresses in Typical Plate Girders, Uniform Load Applied at the Centroid

the values of K for riveted plate girders be taken equal to one third those for identical monolithic sections. Curves ABCD of Figs. 11(a) and 11(b) may therefore be slightly on the conservative side. There is need of further tests to confirm Mr. Madsen's findings.

Curves AEF of Figs. 10 and 11 were computed by the formulas of the paper, using constants consistent with those given in Table 4(a) for carbon steel and loads applied on the centroids of the sections. Values derived from:

$$f = 33{,}000 - 9.17 \left(\frac{l}{b}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (66)$$

are also included. Eq. 66 was derived by multiplying the commonly used formula for carbon steel working stresses,

$$f = 18{,}000 - 5 \left(\frac{l}{b}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (67)$$

by the safety factor $\dfrac{33{,}000}{18{,}000} = 1.83$.

The plate girder of Fig. 11(a) is of the same section as that used for illustrative purposes in Part III of the paper. A similar section, but with two cover plates instead of four, is included in Fig. 11(b).

In all cases, both of rolled beams and of plate girders, at the higher ratios of $\dfrac{l}{b}$, Mr. de Vries' formulas yield results very close to those given by Professor Timoshenko. At the lower ratios of $\dfrac{l}{b}$, however, values proposed by Mr. de Vries are considerably less than those by Professor Timoshenko. Furthermore, the transition curves AE appear to drop off too rapidly, for the points E should practically coincide with the points C on the Timoshenko curves.

The reasons for this characteristic property of the de Vries formulas can best be shown by a mathematical analysis. The notation used in the paper will be adhered to, but the list of symbols given in Appendix II should be supplemented by the following: m equals a factor whose value is dependent upon the type of loading; μ equals Poisson's ratio, whose value for steel is 0.30; and a is a torsion bending constant equal to:

$$a = \frac{d}{2}\sqrt{\frac{2(1+\mu)\, I_y}{K}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (68)$$

The general equation for the critical value of the bending moment at which buckling occurs is:[2]

$$M = \frac{m\sqrt{B\,C}}{l} \quad \ldots\ldots\ldots\ldots\ldots\ldots (69)$$

It is convenient to consider a beam subjected to pure bending, since for pure bending the value of the factor m is simply:[32] $m = \pi \sqrt{1 + \pi^2 \frac{a^2}{l^2}}$.

Making this substitution for m, the value of the critical compressive fiber stress is:

$$f = \frac{M\,y}{I} = \frac{d}{2\,I_x}\,\pi\,\sqrt{1 + \pi^2\frac{a^2}{l^2}}\;\frac{\sqrt{B\,C}}{l} \ldots\ldots\ldots\ldots\ldots (70)$$

Eq. 70 may be expanded and written:

$$f = \frac{E}{2}\left(\frac{\pi\,d}{l}\right)^2 \sqrt{\left(\frac{l}{\pi\,d\,I_x}\right)^2 \frac{I_y}{2}\,\frac{K}{(1+\mu)} + \left(\frac{I_y}{2\,I_x}\right)^2} \ldots\ldots\ldots (71)$$

If the second term under the radical is dropped, Eq. 71 becomes:

$$f = \frac{E\,\pi\,d}{2\,l\,I_x}\sqrt{\frac{I_y\,K}{2\,(1+\mu)}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (72)$$

Consider now a symmetrical rolled beam section, consisting of a web plate and two flanges. In such a section, the effect of the web on the moments of inertia I_x and I_y and on the torsion constant K is small and may be neglected. Approximately, then,

$$I_x = \frac{b\,t\,d^2}{2}; \qquad I_y = \frac{b^3\,t}{6}; \qquad \text{and} \qquad K = \frac{2\,b\,t^3}{3} \ldots\ldots\ldots (73)$$

Substituting these values in Eq. 72 and also evaluating E, μ, and π,

$$f = \frac{19{,}483{,}000}{\frac{l\,d}{b\,t}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (74)$$

Eq. 74 is of the type proposed in the paper. It should be recalled that, in its derivation, the second term under the radical in Eq. 71 was dropped. By comparing curves (*b*) and (*c*) of Fig. 12, the effect of dropping this term may readily be seen. The curves were computed for a 36WF160 beam. Curve (*a*) represents the critical stresses in a beam loaded uniformly along the centroid of the section over its entire length. In curve (*b*), critical stresses are shown for a beam subjected to pure bending. The ordinates of curve (*b*) were computed by Eq. 71. The ordinates of curve (*c*) were computed by Eq. 74. There is fairly close agreement between curves (*a*) and (*b*), indicating that the error

[32] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1936, p. 259, Chapter V.

introduced by assuming pure bending is not great. Curves (*b*) and (*c*) agree closely at the higher ratios of l/b, but curve (*c*) is considerably below curve (*b*) at the lower ratios of l/b.

Applying Eq. 71 to the solution of the 36WF160 beam, the following comparisons may be made:

$$\frac{l}{b} = 20; \qquad f = 3{,}331{,}100 \times \sqrt{0.00005854 + 0.00019994} = 53{,}500$$

$$\frac{l}{b} = 100; \qquad f = 133{,}250 \times \sqrt{0.00146344 + 0.00019994} = 5{,}430$$

For $l/b = 20$, the value of the second term under the radical is more than three times that of the first term, whereas for $l/b = 100$, the value of the second term is less than one seventh that of the first. Obviously for short beams (low values of l/b), the second term may not be ignored, as was done in Eqs. 72 and 74.

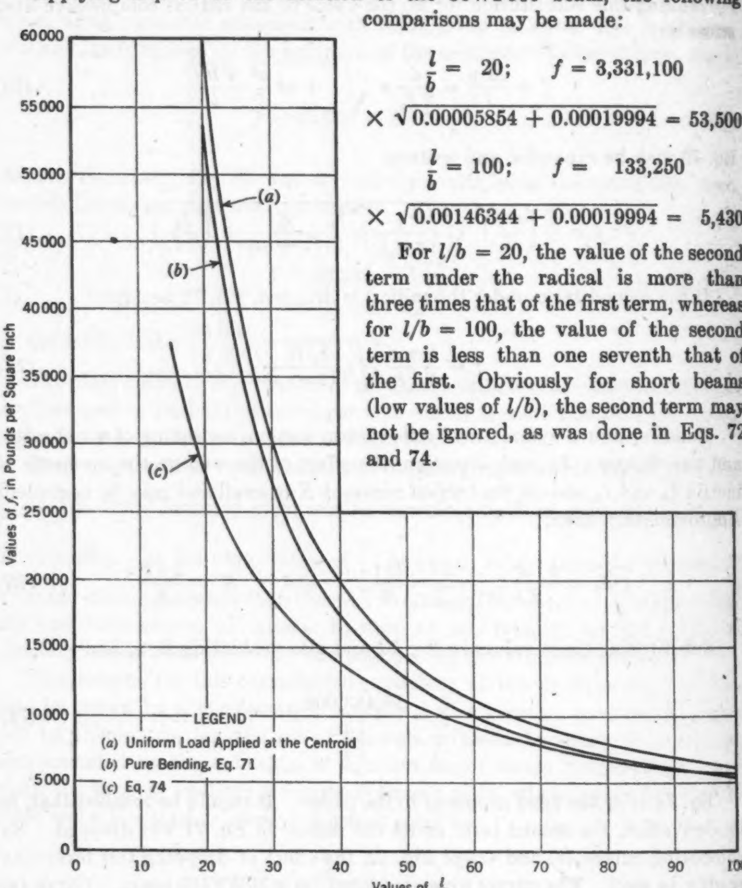

FIG. 12.—COMPARISON OF CRITICAL STRESS FORMULAS AS APPLIED TO 36WF160 BEAM

The foregoing analysis applies particularly to symmetrical, rolled sections consisting of one web plate and two flanges. For built-up girders, consisting of flange angles, cover plates, and web plate, the approximations of Eq. 73 are no longer valid, since a large part of the flange area is concentrated in the flange angles. For this reason, the de Vries formulas do not accurately reflect the effect on the critical stresses of making minor changes in the cross section

of a girder. For example, in Figs. 11(*a*) and 11(*b*), by comparing the curves ABCD, the reduction in critical stress due to the omission of the two cover plates is seen to vary between 20% and 25%. On the other hand, curves AEF, representing the de Vries formulas, indicate a constant reduction of 37.5% for all values of l/b greater than 20.

The formulas proposed in the paper are particularly applicable to rolled beams with high ratios of unsupported flange length to flange width, but they should not be applied to beams with low ratios of unsupported flange length to flange width.

H. N. Hill,[33] Assoc. M. ASCE.—Inadequacy of the ratio of unsupported span length to flange width $\left(\frac{l}{b}\right)$ as a criterion of the stability of a compression flange against lateral buckling has long been recognized. As early as 1924 S. Timoshenko[34] indicated this inadequacy and presented theoretical solutions for the problem of lateral buckling of I-beams under various loading conditions. There remained, however, the task of reducing the complicated theoretical solutions to some simplified form that could be conveniently applied by the designing engineer and yet that would retain a satisfactory degree of accuracy. The significant contribution of the present paper lies in the development of a simple parameter relating the stability of the compression flange to the dimensions of an I-beam, with sufficient accuracy for many desgin purposes.

The price of simplicity in design formulas is generally a restriction in the field of application and the acceptance of some sacrifice in accuracy. There can be no doubt that the simple design formulas proposed by the author are a vast improvement over the usual formulas involving only l/b. Moreover, the author has demonstrated, by comparison with theoretical solutions, that, for a wide group of I-beams, the simple formulas have a degree of accuracy sufficient for many design needs. It may be well, however, to examine the limitations of these simple formulas, which can best be done by examining the steps necessary to derive the simple formulas on a rational basis.

The buckling stress in the compressive flange of a symmetrical I-beam, with loads applied at the neutral axis, can be expressed as:

$$f_{cr} = R\sqrt{\frac{I_y K d^2}{I^2_x l^2} + T\frac{I^2_y d^4}{I^2_x l^4}} \quad \text{.....................(75)}$$

in which

$$R = \frac{c}{2}\frac{E}{\sqrt{2(1+\mu)}} \quad \text{.....................(76)}$$

$$T = \frac{2(1+\mu)\pi^2}{4} \quad \text{.....................(77)}$$

$$I^2_y = \frac{b^6 t^2}{36}\ ;\ I^2_x = U\frac{b^2 t^2 d^4}{4} \quad \text{.....................(78)}$$

[33] Asst. Chf. Engr., Design Div. of Research Laboratories, Aluminum Co. of America, New Kensington, Pa.

[34] "Beams Without Lateral Support," by S. Timoshenko, *Transactions*, ASCE, Vol. LXXXVII, 1924, p. 1247.

and

$$K = W \frac{2\,b\,t^3}{3} \qquad (79)$$

In Eqs. 76 through 79, c is a coefficient dependent on the nature of loading and restraint; μ is Poisson's ratio; U is equal to $\left(1 + \frac{t_w\,d}{6\,b\,t}\right)^2$; W is equal to $1 + \frac{t_w^3\,d}{2\,b\,t^3}$; and t_w is the thickness of the beam or girder web.

By substitution in Eq. 75,

$$f_{cr} = R \sqrt{\frac{4}{9}\frac{W}{U}\frac{b^2\,t^2}{d^2\,l^2} + \frac{T}{9}\frac{1}{U}\frac{b^4}{l^4}} \qquad (80)$$

For steel beams, in which $E = 29{,}000{,}000$ and $\mu = 0.28$, $R = 9{,}060{,}000\,c$ and $T = 6.31$. To evaluate U and W, twenty-three I-sections representing extremes in wide flange beams, light beams, joists, and American standard beams have been considered. The limiting values obtained are $0.75 < \frac{W}{U} < 1.07$ and $0.44 < \frac{1}{U} < 0.81$. Eq. 80 can now be written:

$$f_{cr} = 9{,}060{,}000\,c \sqrt{C_1 \left(\frac{b}{l}\right)^2 \left(\frac{t}{d}\right)^2 + C_2 \left(\frac{b}{l}\right)^4} \qquad (81)$$

in which $0.33 < C_1 < 0.48$ and $0.31 < C_2 < 0.57$.

An equation similar in form to Eq. 7 can be obtained by neglecting the second term under the radical in Eq. 81, which then becomes

$$f_{cr} = \frac{9{,}060{,}000\,c\,\sqrt{C_1}}{\dfrac{l\,d}{b\,t}} \qquad (82)$$

For a uniformly distributed load at the neutral axis and the ends of the unsupported length simply supported against lateral deflection, c is equal to 3.54.[35] Comparing Eq. 82 with the equation for long beams for case (*b*), Fig. 4, $32{,}100{,}000\,\sqrt{C_1} = 24{,}000{,}000$; or $\sqrt{C_1} = 0.748$. According to the limiting values for C_1 in Eq. 81, for the group of I-sections considered, $\sqrt{C_1}$ may be as low as 0.575. Consequently, for beams having extremely large values of l/b (in which case the second term under the radical in Eq. 81 is truly negligible), the author's equation can give buckling stress values as much as 30% higher than the theoretically correct values. This situation can only obtain in extremely long spans of narrow flange beams, which will buckle at very low stresses, and is very probably of no importance in ordinary design problems. It may be well to keep this limitation in mind, however, in certain handling and erection problems involving long narrow beams.

The inaccuracies introduced by neglecting the second term under the radical of Eq. 81 will depend on the unsupported span length of the beam. Since the

[35] "The Lateral Instability of Deep Rectangular Beams," by C. Dumont and H. N. Hill, *Technical Note No. 601*, National Advisory Committee for Aeronautics, Washington, D. C., 1937.

second term varies inversely as l^4 and the first term varies inversely as l^2, it is apparent that the importance of the second term increases as the span length decreases. This accounts for the increased discrepancy between the plotted points and the curves (within the region of elastic action) as l decreases in the plots of Figs. 2, 4, and 5. The curves become increasingly conservative as the span length decreases. Again the discrepancies, as indicated by the plots in Figs. 2, 4, and 5, do not constitute a valid objection to the use of the proposed formulas for general design of standard solid section I-beams of structural grade steels. When dealing with high-strength alloy steels and high-strength lightweight alloys of aluminum and magnesium, however, relatively short beams can buckle at stresses within the elastic range. In such cases, theoretical buckling stress values may be more than 50% greater than the values obtained by simplified formulas like Eq. 7. In structures in which these materials are used, lightweight is generally of primary importance, and the introduction of refinements in design is warranted to secure maximum weight saving. Such refinements in design usually entail some sacrifice in simplicity of design formulas.

Possibly the earliest instance of the inclusion of a rational treatment of the lateral buckling problem in a set of design rules is the "Structural Aluminum Handbook,"[36] published in 1938. The treatment is based on a direct application of Eq. 75, for the case of a beam under pure bending, with the ends of the laterally unsupported length simply supported against lateral deflection. The value of c in Eq. 76 for this case is π. (Values of c for numerous other conditions of loading—on the neutral axis—and restraint are available.[35] The fact that the author has been able to represent the cases of flange loading by the same type of formula as that applicable to loading on the neutral axis, and with about the same degree of accuracy, suggests that the cases of flange loading might also be adequately represented by Eq. 75, by substitution of the proper value for c.) Since the equivalent slenderness ratio method is used throughout this handbook to handle buckling in the plastic range, the buckling parameter is expressed in terms of an equivalent radius of gyration ρ:

$$\rho = \sqrt{\frac{0.2}{S_e} \sqrt{I_y(K\, l^2 + 13.1\, I_f\, d^2)}} \qquad (83)$$

in which S_e is the section modulus about the axis normal to the web (compression side); and I_f is the moment of inertia of the compression flange about an axis through the centroid of the flange, parallel to the web ($I_f = \frac{I_y}{2}$ for symmetrical I-sections—the term I_f being introduced to make the equation applicable to I-sections with unequal flanges).

Although the above equation may have a formidable appearance to a designer accustomed to the utmost simplicity in design formulas, the quantities involved are handbook values, or, in the case of I_f, are easily computed, and the mathematical manipulations involved can be readily and rapidly performed

[36] "Structural Aluminum Handbook," Aluminum Co. of America, 1938.

with the aid of a slide rule. When designing lightweight structures in high-strength and low-modulus materials, the appreciable saving in weight that may be realized by the use of the more complicated Eq. 83 will easily outweigh the slight increase in effort required for its application.

The author is to be highly commended for having developed the simple buckling parameter $\frac{l\,d}{d\,t}$ for I-beams and for having proposed a set of simple design formulas which should adequately handle most design problems concerned with the lateral buckling of solid I-beams of structural grade steels. The writer feels, however, that it is desirable that the limitations of design formulas based on this parameter be recognized, and it is important that such formulas shall not be considered as providing adequate design methods for all problems involving the lateral buckling of beams.

H. D. Hussey,[37] M. ASCE.—There has been a need for a formula that takes account of the torsional property of the beam. The basic theory of slender beams has been published for many years, but it has remained for Mr. de Vries to demonstrate how it can be put into simple form.

Eq. 9 appears unduly conservative for use as a general design formula. The author has considered several types of loading but he has omitted any reference to a beam under pure bending, which is the most general form of beam loading. Loadings covered by the author should be considered only as special cases. A formula will be developed, in this discussion, for a beam under pure bending.

When an abstract of this paper was read at the Annual Meeting of the Society in 1945, the following beam formulas were in general use: American Institute of Steel Construction specifications for buildings—

$$f_a = \frac{22{,}500}{1 + \frac{l^2}{1{,}800\,b^2}} \quad \text{(maximum 20,000)} \qquad \text{(84a)}$$

and American Railway Engineering Association and American Association of State Highway Officials specifications for bridges—

$$f_a = 18{,}000 - 5\,\frac{l^2}{b^2} \qquad \text{(84b)}$$

in which f_a is the maximum allowable compressive unit stress in bending. When Eq. 9 is written in the form—

$$f_a = \frac{12{,}000{,}000\; t/d}{\frac{l}{b}} \qquad \text{(84c)}$$

—the stresses f_a can be plotted as ordinates against the corresponding ratio l/b as abscissas. Each beam will thus be represented by a separate graph, de-

[37] Designing Engr., Am. Bridge Co., New York, N. Y.

pending upon the value of the ratio t/d, as shown in Fig. 13. Curves for Eq. 84*c* in Fig. 13 represent the following beam sections: (*a*) 12 B 14 J (t/d = 0.0188); (*b*) 12 B 16½ L (t/d = 0.0224); (*c*) 30WF108 (t/d = 0.0255); and (*d*) 36WF230 (t/d = 0.0351). There are more than forty rolled beams with values of t/d less than 0.0351. These include practically all the popular lightweight sections of each depth. It will be noted that the strength of these forty beams, when calculated by Eq. 84*c*, is considerably less than when calculated by Eq. 84*a*. The strength of many of these beams falls far below that represented by Eq. 84*b*, in spite of the fact that their strength is derived from a basic unit stress of 20,000 and that Eq. 84*b* is based on 18,000.

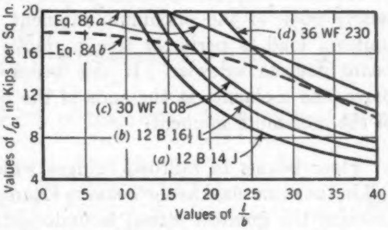

FIG. 13.—ALLOWABLE STRESSES FOR A SIMPLE BEAM, AS COMPUTED BY EQS. 84

For example, the solution of Eq. 84*a*, for an assumed ratio l/b = 30, yields a value of f_a = 15,000. In contrast with this, the corresponding value of f_a for the following beams, when calculated by Eq. 84*c*, is:

Section	
30WF108.............	10,200
12 B 16½ L............	8,960
12 B 14 J..............	7,520

These examples show that the allowable stresses for many beams, when derived from Eq. 84*a*, were actually at, or near, the critical stresses as determined by Eq. 9.

It is interesting to analyze the loads and moments on typical beams, as is done in the following problems:

Example 1.—The theory of lateral buckling of beams, as illustrated by Fig. 1, is based on a simply supported beam in which the moment diagram varies from zero at the two ends to a maximum value at the center. When the unsupported length of the beam is less than the beam span, the moment diagram for this part of the span is different from that for the entire beam in having moments at the two ends.

Example 2.—Assume that a beam supports two equal concentrated loads symmetrically spaced on the beam, and that the loads divide the beam into three unsupported parts. When the three parts are isolated it is found that the middle part is under pure bending and each of the two end lengths has a moment diagram which varies from zero at one end to a maximum at the other.

Example 3.—Next assume that the beam in Fig. 1, which supports a single concentrated load at its center, is so long that it is held laterally at the third points, dividing the beam into three unsupported lengths. Assume, also, that the concentrated load is perfectly free to move transversely with the beam as the beam deflects sidewise, as shown in Fig. 1. The middle third of this

beam has a maximum moment at its center, but there are moments at the two ends of this part that are two thirds as great as the maximum moment.

Example 4.—If the load on the beam in Example 3 were uniform, instead of concentrated, the moment at the two ends of the middle third would be nearly 90% of the maximum moment. It is assumed, of course, that the uniform load is perfectly free to move transversely with the beam as the beam deflects sidewise. If this beam were divided into more than three parts, the moments at the ends of the middle part would be more than 90% of the maximum moment.

Floor beams in railroad bridges which have symmetrically placed loads, fall in the same class as the beam in Example 2. The middle of the beam, which sustains the greatest stress, is under pure bending. Deck plate girders and stringers in the ordinary railroad bridge are in the class with the beam in Example 4, which has a uniform load. A long deck girder is divided into many panels by the lateral system. If one panel near the center of this girder is isolated, moments will be found at the ends of this panel that are nearly as great as the maximum moment in the panel. The uniform load on the top flange of the girder produces very little change in moment throughout the length of the panel. The principal effect of this top flange load is to contribute to the moments at the two ends of the panel. This girder, therefore, should be considered as a beam under pure bending and not as a beam under top flange loading.

One of the principal considerations in this problem is the nature of the load supported by the beam. To apply this beam theory to a practical problem, the load must be perfectly free to move transversely with the beam as the beam deflects sidewise. If the load is not free to move sidewise, the problem is changed radically and the compression flange is greatly strengthened. For example, if the load in Fig. 1 is applied at the top flange of the beam and the load is perfectly free to move sidewise, the strength of the beam is proportional to the values of the factor k as given in Col. 2, Table 1. However, if this load is not free to move sidewise, the problem is transformed into the problem illustrated in Fig. 8, and the strength of the beam is proportional to the factor k as given in Col. 8, Table 1. The strength of the latter beam is much greater than that of the former.

The number of beams in actual structures, which support loads that are perfectly free to move sidewise, is so small that such beams should be considered as special cases. A trolley beam, for instance, which supports a free concentrated load at the bottom flange, is 50% to 150% stronger than the beam used by the author in developing his proposed Eq. 9.

It is apparent from Eq. 4 that there are three fundamental variables in the solution of the beam problem—length, section, and type of loading. In attempting to present a simple formula the author has included only the first two of these variables in the parameter, $l\,d/(b\,t)$, of Eq. 9. He has covered the third variable, the type of loading, by using a single constant—12,000,000—which produces a formula that is safe for the most severe loading, irrespective of the frequency of its occurrence.

S. Timoshenko[38] has demonstrated the theory of beams subjected to pure bending. The value of the critical moment for this type of loading may be expressed as follows:

$$M_{cr} = \frac{\pi^2 E I_y}{l^2} \frac{d}{2} \sqrt{1 + \frac{K l^2}{6.4 I_y d^2}} \text{ (assuming } \nu = 0.30) \ldots\ldots (85)$$

in which ν is Poisson's ratio. The value of the critical buckling unit stress (for a symmetrical section) is:

$$f = \frac{\pi^2 E}{4 \left(\frac{l r_x}{r_y d}\right)^2} \sqrt{1 + \frac{K l^2}{6.4 I_y d^2}} \ldots\ldots\ldots\ldots\ldots\ldots (86)$$

in which r_x and r_y are the radii of gyration about the x-axis and y-axis, respectively.

Eq. 86 may be simplified by the use of two close approximations. First, the ratio $\frac{d}{r_x}$ for rolled beam sections is nearly constant and equal to 2.45. Second, the torsion constant K can be represented for rolled beam sections by the approximate formula:

$$K = 0.30 A_s t^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (87)$$

in which A_s is the sectional area of the beam and t is the thickness of the flanges. (Eq. 87 is exact for many sections. Since K is under the radical in Eq. 86, any error due to the use of Eq. 87 has only a small effect on the value of the critical stress.)

Making use of Eq. 87 and assuming that $\left(\frac{d}{r_x}\right)^2 = 6$, Eq. 86 becomes:

$$f = \frac{444{,}000{,}000}{\left(\frac{l}{r_y}\right)^2} \sqrt{1 + \frac{1}{22}\left(\frac{l t}{r_y d}\right)^2} \ldots\ldots\ldots\ldots (88a)$$

The critical buckling stress for rolled beams may be written:

$$f = \frac{444{,}000{,}000}{\left(n \frac{l}{r_y}\right)^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (88b)$$

in which

$$n^2 = \frac{1}{\sqrt{1 + \frac{1}{22}\left(\frac{l t}{r_y d}\right)^2}} \ldots\ldots\ldots\ldots\ldots\ldots (89)$$

[38] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1936, p. 259.

Numerical values of n are as follows:

$\frac{lt}{r_y d}$	n	$\frac{lt}{r_y d}$	n
0	1.00	8	0.71
1	0.99	10	0.65
2	0.96	12	0.60
3	0.92	14	0.56
4	0.87	16	0.53
5	0.83	18	0.50
6	0.79	20	0.48
		24	0.44

A formula for working stresses can be obtained by dividing Eq. 88*b* by an appropriate factor of safety. Using a factor of safety of 1.65, for instance, the working formula becomes:

$$f_a = \frac{270{,}000{,}000}{\left(n\,\frac{l}{r_y}\right)^2} \qquad (90a)$$

Eq. 90*a* may be expressed in a very simple form as follows:

$$f_a = \left[\frac{16{,}400}{n\,\frac{l}{r_y}}\right]^2 \qquad (90b)$$

Eq. 90*b* avoids the use of large numbers that are involved in the solution of Eq. 90*a*.

By Eq. 90*b*, with $l/b = 30$, $l/r_y = 153$, $\frac{l\,t}{r_y\,d} = 3.9$, and $n = 0.875$, the allowable unit stress for the 30WF108 beam is 15,000. This is in sharp contrast with the value of 10,200 determined by Eq. 9 and agrees exactly with the value of 15,000 obtained by the use of Eq. 84*a*. Values of the coefficient k in Eq. 4, for a beam subject to pure bending, are as follows:

$\frac{l}{a}$	k	$\frac{l}{a}$	k
2	2.926	8	6.753
3	3.413	9	7.490
4	3.996	10	8.236
5	4.640	11	8.988
6	5.322	12	9.746
7	6.029	13	10.51
		14	11.27

A comparison of these values of k with those given in Table 1 reveals that a beam supporting a uniform load at the centroid of the section is 13% stronger, and when supporting a concentrated load at its centroid it is 36% stronger, than it is under pure bending.

The author mentions the erection problem of picking long beams at the ends, as a condition of a uniform load at the centroid. It will be recognized that a long beam hanging in erection slings is not the same problem as the beam shown in Fig. 1. The ends of the beam in Fig. 1 are held in a vertical position against rotation. When a beam is picked off the ground, however, the ends can rotate as the beam buckles laterally. It is hoped that the author will extend his investigation to cover this particular condition.

This problem is of such interest to erection engineers that it deserves further study. One can compute the span length at which a simple-span beam will buckle from its own weight, when the ends are blocked so that they cannot rotate. Using Eq. 85, and increasing it by 13% to make it applicable to a uniform load, will give the critical moment at which such a beam will buckle. Substituting $\frac{w\,l^2}{8}$ for the moment produces an equation from which the desired length can be determined.

When solving Eq. 85 for long beams, the numerical value of the second term under the radical sign becomes so great as compared to unity, that the latter may be neglected. A solution of Eq. 85 then becomes:

$$M_{cr} = \frac{\pi^2 E\,I_y}{5\,l}\sqrt{\frac{K}{I_y}}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(91)$$

Increasing Eq. 91 by 13%, and substituting $M_{cr} = \frac{w\,l^2}{8}$ and $K = 0.30\,A_s\,t^2$, leads to the following equation for rolled beams:

$$l^3 = 9.77\,\frac{E\,A_s\,t\,r_y}{w}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(92a)$$

in which w equals the weight of the beam per inch. Noting that, for steel beams, $w/A_s = 0.2833$ lb (the weight of 1 cu in. of steel), the following simple equation can be written:

$$l = 1{,}016\,\sqrt[3]{r_y\,t}\text{ (inches)}\ldots\ldots\ldots\ldots\ldots\ldots(92b)$$

Eq. 92*b* gives the length of a simple span rolled beam which will buckle from its own weight. For example, $l = 110$ ft for a 36WF150, and 98 ft for a 30WF108 beam.

If the foregoing simple-span beam is picked up at the ends, the web blocking has been removed and the ends can rotate as the beam deflects laterally. While hanging in the slings, the centers of the two supports will lie in the vertical plane which passes through the center of gravity of the beam. If the twisting of the beam is neglected (assuming an infinite torsional rigidity) and lateral deflection only is considered, the following formula can be derived:

$$l^4 = 120\,\frac{E\,I_y\,h}{w}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(92c)$$

in which h is the distance from the support to the centroid of the beam, in the plane of the web. If the slings are attached to the top flange of the beam, h

may be assumed equal to $d/2$. For this case Eq. 92c becomes:

$$l^4 = 60 \frac{E\, I_y\, d}{w} \qquad \text{(92d)}$$

Introducing the value of $w/A_s = 0.2833$ for steel beams, Eq. 92d reduces to:

$$l = 282 \sqrt[4]{r_y^2\, d} \text{ (inches)} \qquad \text{(92e)}$$

Solving Eq. 92e for the beams considered in connection with Eq. 92b a length of 89 ft is determined for a 36WF150 beam, and 79 ft for a 30WF108 beam.

Eq. 92e gives the length at which a steel beam will buckle when hanging in slings at the ends, assuming that the torsional rigidity of the beam is infinite. If the true torsional rigidity of the beam were considered, the correct length should be less than that found by Eq. 92e.

Acknowledgment.—The writer wishes to acknowledge the assistance given to him by George E. Howe and C. W. Wixom, Members, ASCE, in the preparation of this discussion. The former was the first to indicate the extremely low unit stresses permitted by Eq. 9 for L-beams and J-beams, as compared with those derived from Eq. 84a. The latter suggested the form of Eq. 90b.

H. G. BRAMELD,[39] ESQ.—An excellent case is made for approximate formulas for critical and working buckling stresses, in so far as rolled steel joists are concerned. Unfortunately, agreement with the fundamental equation (Eq. 4) is not good in the case of plate girders with thin flanges. Startling results were obtained when the equations were applied to the girders of a bridge in which the writer is interested.

The girders vary in depth from 86 in. to 170 in. and are braced laterally at intervals of 22 ft. Their properties are as follows:

Case I.—Depth: 86 in. Make-up: Two flange plates, 18 in. by $\frac{3}{8}$ in.; four flange angles, 8 in. by 8 in. by $\frac{5}{8}$ in.; and one web plate, 84 in. by $\frac{3}{8}$ in. For this section, $I_y = 818$ in.^{4}; $I_x = 108{,}000$ in.^{4}; and the torsion constant = 26.6. The equivalent thickness of the compression flange is found to be $\frac{6\, I_y}{b^3} = 0.84$ in. From Eq. 7, $f = \dfrac{20{,}000{,}000}{\dfrac{l\, d}{b\, t}} = \dfrac{20{,}000{,}000}{\dfrac{264 \times 86}{18 \times 0.84}} = 13{,}400$ lb per sq in. However, by extrapolation of k in Table 1, with $a = 0.806\, d \sqrt{\dfrac{I_y}{k}} = 380$ in., and $k = 2.9$, Eq. 4 yields $f = \dfrac{818 \times 86^2}{108{,}000 \times 380^2} \times 29{,}000{,}000 \times \dfrac{380^2}{264^2} \times 2.9 = 67{,}000$ lb per sq in., or just five times the approximate result.

[39] Designing Engr., Bridge Board, Brisbane, Queensland, Australia.

Case II.—Depth: 170 in. Make-up: One web plate, 168 in. by $\frac{3}{8}$ in., with flanges the same as in case I. By Eq. 7, f = 6,750 lb per sq in. and, by Eq. 4, f = 48,000 lb per sq in.

Case III.—Depth: 86 in. Make-up: Six flange plates, 18 in. by $\frac{3}{8}$ in.; four flange angles, 8 in. by 8 in. by $\frac{5}{8}$ in.; and one web plate, 84 in. by $\frac{3}{8}$ in. By Eq. 7, f = 21,000 lb per sq in. and, by Eq. 4, f = 90,000 lb per sq in.

Case IV.—Depth: 170 in. Make-up: One web plate, 168 in. by $\frac{3}{8}$ in., with flanges the same as in case III. By Eq. 7, f = 10,700 lb per sq in. and, by Eq. 4, f = 64,000 lb per sq in.

These girder flanges when treated as struts were found to have a safe stress between 16,000 lb per sq in. and 17,000 lb per sq in., consistent with an intrinsic eccentricity of 0.45 in. and an extreme fiber stress of 20,000 lb per sq in. It is apparent, therefore, that the equation for safe working stresses cannot reasonably be applied to deep plate girders and that this fact should be noted in codes using the new formula.

EDWIN H. GAYLORD,[40] ASSOC. M. ASCE.—In a previous paper on the strength of beams as determined by lateral buckling,[41] it was suggested that the critical stress for a simply supported beam subjected to pure bending could be used as a design criterion for most cases of transverse loading. From the formula for the critical bending moment in pure flexure,[27] it can be shown that the critical stress is expressed by Eq. 4 with the factor k given by:

$$k = \frac{\pi^2}{4}\sqrt{1 + \frac{1}{\pi^2}\left(\frac{l}{a}\right)^2} \qquad (93)$$

Eq. 7 can be obtained from Eq. 4 by substituting approximate values for I_x, I_y, and the torsion constant K, using the value of k given by Eq. 93, with the first term under the radical omitted so that,

$$k = \frac{\pi\, l}{4\, a} \qquad (94)$$

Values of k computed from Eqs. 93 and 94 are given in Cols. 3 and 5, respectively, Table 8. In the same table, Col. 2 gives values of k for a uniform load applied at the top flange. These values are taken from Col. 5, Table 1, except as noted. Granting that a design formula should be based on the case of a uniform load applied at the top flange, the errors involved in using the k-values of Cols. 3 and 5 are indicated in Cols. 4 and 6, Table 8. For small values of l/a, both approximate values of k are considerably in error.

Since Eq. 93 overestimates values of k for small l/a-ratios, whereas Eq. 94 underestimates them, it is evident that a better value might be obtained by arbitrarily reducing the first term under the radical of Eq. 93. Col. 7, Table

[40] Prof. and Chairman, Dept. of Civ. Eng., Ohio Univ., Athens, Ohio.

[41] "Strength of Slender Beams," by George Winter, *Transactions*, ASCE, Vol. 109, 1944, p. 1339.

8, gives values of k computed from the equation:

$$k = \frac{\pi^2}{4} \sqrt{0.50 + \frac{1}{\pi^2}\left(\frac{l}{a}\right)^2} \quad \text{(95)}$$

Col. 8 shows that these values check very well with those of Col. 2, even for the extreme values of l/a which were not included in Table 1.

[a] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1936, pp. 268 and 269, Table 23 and Eq. (h).

Eq. 95 can be put into more convenient form by using the first two terms of the binomial expansion for $\sqrt{1 + x}$. If $x \leqq 1$, the error of this approximation does not exceed $+6\%$. The equation may be written:

$$k = 0.707 \frac{\pi^2}{4} \sqrt{1 + 0.203 \left(\frac{l}{a}\right)^2} \quad \text{(96a)}$$

and also,

$$k = \frac{\pi}{4}\frac{l}{a} \sqrt{1 + 4.93 \left(\frac{a}{l}\right)^2} \quad \text{(96b)}$$

From these equations:

$$k = 1.745 \left[1 + 0.075 \left(\frac{l}{a}\right)^2 \right] \quad \text{(97a)}$$

$$k = \frac{\pi}{4}\frac{l}{a} \left[1 + 1.75 \left(\frac{a}{l}\right)^2 \right] \quad \text{(97b)}$$

The coefficient of the second term in the brackets has been reduced from its binomial expansion value. This was done because the effect of this term is greatest in the region where the k-values of Col. 7, Table 8, are most in excess of the values of Col. 2. The equations give approximately equal values when

$l/a = 2$. Eq. 97*a* is to be used if $l/a < 2$, and Eq. 97*b* if $l/a \geqq 2$. Col. 9, Table 8, gives values of k computed from Eqs. 97; and Col. 10 compares these values with those of Col. 2.

If the values of k from Eqs. 97 are substituted in Eq. 4, with $E = 30 \times 10^6$ lb per sq in.,

$$f = \frac{52.3 \times 10^6}{\frac{I_x}{I_y}\left(\frac{l}{d}\right)^2}\left[1 + 0.075\left(\frac{l}{a}\right)^2\right] \text{ if } l/a < 2 \ldots\ldots\ldots (98a)$$

$$= \frac{23.6 \times 10^6}{\frac{I_x}{I_y}\left(\frac{l}{d}\right)^2}\left(\frac{l}{a} + 1.75\frac{a}{l}\right) \text{ if } l/a \geqq 2 \ldots\ldots\ldots\ldots (98b)$$

Applying the factor of safety used by the author to Eqs. 98, formulas for design are:

$$f = \frac{31.5 \times 10^6}{\frac{I_x}{I_y}\left(\frac{l}{d}\right)^2}\left[1 + 0.075\left(\frac{l}{a}\right)^2\right] \text{ if } l/a < 2 \ldots\ldots\ldots (99a)$$

$$f = \frac{14 \times 10^6}{\frac{I_x}{I_y}\left(\frac{l}{d}\right)^2}\left(\frac{l}{a} + 1.75\frac{a}{l}\right) \text{ if } l/a \geqq 2 \ldots\ldots\ldots\ldots (99b)$$

Except for the factor a, these equations are in terms of common properties of beams. They are relatively simple to use if tables of the factor a are available.[8] A limit for l/a beyond which the error in the use of Eq. 9 is inconsequential can be established from Table 8. If it be desired that the error not exceed 5%, then the approximate k of Col. 5 should not be used if $l/a < 5$. The error will not exceed 8% if $l/a > 4$. (This is exclusive of errors inherent in approximations to I_x, I_y, and K, through which Eq. 7 is derived from Eq. 4.)

If tables of the factor a are not available, the ratio l/a may be computed from the equation:

$$\frac{l}{a} = 1.24\frac{l}{d}\sqrt{\frac{K}{I_y}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (100)$$

This equation was derived from the relation $C = \frac{E\, I_y\, d^2}{4\, a^2}$, with Poisson's ratio equal to 0.3. The torsion constant K can be computed with sufficient accuracy in most cases by means of the familiar equation $K = \frac{1}{3}\Sigma b\, t^3$, or, if desired, by a more accurate procedure described elsewhere.[10]

Eqs. 99 may be presented in a different form by calculating I_x, I_y, and K terms of the beam flanges only, that is, $I_x = \frac{b\, t\, d^2}{2}$, $I_y = \frac{t\, b^3}{6}$, and $K = \frac{2\, b\, t^3}{3}$. However, the equations are first written in the following form, by factoring

l/a from the brackets and parentheses, and substituting from Eq. 100:

$$f = \frac{39 \times 10^6}{\frac{I_x}{\sqrt{K I_y}} \frac{l}{d}} \left(\frac{a}{l} + 0.075 \frac{l}{a} \right) \text{ if } l/a < 2 \ldots\ldots\ldots\ldots (101a)$$

$$f = \frac{17.5 \times 10^6}{\frac{I_x}{\sqrt{K I_y}} \frac{l}{d}} \left[1 + 1.75 \left(\frac{a}{l} \right)^2 \right] \text{ if } l/a \geqq 2 \ldots\ldots\ldots (101b)$$

When the substitutions for I_x, I_y, and K are made,

$$f = \frac{26 \times 10^6}{\frac{l\,d}{b\,t}} \left(\frac{a}{l} + 0.075 \frac{l}{a} \right) \text{ if } l/a < 2 \ldots\ldots\ldots\ldots (102a)$$

$$f = \frac{12 \times 10^6}{\frac{l\,d}{b\,t}} \left[1 + 1.75 \left(\frac{a}{l} \right)^2 \right] \text{ if } l/a \geqq 2 \ldots\ldots\ldots\ldots (102b)$$

The l/a-ratios in the brackets and parentheses of Eqs. 102 are not expressed in terms of l, d, b, and t because of large errors that could result. The reason for the errors is found in Eq. 100. The value of K expressed in terms of the flanges only may be in error by as much as 50%, whereas the value of I_y is practically unaffected by omitting web moment of inertia. In the substitutions outside the brackets, the error in K is compensated for by an error in I_x. For a 12 B 16.5[42] section, $K = 0.052$ in.^{4} and $I_x = 77.5$ in.^{4} if the flanges only are considered; $K = 0.098$ in.^{4} and $I_x = 105$ in.^{4} if the web is included. The ratio $I_x/\sqrt{K}$ for the true values is 336, and for the approximate values, 340. Calculations for several beams chosen at random showed variations of as much as 8%.

If values of the factor a, or K, are not available, their calculation may be avoided by writing Eq. 100 as $\frac{l}{a} = 1.24 \frac{l}{d} \frac{I_x}{I_x} \sqrt{\frac{K}{I_y}}$ and substituting the approximate values for K, I_y, and the I_x in the denominator. This procedure introduces the same compensating errors mentioned previously, and results in:

$$\frac{l}{a} = 5 \frac{l}{d} \frac{I_x}{b^2 d^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (103)$$

This value of l/a may be substituted in Eq. 102b to obtain:

$$f = \frac{12 \times 10^6}{\frac{l\,b}{d\,t}} \left[1 + 0.07 \left(\frac{b^2 d^2/I_x}{l/d} \right)^2 \right] \text{ if } \frac{l}{d} \geqq \frac{0.3\, b^2 d^2}{I_x} \ldots\ldots (104)$$

Eq. 104 should be particularly useful, since it contains only common properties of sections. After selecting a beam according to Eq. 9, the designer need calculate only the second term in the brackets to determine the percentage by

[42] "Steel Construction Manual," A.I.S.C., 5th Ed., 1947, p. 24.

which the allowable stress, as given by Eq. 9, should be increased. Eq. 102a is not written with the l/a-ratio expressed in terms of Eq. 103, because the result is cumbersome. However, for $l/a = 1.5$, the value of f given by Eq. 102b exceeds by only 5% the value given by Eq. 102a, so that Eq. 102b, or Eq. 104, probably can be safely used for $l/a \geqq 1.5$. The l/d limitation stated after Eq. 104 is based on this assumption. Thus, Eq. 104 will be applicable to the design of practically any rolled shape or plate girder, and Eq. 99a or its equivalent, Eq. 102a, may be used for light-gage beams.

A simple criterion to determine whether the second term in the brackets of Eq. 104 is significant can be established. As stated previously, if $l/a > 5$, Eq. 9 will err by about 5%. Therefore, from Eq. 103,

$$\frac{l}{d} \geqq \frac{b^2\,d^2}{I_z} \qquad (105)$$

is an index of the accuracy of Eq. 9.

One other convenient form for Eqs. 98 will be given. The radius of gyration for the axis perpendicular to the web of the I-section and the WF-section varies from about 0.375 d to 0.425 d. If an average value of $r_z = 0.41\ d$ is assumed, formulas for the critical stress for the I-section and the WF-section are:

$$f = \frac{310 \times 10^6}{\left(\frac{l}{r_y}\right)^2}\left[1 + 0.075\left(\frac{l}{a}\right)^2\right] \text{ if } l/a < 2 \qquad (106a)$$

$$f = \frac{140 \times 10^6}{\left(\frac{l}{r_y}\right)^2}\left(\frac{l}{a} + 1.75\,\frac{a}{l}\right) \text{ if } l/a \geqq 2 \qquad (106b)$$

These equations are particularly simple in form. However, they may overestimate values of f given by Eqs. 99 by as much as 10%, and may underestimate them by as much as 15%.

The following examples illustrate the use of the equations in this discussion. It is assumed that the maximum allowable bending unit stress is 20,000 lb per sq in. Since the American Institute of Steel Construction has adopted Eq. 9 in its 1947 design specifications,[43] diagrams based on that equation[44] can be used for these problems. The data given do not include the moment due to the weight of the beam.

Example 1.—A simply supported beam on a span of 55 ft is to resist a moment of 450 kip-ft. The diagrams referred to indicate that a 30WF190 section is required. For this section, $a = 121.9$ and $l/a = 5.41$. Therefore, the allowable stress is predicted with sufficient accuracy by Eq. 9. Using Eq. 105, $\frac{l}{d} = 22$ and $\frac{b^2\,d^2}{I_z} = 23.3$, which indicates that Eq. 9 is in error by somewhat over 5%. Instead of checking with Eq. 105, the second term in the brackets of Eq. 104 may be calculated. It is found to be 0.078, which shows that Eq. 9 underestimates the allowable stress by about 7%.

[43] "Steel Construction Manual," A.I.S.C., 5th Ed., 1947, p. 286.
[44] *Ibid.*, p. 203.

Example 2.—A simply supported beam on a span of 24 ft is to resist a moment of 400 kip-ft. The diagram shows that 24WF110 is the lightest section that can be used. For this section, $l/a = 288/108 = 2.67$, and, since the diagram also shows that the allowable stress was reduced for buckling, the section may be unnecessarily large. Using Eq. 105, $\frac{l}{d} = 12$ and $\frac{b^2 d^2}{I_z} = 25.5$.

The allowable stress for a 24WF100 section is given by Eqs. 99*b*, 102*b*, and 104 as 21,100, 20,800, and 22,200 lb per sq in., respectively. From Eq. 106*b*, with the factor of safety used to obtain Eq. 99*b*, $f = 22{,}300$ lb per sq in. According to Eq. 9, however, $f = 16{,}100$ lb per sq in. Since the more nearly correct values exceed the stated maximum allowable of 20,000 lb per sq in., the allowable moment is $\frac{20 \times 249}{12} = 415$ kip-ft. Because the moment due to its weight is only 7.2 kip-ft, the 24WF100 is satisfactory. Thus, in this example, a few minutes of the designer's time saves 240 lb of steel.

Example 3.—A simply supported beam on a span of 18 ft is to resist a moment of 490 kip-ft. From the diagram, a 30WF124 or a 24WF120 section may be used. The diagram shows that the allowable stress for 24WF120 is greater than 20,000 lb per sq in., and there is no need to investigate the 24 × 12-group further. However, the allowable stress for 30WF124, as given by Eq. 9, is below 20,000 lb per sq in.; and it may be underestimated. The ratio $l/a = 216/105.1 = 2.06$ shows this to be the case; or, using Eq. 105, since $\frac{l}{d} = 7.2$ and $\frac{b^2 d^2}{I_z} = 18.8$, the allowable stress is seen to be underestimated considerably. For a 30WF108 section, the allowable stress as given by Eqs. 99*b*, 102*b*, 104, and 106*b* is 22,500, 22,600, 24,400, and 21,300 lb per sq in., respectively. According to Eq. 9, $f = 14{,}900$ lb per sq in. Then $M = \frac{20 \times 299}{12} = 498$ kip-ft. The moment due to the weight of the beam is 4.4 kip-ft. In this example, the weight saving is 10% compared to section 24WF120, and 13% compared to 30WF124.

The foregoing examples have been chosen to show extreme differences; it is true that there are many cases in which comparable savings could not be made because of the necessarily limited range of standard sections. It has been assumed that Eqs. 98 apply as long as the critical stress is less than the yield point (assumed to be about 33,000 lb per sq in.). Strictly speaking, the equations are not correct if the critical stress exceeds the proportional limit. Transition curves to accompany the equations in this discussion could undoubtedly be developed, but the writer did not attempt them. The author's transition equations are subject to errors comparable to those in Eq. 7. The examples might give the impression that Eq. 7 errs only when the critical stress is in the region of the proportional limit of carbon steel. Two illustrations will show that this is not the case. The critical stress for a 12-in. 14-lb joist[42] on a span of 12 ft is 10,400 lb per sq in. according to Eq. 7, whereas Eq. 98*b* gives a critical stress of 13,900 lb per sq in. For an 8WF17 section on a span of 15 ft, Eqs. 7 and 98*b* give 22,400 and 27,000 lb per sq in., respectively. It is pertinent

to observe that the difference between the two equations is even more significant for beams of high-yield steel.

Since there are some types of loading which subject a beam to pure flexure, or at least approximately so, formulas for the critical stress for this case may be useful. Substitution of the value of k from Eq. 93, as given by the first two terms of the binomial expansion in Eq. 4, leads to the following formulas for the bending critical stress in pure bending:

$$f = \frac{74 \times 10^6}{\frac{I_x}{I_y}\left(\frac{l}{d}\right)^2}\left[1 + 0.04\left(\frac{l}{a}\right)^2\right] \text{ if } \frac{l}{a} < 3 \ldots\ldots\ldots\ldots (107a)$$

$$f = \frac{23.5 \times 10^6}{\frac{I_x}{I_y}\left(\frac{l}{d}\right)^2}\left(\frac{l}{a} + 4\frac{a}{l}\right) \text{ if } \frac{l}{a} \geqq 3 \ldots\ldots\ldots\ldots (107b)$$

The coefficient of the second term in the brackets and parentheses has been reduced from the value obtained through the binomial expansion. For $0 \leqq l/a \rightarrow \infty$, the equations give values of f which differ by a maximum of -2% from the values computed with k as given by Eq. 93. The second term in the brackets of Eq. 107a may be omitted if $l/a < 1$; and the corresponding term in Eq. 107b may be omitted if $l/a > 10$. The maximum error resulting from these omissions is about -5%. The value of l/a may be computed from Eq. 100 or Eq. 103 if tables of the factor a are not available.

Mr. de Vries is to be commended for having presented a design formula for beams subject to lateral buckling which, although eminently simple in form, is far superior to previous formulas. In most cases it predicts the critical stress with a good degree of accuracy. The writer has shown how the designer may determine the precision of the formula for any case, and easily obtain a better estimate when necessary. Furthermore, since either Eq. 99b or 102b is simpler to use than is Eq. 104, the writer suggests that the American Institute of Steel Construction list in future editions of its manual values of the factor a not only because it is useful in the problem of lateral buckling of beams, but also because it is necessary in the analysis of torsion.

Oliver G. Julian,[45] M. ASCE.—The formulas given in this paper are the acme of simplicity and far more rational than most specification requirements. With the notable exceptions of members—(a) which are unflanged, asymmetrical, or have boxed cross sections; (b) those for which $\sqrt{1 - I_y/I_x}$ is appreciably different from unity; (c) those with limber webs such that cross sections may distort in their planes so that the effective torsional rigidity of the member is not wholly effective; and (d) those with thin wide flanges such as are made from sheet metal—the author's formulas should give results which are fairly reasonable and conservative. It should be especially empha-

[45] Chf. Structural Engr., Jackson and Moreland, Cons. Engrs., Boston, Mass.

sized that, as plainly stated[46] by Professor Timoshenko, the Timoshenko formulas (with which Mr. de Vries compares his formulas) were derived for deep narrow members such as I-beams rather than wide-flanged members and do not take account of relative horizontal to vertical stiffness.

Notation.—In addition to the notation introduced by the author, the following listed letter symbols are used in this discussion:

$a^2_1 = \frac{E\,I_y}{G\,K}\left(\frac{h}{2}\right)^2$;

G = modulus of rigidity;

H = distance of the load above the shear center; if the load is below the shear center, H is negative;

h = distance between flange centroids;

j = ratio of the product of l and the critical transverse loading force to the critical moment; for pure flexure j equals unity;

m = a factor;

n = a factor;

P_{cy} = Euler's critical load for failure of a pin-ended column by flexure about a principal axis y;

P_w = Wagner's critical load for failure of a column by torsion; thus —

$$P_w = \frac{1}{\bar{r}^2}\left[G\,K + P_{cy}\left(\frac{h}{2}\right)^2\right] = \frac{G\,K}{\bar{r}^2}\left[1 + \pi^2\left(\frac{a_1}{l}\right)^2\right] \quad \text{.....(108)}$$

$\bar{r}_y$ = radius of gyration about a principal axis y;

S = section modulus about the x-axis; and

J = polar moment of inertia.

The earliest work on the elastic stability of beams with which the writer is acquainted is that of A. G. M. Michell,[47] published in 1899. Based on geometrical relations, on the differential equations of equilibrium, and on the assumption that the flexural rigidity about the y-axis may be of the same order as, or much smaller than, that about the x-axis whereas the torsional rigidity about the longitudinal z-axis is small as compared to the flexural rigidity about the x-axis, Mr. Michell derives expressions defining the critical loads for symmetrical prismatic and cylindrical beams, subjected to various types of loads including the case in which opposite forces are applied parallel to the axis at symmetrical points in the plane of the greatest rigidity. Rearranged, Mr. Michell's expression defining the first mode of instability for the latter case is

$$M^2 = \left(\frac{\pi^2}{l^2} - \frac{P}{E\,I_y}\right)\frac{E\,I_y\,G\,K}{1 - I_y/I_x} \quad \text{...............(109)}$$

in which P and M represent the concomitant critical axial load and moment, respectively. If I_y/I_x is neglected, Eq. 109 is identical with the result[48] given

[46] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1936, p. 239 et seq.; also see section headings 49 et seq.

[47] "Elastic Stability of Long Beams Under Transverse Forces," by A. G. M. Michell, *The London, Edinburgh and Dublin Philosophical Magazine and Journal of Science*, Vol. XLVIII, 5th Series, 1899, p. 298.

[48] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1936, p. 243, Eq. (*h*).

by Professor Timoshenko for a similar case in which I_y is considered as of a smaller order than I_x. For pure flexure and in terms of critical fiber stress, Eq. 109 becomes

$$f^2 = \frac{\pi^2 d^2 E I_y G K}{4 l^2 I^2_x (1 - I_y/I_x)} \quad (110)$$

Neglecting I_y/I_x and using the following rough approximations—$\pi^2 = 10$; $I_x = \frac{d^2}{2} b t$; $I_y = \frac{b^3 t}{6}$; $K = \frac{2}{3} b t^3$; and $E G = 360 \times 10^{12}$—Eq. 110 yields the author's basic Eq. 7.

The rationalization of the author's basic equation from the Michell theory involves:

1. Considering the member as subjected to equal opposed end couples rather than to transverse loads.
2. Neglecting the flexural rigidity of the flanges about the y-axis of the beam, which amounts to equating P_w to $\frac{G K}{l^2}$ or equating a_1 to zero. For short beams this may lead to ultraconservative design.
3. Neglecting the torsional rigidity of fillets and the web, and using the value of K applicable to extremely wide thin rectangles. The first may lead to errors in K of 25% or more on the conservative side, whereas the latter errs on the daring side.[49,50]
4. Neglecting I_y/I_x as compared to unity. For many members in common use, this may lead to errors of 25% or more on the conservative side.
5. Assuming that the beam flanges and web act as a unit without appreciable warping of cross sections in their planes.[20]
6. Assuming that the areas of the flanges are fully effective in resisting flexure. In the case of thin wide flanges this may lead to errors of dangerous magnitude.[51]
7. Assuming that the cross section of the member is symmetrical or has point symmetry, as for a Z-bar.

The sum total of the errors that may be introduced by assumptions 1 to 7 may be far from negligible.

For a flanged beam, the formula corresponding to Michell's solution for a symmetrical prismatic member subjected to end couples is:

$$M^2 = \frac{\pi^2 E I_y G K \left[1 + \pi^2 \left(\frac{a_1}{l}\right)^2\right]}{l^2 (1 - I_y/I_x)} = \frac{J^2 P_{ey} P_w}{1 - I_y/I_x} \quad (111a)$$

[49] "Theory of Elasticity," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1936, p. 248, "Table of Constants for Torsion of a Rectangular Bar."

[50] "Structural Beams in Torsion," by Inge Lyse and Bruce G. Johnston, *Transactions*, ASCE, Vol. 101, 1936, p. 861, Eq. 6.

[51] "Strength of Thin Steel Compression Flanges," by George Winter, *ibid.*, Vol. 112, 1947, p. 527.

For purposes of comparison it will be found convenient to write Eq. 111*a* as:

$$M^2 = n^2 \frac{\pi^2}{l^2} E\, I_y\, G\, K \left[1 + \pi^2 \left(\frac{a_1}{l}\right)^2\right] = \frac{m^2\, E\, I_y\, G\, K}{l^2} \quad \text{.....(111}b\text{)}$$

in which

$$n^2 = \frac{1}{1 - I_y/I_x} \quad \text{.......................(112}a\text{)}$$

and

$$m^2 = n^2\, \pi^2 \left[1 + \pi^2 \left(\frac{a_1}{l}\right)^2\right] \quad \text{................(112}b\text{)}$$

A number of values of n and m are shown in Fig. 14(a). If the torsional rigidity

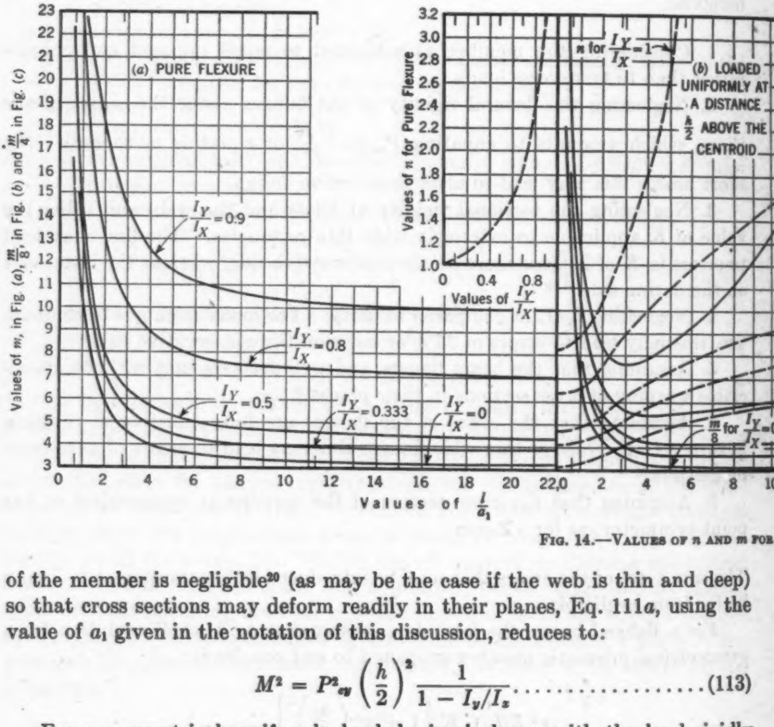

FIG. 14.—VALUES OF n AND m FOR A

of the member is negligible[20] (as may be the case if the web is thin and deep) so that cross sections may deform readily in their planes, Eq. 111*a*, using the value of a_1 given in the notation of this discussion, reduces to:

$$M^2 = P^2_{cy} \left(\frac{h}{2}\right)^2 \frac{1}{1 - I_y/I_x} \quad \text{..................(113)}$$

For a symmetrical, uniformly loaded, simple beam with the load rigidly attached to the member a distance H above the centroidal axis an approximate solution corresponding to Eq. 111*a* is:

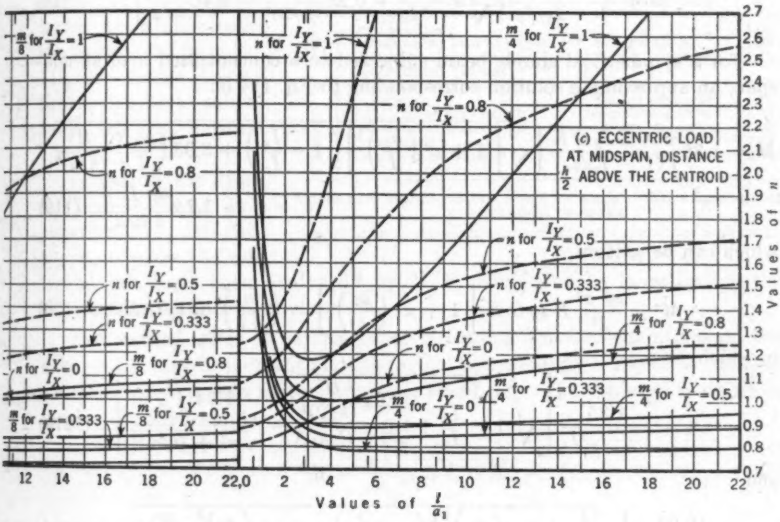
$$M = 1.13 \frac{\pi \sqrt{E\, I_y\, G\, K}}{l\,(1 - I_y/I_x)} \left\{ \sqrt{\left[1 + \pi^2 \left(\frac{a_1}{l}\right)^2\right]\left(1 - \frac{I_y}{I_x}\right) + 2.07 \left(\frac{a_1}{l}\right)^2 \frac{H^2}{(h/2)^2}} - 1.43 \frac{a_1}{l} \frac{H}{h/2} \right\} \quad \text{..(114)}$$

This solution is derived by considering the exchange of energy that occurs while the beam is twisting and buckling, account being taken of the deformation about the x-axis as well as that about the y-axis and the z-axis. Eq. 114 can be written:

$$M^2 = \frac{n^2\,\pi^2}{l^2}\,E\,I_y\,G\,K\left[1 + \pi^2\left(\frac{a_1}{l}\right)^2\right] = \left(\frac{m}{8\,l}\right)^2 E\,I_y\,G\,K \ldots\ldots(115)$$

in which

$$n = \frac{1.13}{1 - I_y/I_x}\left[\sqrt{1 - \frac{I_y}{I_x} + \frac{2.07\,\frac{H^2}{(h/2)^2}}{\pi^2 + (l/a_1)^2}} - \frac{1.43\,\frac{H}{h/2}}{\sqrt{\pi^2 + (l/a_1)^2}}\right] \ldots(116a)$$



SIMPLE SYMMETRICAL FLANGED BEAM

and

$$m = \frac{28.4}{1 - I_y/I_x}\left\{\sqrt{\left[1 + \pi^2\left(\frac{a_1}{l}\right)^2\right]\left(1 - \frac{I_y}{I_x}\right) + 2.07\left(\frac{a_1}{l}\right)^2\frac{H^2}{(h/2)^2}} - 1.43\,\frac{a_1\,H}{l\,h/2}\right\} \ldots(116b)$$

A number of values of n and $\frac{m}{8}$ are shown in Fig. 14(b). From a comparison of these values and those pertaining to pure flexure, it will be noted that, when $\frac{l}{a_1}$ is small, the critical moment for this case is considerably less than that for a similar beam subjected to pure flexure. If I_y/I_x is small, the beams are about on a par when $l/a_1 = 11.3$; this value of l/a_1 increases as I_y/I_x increases. When l/a_1 is large, the critical moment for the uniformly loaded beam is some-

what more than the corresponding moment for a similar beam subjected to pure flexure. Equating h to d Eq. 115 yields the following approximate expression for critical fiber stress:

$$f = \frac{I_y\, d^2\, E}{I_x\, l^2}\,\frac{n\,\pi}{4}\sqrt{\pi^2 + \left(\frac{l}{a_1}\right)^2} \quad \ldots\ldots\ldots\ldots\ldots (117)$$

Eq. 117 is identical to Eq. 4 if the insignificant terms (those beyond the first) in the Fourier series used by the author are neglected and I_y/I_x is equated to zero. As K approaches zero, the value of M given by Eq. 115 approaches:

$$M = \frac{0.565\, P_{cy}\, h}{1 - I_y/I_x}\left[\sqrt{1 - \frac{I_y}{I_x} + 0.21\,\frac{H^2}{(h/2)^2}} - 0.46\,\frac{H}{h/2}\right] \quad \ldots\ldots (118)$$

For a symmetrical simple beam subjected to a concentrated load at mid-span, an approximate solution corresponding to Eq. 114 is:

$$M = 1.35\,\frac{\pi\,\sqrt{E\, I_y\, G\, K}}{l\,(1 - I_y/I_x)}\left\{\sqrt{\left[1 + \pi^2\left(\frac{a_1}{l}\right)^2\right]\left(1 - \frac{I_y}{I_x}\right) + 3.03\left(\frac{a_1}{l}\right)^2\frac{H^2}{(h/2)^2}} - 1.74\,\frac{a_1}{l}\,\frac{H}{h/2}\right\} \quad \ldots (119)$$

which can be written

$$M^2 = \frac{n^2\,\pi^2}{l^2}\, E\, I_y\, G\, K\left[1 + \pi^2\left(\frac{a_1}{l}\right)^2\right] = \left(\frac{m}{4\,l}\right)^2 E\, I_y\, G\, K \quad \ldots (120)$$

in which

$$n = \frac{1.35}{1 - I_y/I_x}\left[\sqrt{1 - \frac{I_y}{I_x} + \frac{3.03\,\frac{H^2}{(h/2)^2}}{\pi^2 + (l/a_1)^2}} - \frac{1.74\,\frac{H}{h/2}}{\sqrt{\pi^2 + (l/a_1)^2}}\right] \quad \ldots (121a)$$

and

$$m = \frac{16.93}{1 - I_y/I_x}\left\{\sqrt{\left[1 + \pi^2\left(\frac{a_1}{l}\right)^2\right]\left(1 - \frac{I_y}{I_x}\right) + 3.03\left(\frac{a_1}{l}\right)^2\frac{H^2}{(h/2)^2}} - 1.74\,\frac{a_1}{l}\,\frac{H}{h/2}\right\} \quad \ldots (121b)$$

A number of values of n and $m/4$ are shown in Fig. 14(c). As K approaches zero, the value of M given by Eq. 119 approaches:

$$M = \frac{0.675\, P_{cy}\, h}{1 - I_y/I_x}\left[\sqrt{1 - \frac{I_y}{I_x} + 0.31\,\frac{H^2}{(h/2)^2}} - 0.56\,\frac{H}{h/2}\right] \quad \ldots\ldots (122)$$

Flexural members are often loaded so that the moment between points of restraint, as regards rotation about their longitudinal axes, is substantially constant. For this case, if the loading is uniformly distributed, a safe but reasonable approximation of the critical moment can be obtained by using Eq. 114 with unity substituted for the constant 1.13. If the loading is con-

centrated midway between points of torsional restraint, Eq. 119 applies approximately provided 1.00 is substituted for the constant 1.35. If the loading is concentrated at points of torsional restraint, the formulas applicable to pure flexure apply without modification.

The author does not mention cantilever beams. As far as the writer knows, a satisfactory solution of the problem pertaining to a flanged cantilever in which the effective torsional constant is not negligible has not been published to date. Safe, but rough, approximations of the critical moment pertaining to such cantilevers subjected to concentrated terminal loads, can be obtained from Eq. 119, for simple beams, provided 1.27 is substituted for the constant 1.35.

TABLE 9.—Effect of Types of Loading and End Conditions

Case	Type of loading	End conditions	n
1	Pure bending	...	1.00
2	Concentrated load at midspan	Fixed ends[a,b]	1.06
3	Uniformly distributed load	Simply supported	1.13
	Concentrated Load at:		
4	The free end	Cantilever	1.27
5	Midspan	Simply supported	1.35
6	0.35 times span length	Simply supported	1.38
7	0.15 times span length	Simply supported	1.53
8	Pure bending	Fixed ends[b]	2.00
9	Uniformly distributed load	Cantilever	2.04

[a] Ends fixed against rotation about the x-axis. [b] Ends fixed against rotation about the y-axis.

Various cases in which the load is placed at a considerable distance above or below the centroidal axis have been analyzed[52] by H. S. Richmond by investigating the differential equations of equilibrium.

The marked effect of various types of loading and end conditions on the value of the critical moment may be further appraised by a glance at Table 9, which pertains to deep narrow prismatic members. The values of n are those involved in the formula:

$$M = \frac{n \pi}{l} \sqrt{E I_y G K} \qquad (123)$$

The supported ends of all members are considered fixed as regards rotation about a longitudinal axis but, unless otherwise stated, are free to rotate about the x-axis and the y-axis. In all cases, the loading is on a level with the centroidal axis. Table 9 was compiled from data given by John Prescott[53] and by Professor Timoshenko.[2]

It appears unfortunate that the author, in his notation, designated l as "the laterally unsupported length of the compression flange." A better designation for l would appear to be "length of member between points of fixity as regards rotation about a longitudinal axis." This usage has been adopted in this discussion It should be emphasized that the author's equations, those given in the references, and in this discussion are based on the ends of the member being fixed as regards torque about a longitudinal axis. Ample

[52] "Elastic Equilibrium in the Theory of Structures," by H. S. Richmond, *Transactions*, ASCE, Vol. 94, 1930, p. 845.

[53] "Applied Elasticity," by John Prescott, Longmans, Green & Co., London, 1924, p. 499.

provision for such restraint is most important but is often neglected in practice.

The columns of free-standing, two-dimensional, frames cannot be said to fix the ends of the beams which are component parts of the frame; the columns will flex normal to the plane of the frame and will thereby allow the ends of the beams to rotate about longitudinal axes. For such cases the stability of the frame as a unit should be considered.

The analysis under discussion assumes that the loading is perfectly free to rotate and move transversely. Quite often this is not so in practice (or tests); frequently the loading is so attached to the member as to stabilize it as regards torque and transverse movement.

The writer has grave doubts regarding the safety of the author's proposal (last paragraph under "Conclusions") to allow the same unit stresses in asymmetrical sections as are used for symmetrical sections; nor can he agree that asymmetrical sections are seldom used as long beams. Towers are often built entirely of angles, all of which are subject to flexure due to eccentric end conditions. It is not clear how the author's formulas, or other formulas based on the torsional rigidity of symmetrical sections, can be applied rationally to such a section as an angle or a T-section. If the horizontal leg (flange) is in compression, b and t may be taken from its cross-sectional dimensions, but it cannot be said that the compression flange is supported by the tension flange; the latter is not present. Also, it is evident that an angle or tee has considerably less torsional rigidity than an I-beam or H-section, the flanges of which have values of b and t identical with those of the angle or tee. H. N. Hill,[54] Assoc. M. ASCE, and George Winter,[20] M. ASCE, have given formulas applicable to asymmetrical I-beams of such proportions that $\sqrt{1 - I_y/I_x}$ is approximately equal to unity. J. N. Goodier has given[55] formulas applicable to deep asymmetrical members subjected to axial load as well as flexure.

Many members, such as crane girders, are ordinarily subjected to flexure about both principal axes, together with torque about a longitudinal axis. This case is not covered by the author. C. O. Dohrenwend, Assoc. M. ASCE, has analyzed[56] this problem for the special case in which a prismatic member is subjected to pure flexure about both principal axes, together with an applied torque at midspan, I_y and K being assumed small as compared to I_x.

The author's method of analyzing the stability of a plate girder appears to contain a series of judgment adjustments for which he no doubt has ample empirical justification. It is hoped that, in his closing discussion, he will explain fully his reasons for these adjustments.

Although included in the scope of the title, the author's equations are obviously not meant to apply to light-gage structural members made of sheet metal of such dimensions that the entire section is not fully effective in resisting torsion and flexure. Such members (made of steel) have been analyzed by Professor Winter using semi-empirical methods.[51] The results of this analysis

[54] "The Lateral Instability of Unsymmetrical I-Beams," by H. N. Hill, *Journal of the Aeronautical Sciences*, Vol. 9, No. 5, 1942.

have been incorporated, in abbreviated form, in specifications of the American Iron and Steel Institute (A.I.S.I.)[25] issued in April, 1946.

Flexural members are often subjected to a combination of at least three types of loading—end couples, distributed loads, and concentrated loads. As has been indicated, the critical moments for each of these loadings may differ considerably. It can be shown,[53,57] that a sufficient (as distinguished from a necessary) condition of stability is defined by:

$$\sum \frac{M}{M_{cr}} = 1 \qquad (124)$$

in which the terms in the numerators pertain to the actual loading, whereas those in the denominators pertain to the critical condition for that type of loading acting alone. This simple rule will give results that are ordinarily reasonable although somewhat on the safe side.

The author, quite rightly, introduces transition curves between the proportional limit and the yield-point strength of the material. The validity of these transition curves might be supported by assuming initial imperfections, as has been done by Professor Winter in deriving secant formulas for beams,[19] or by taking the moduli E and G as variables above the proportional limit, and building up a mathematical argument on these premises.

For conventional, symmetrical steel members, subjected to flexure about the principal x-axis, the writer suggests the use of the following in lieu of the author's basic Eq. 7:

$$f = \frac{56.1 \times 10^6}{S\,l}\, n \sqrt{I_y\, K + \frac{6.5\, I^2_y\, h^2}{l^2}} = \frac{17.86 \times 10^6}{S\,l} \frac{m}{j} \sqrt{I_y\, K} \qquad (125)$$

in which E and G have been taken as 29×10^6 and 11×10^6, respectively. Eq. 125 can be applied to other materials such as the structural aluminum alloys by suitable modifications of these moduli. The most important values of n and m/j encountered in practice might well be tabulated and exhibited graphically in standard handbooks, together with values of K, a_1, $I_y\, K$, and $I^2_y\, h^2\; 1/s\,\sqrt{I_y\, R}$ for each section as has been done for K in the Structural Aluminum Handbook.[58]

By using the approximate values of I_x, I_y, and K given after Eq. 110 and equating h to d, Eq. 125 can be written in the roughly approximate form:

$$f = \frac{18.7 \times 10^6}{l\, d/b\, t}\, n \sqrt{1 + 1.62\, \frac{b^2\, d^2}{t^2\, l^2}} \qquad (126)$$

If n is taken as unity (its value for pure flexure when I_y/I_x is negligible) and if the second term in the radical is neglected, Eq. 126 is substantially the author's basic Eq. 7 (the difference occurs on account of differences in assumed

[57] "Rayleigh's Principle," by G. Temple and W. G. Bickley, Oxford Univ. Press, England, 1933, pp. 31 and 41.

[58] "Structural Aluminum Handbook," Aluminum Co. of America, New Kensington, Pa., 1945.

values of the elastic moduli). However, unity, in many cases, is a poor approximation for n and the second term in the radical may be far from negligible; in fact, for the shorter members, this term is the predominating term. This accounts for the increasing divergence between the author's formula and others as l decreases.

In Fig. 15 a comparison is made, for a 14-in., 142-lb wide-flanged beam, between the author's basic Eq. 7 and Eq. 125, for two cases frequently encountered in practice—(*a*) pure flexure; and (*b*) a uniformly distributed load on

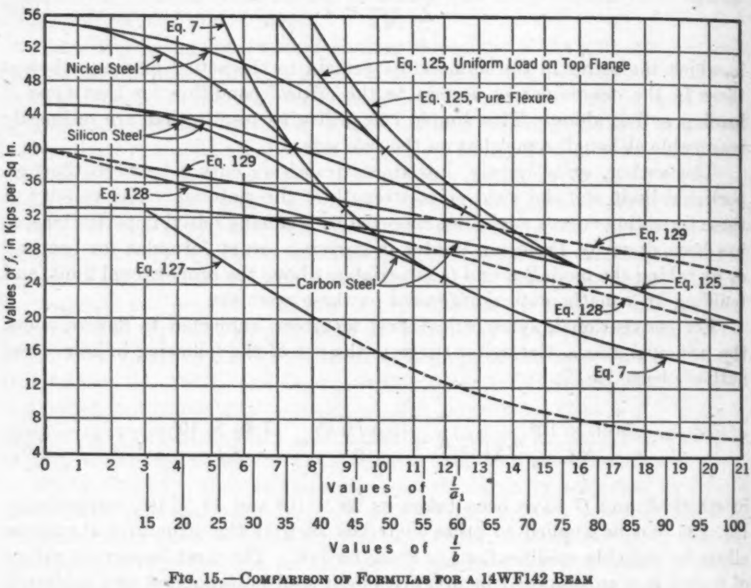

FIG. 15.—COMPARISON OF FORMULAS FOR A 14WF142 BEAM

the top flange, $H = d/2$. Arbitrary transition curves between the approximate proportional limits and the yield points for each of the classes of steel mentioned by the author have been drawn in this figure. For purposes of ready comparison, the loci of the following formulas have also been shown:

$$f = \frac{37{,}200}{1 + \frac{(l/b)^2}{1{,}800}} \quad \text{.......................(127)}$$

$$f = 40{,}000 - 60\frac{l}{r_y} \approx 40{,}000 - 208\frac{l}{b} \quad \text{............(128)}$$

and

$$f = 40{,}000 - 40\frac{l}{r_y} \approx 40{,}000 - 139\frac{l}{b} \quad \text{............(129)}$$

Eq. 127 will be recognized as the A.I.S.C. specification (1936) formula[59] multi-

[59] "Specifications for the Design Fabrication and Erection of Structural Steel for Buildings," A.I.S.C., 1936.

plied by 1.65, which is the safety factor implied therein. Eqs. 128 and 129 between $\frac{l}{r_y} = 50$ and 190 $\left(\frac{l}{b} \text{ between 15 and 55 approximately}\right)$ represent the results of four sets of tests on I-beams and H-beams reported[60] by Herbert F. Moore in 1913. Eq. 128 applies to pure flexure, whereas Eq. 129 applies to the uniformly distributed load case (without taking account of the effect of H). The parts of the loci of these equations which are beyond the somewhat limited range of the tests are shown dotted in Fig. 15. These test results appear to indicate clearly that transition curves such as those introduced by the author are fully warranted.

All the beam formulas given in this discussion pertain to critical (ultimate) conditions. In practice, these formulas should be divided by an appropriate safety factor; or, preferably, the loads should be multiplied by a suitable factor of overload. The latter procedure is especially preferable if the member under consideration is subjected to a combination of flexural and axial loads, in which case the principle of superposition obviously does not apply.

Mr. de Vries is to be commended for having performed a series of tedious calculations most precisely and for again raising an important, but somewhat controversial, subject for discussion. It is unfortunate that test results over an extended range of member sizes, shapes, lengths, loading, and end conditions, with which the author's results and other calculations may be compared, apparently are not available. The writer regrets that space limitations do not permit discussing the paper in detail or to the extent it fully warrants.

In addition to the references cited by the author, and in discussion, several others are especially worthy of note.[61,62,63,64,65,66,67] No attempt has been made to make this list complete.

The writer is indebted to James Adam, Jr., for aid in preparing the illustrations in this discussion.

KARL DE VRIES,[68] M. ASCE.—The general tenor of the discussions has been to the effect that the writer's proposed working, or specification, formula, Eq. 9, is reasonable for most conditions, but that it falls down for very short, slender beams and for plate girders. The writer, in this closing discussion, will attempt to show wherein the discussers have made approximations which he

considers incorrect, or have used assumed loadings or conditions which practically cannot exist. The writer also proposes modification of specification requirements to permit the use of the full basic unit stress, without reduction, for the case of braced beams.

The writer believes firmly that Eq. 4 is the best and simplest formula for beams in buckling; and substitutions of approximate values for its ratio of

moments of inertia and simplifications of its k-values, listed in Table 1, will lead to approximated or distorted results, which should not be compared critically with the true values determined from Eq. 4. Formulas for beams in pure bending are generally used by the discussers. They are simpler than those for most other loadings, but, if other formulas are available, they do not deserve this consideration, as will be proved in this discussion.

The simple beam, with its own weight uniformly distributed along its centroid, will have its lowest critical stress if its carried load is uniformly distributed along the top flange (see k-values in Table 1). For relatively short beams the weight of the beam will be a small part of the total load; but as span lengths increase, the weight of the beam will form an increasing portion of the total load until the beam is capable of supporting only its own weight. Uniform top

flange and centroid loads, then, should be the ones considered for writing a specification formula of the type of Eq. 9. Mr. Van Eenam finds disagreement on centroid load stresses for two 36WF beams, but his computations are based on approximate values for I_x, I_y, and k. Since the true values are known, the critical stresses for centroid loading have been computed accurately by the writer and are given in Table 10. The values thus determined show that,

for these two beams, consistent safety factors for the most unfavorable loading exist. The 36WF194 and 36WF160 sections have the torsional bending constants a = 109.9 in. and a = 128.6 in. respectively.[69] Their critical stresses for uniform centroid and top flange loads are computed in Cols. 5 and 8, Table 10; the corresponding failure stresses computed from the formulas of Table 4 are given in Cols. 6 and 9; and the ratios of critical stress to the corresponding failure stress are shown in Cols. 7 and 10. Col. 11, Table 10, gives the working stress from the proposed specification formula Eq. 9; Col. 12 shows the unit stress resulting from the weight of the beam, w, which is 194 and 160 lb per lin ft, respectively; Col. 13, Table 10, lists the unit stresses that are available

[69] "Bethlehem Manual of Steel Construction," *Catalogue S-47*, Bethlehem Steel Co., Bethlehem, Pa., 1934, p. 285.

for top flange load. The load at the centroid causes the unit stress f_c (Col. 12), but f_{cc} (Col. 5) would be critical; the load at the top flange causes the unit stress f_t (Col. 13) and f_{ct} (Col. 8) would be critical; the critical stress of the beam is reached when both stresses, f_c and f_t, are increased n times, or when

$$\left(\frac{f_c}{f_{cc}} + \frac{f_t}{f_{ct}}\right) n = 1 \qquad (130)$$

in which n is the least factor of safety which the working formula, Eq. 9, has with the critical stress, Eq. 4; n is computed in Cols. 14 to 17. Col. 10, Table 10, gives the close relationship between Eq. 7 and Eq. 4, and Col. 17 shows the nearly constant safety factor regardless of l/a. Since all rolled beams show critical stresses well above the proportional limit for $l/a = 2$ (see also Table 2), similar results will be obtained for all rolled beams, and only special deep sections with thin flanges, having useful lengths below the limit $l/a = 2$, show excessively high safety factors.

To apply Eq. 4 to a thin-flanged deep section with computable a, it was assumed that a rolled beam was cut in the middle of the web, and that 2-ft, 4-ft, and 6-ft additional webs were inserted and welded between the beam halves. It was found for these thin-flanged deep beams that the l/a-ratio for long lengths is larger than 2 and that therefore good agreement of Eqs. 4 and 7 is maintained; but that, for short lengths and increasing depth, Eq. 4 gives critical stresses well above those indicated by Eq. 7. This fault of Eq. 7 has been emphasized by several discussers, especially by Mr. Brameld; but, for reasons explained hereinafter, the writer proposes that the full basic unit working stress be used for such cases.

The treatment of riveted plate girders in the paper has been criticized and preference has been expressed for adherence to Mr. Madsen's[11] findings. Mr. Madsen tested two riveted girders of very small size and thin flanges in torsion and recommended that a K-value equal to one third of that of the identical solid section be used; the writer proposes the modification of Eq. 11, which expresses the properties of the solid section, to Eq. 12. The use of Eq. 12 for thin-flanged girders has the same effect as Mr. Madsen proposes, but the reduction for heavy-flanged girders is less by Eq. 12, and should be less. The writer believes this reduction is necessary not so much for rivet slip, but mostly for the overestimated contribution of the vertical flanges to the K-value of the solid section. In the example of the laminated section of Fig. 6 and its accompanying computations of K, and not considering the effect of the inscribed circle (46.9 in.^{4}), the vertical flange (54.7 in.^{4}) adds about 16% to the total value of K, and will add a similar percentage to the solid K. In a similar example, if the same flange angles are used and the thickness of the cover plates is reduced, the contribution of the horizontal flange (234.0 in.^{4}) is reduced as the cube of its thickness, whereas the vertical flange, which should have a minor influence on torsional stiffness, appears unreduced and has a major influence on the value of K. The same percentage reduction of K for the solid section should not hold for both examples; and it is found that in applying Eqs. 7 and 12 the stresses of the thin-flanged girder correspond to the

use of one third, or less, of the K-value of the solid section in Eqs. 4 and 10, and that for heavier flanged girders the used fraction of K of the solid section is more than one third. The heavy-flanged riveted plate girder, then, showed the same full agreement of Eq. 7 with Eq. 4 as rolled beams and heavy-flanged deep beams; and thin-flanged riveted plate girders showed the same gap between Eqs. 7 and 4 as the corresponding thin-flanged deep beams.

Rolled sections, deep beams, and plate girders with intermediate lateral supports between vertical supports, generally, can be divided into two types. If they are of the deck type, the main load is uniformly distributed along the top flange; since specifications require that the compression flange be stayed by lateral bracing and by cross frames at short intervals, the laterally unsupported lengths are short, and the short beam formulas, Eqs. 8, will limit their working stresses in most cases. If it appears from their properties, however, that they will fall in the range of long beams, then Eq. 7 gives, for them, critical stresses that are too low. This is true for two reasons: First, there is the gap between Eqs. 4 and 7 for short deep beams and plate girders with thin flanges; and, second, at $l/a = 2$, for example, a k-factor of 2.269 for simple beams has been used to compute Eq. 4, whereas, actually, $k = 3.499$ for two-bay beams and is larger for these multiple-bay beams. If they are of the through type with bottom flange bracing and brackets to support the top flange, the laterally unsupported lengths are larger, but limited, since the lengths between vertical supports themselves are limited by specifications; the main load is delivered, say, through floor beams and is a concentrated load at these points; and instead of $k = 2.269$ for $l/a = 2$, as used in Eq. 4 to establish Eq. 7, $k = 5.411$ for two-bay beams and is larger for multiple-bay beams. It seems, then, that no reduction of the basic bending stress is required for beams with intermediate lateral supports, regardless of the unsupported length between the points of attachment of these supports, provided the lengths are within usual specification requirements.

All this adds up to the recommendation that Eqs. 8 and 9 be used for specification purposes if the compression flange of the beam has no intermediate lateral supports between its vertical supports, and that the basic bending stress (for carbon steel, 18,000 lb per sq in. for the American Railway Engineering Association (AREA) and 20,000 lb per sq in. for the American Institute of Steel Construction (AISC)) be used if intermediate lateral supports are provided; t in Eqs. 8 and 9 for plate girders and other compound sections is determined from Eq. 12. It is not proposed to abandon the provision of most specifications that the gross section of the compression flange be not less than the gross section of the tension flange.

Eq. 9 is offered to replace the highly inaccurate l/b-formulas in common use and is conservative for loadings other than the one for which it is derived. For special cases, if specifications do not have to be followed strictly, capacities can be computed from Eq. 4, using the proper k-value from Table 1. The general formulas for k are quite complicated, but Eqs. 21 and 36, which are of most interest, can be simplified by dropping y (see Table 7) and formulas will result which, for simple beams, are correct within a fraction of 1%. For ex-

ample, for uniform top flange load on a simple beam Eq. 36*a* reduces to

$$k = 1.2825\left(\sqrt{0.481\frac{l^2}{a^2} + 5.747} - 1\right) \qquad (131)$$

and for uniform centroid load on a simple beam Eq. 36*b* reduces to

$$k = 0.8895\sqrt{\frac{l^2}{a^2} + 9.87} \qquad (132)$$

and the critical stress may be computed from Eq. 4 since all other terms in that equation are known. A simple method, if a is known as for rolled beams and if l/a is larger than 2, is to increase the working formula, Eq. 9, in the ratio of the proper k-factor of Table 1, Cols. 2, 3, 4, 6, or 7, to that of Col. 5.

The erection problem of picking beams has been mentioned in the paper and Messrs. Hall and Hussey take exception to the statement made. The writer feels that this problem is important enough for a separate paper and beyond the scope of this one.

Professor Winter claims that the writer's formulas do not apply to beams for which $b/t > 20$, and reaches this conclusion from a formula for pure bending. In computing the properties of the beams of Fig. 9, he substitutes actual flange thicknesses in Eq. 7 instead of those determined from Eq. 11, which in this case is preferable to Eq. 12. When t as determined from Eq. 11 is used, close agreement between his and the writer's values results.

Mr. Hall suggests that some wide beams, as the 14WF87 section, fall in the plastic range; the writer's formulas place them there and take full recognition of this fact. Mr. Hall also discusses beams with high $\frac{I_y}{I_x}$-ratios and agrees that it is unnecessary to use his proposed correction factor of Eq. 56. If the correction factor for beams with top flange loading were derived, it would be smaller than the value determined by Eq. 56, and would so complicate Eq. 4 that a general solution of that equation would be impossible. His example of a beam in pure bending, consisting of a single panel of a through plate girder bridge cannot be considered as typical of this condition; it is a multiple-bay beam with load application at the panel points, and gives k-values different from those shown by Mr. Hall.

Mr. Higgins misses in the paper a supporting argument for Eqs. 6. For the steels considered, Col. 5, Table 4, gives proportional limits which are the best the writer could establish, and above which the computed critical stresses do not indicate true stresses. Stresses corresponding to a reduced modulus of elasticity beyond the proportional limit have not been computed; instead, arbitrary transition curves between yield point and proportional limit have been drawn. If the AISC committee on specifications[29] prefers to maintain the basic bending stress up to the intersection with the long beam formula, Eq. 9, then it seems that it introduces a safe and worthwhile simplification, in spite of a slightly lower safety factor which might exist for a short range.

Mr. Hill uses Eq. 75 for centroid load and after making substitutions concludes that the writer's formula for very long lengths may give values 30%

higher than the theoretically correct values. The writer uses Eq. 4 with k of Eq. 36*b* for the same loading and believes it to be more nearly theoretically correct than Mr. Hill's, since the approximations in Eq. 4, considering rolled beams, are entirely negligible. If also, within the practical range of long spans, all beams computed by Eq. 4 check with Eq. 7, then there seems to be no reason why Eq. 7 should give erroneous results. Mr. Hill states that the writer's formulas become increasingly conservative as the span decreases; the writer has already discussed this for the case of top flange loads, and has proved that it leads to a constant safety factor (see Table 10); for other loads this might need consideration especially if high-alloy materials are used.

Mr. Hussey compares the stresses of the proposed formula, Eq. 9, with those of the old AISC specification formula and finds some rolled beams considerably reduced in their allowable stresses; he fails to state that most rolled beams will have their allowable stresses increased. The proposed formula tends to allot to the beam its allowable unit stress according to its computed buckling strength; and if a beam in the past has been designed for its critical stress this practice does not have to be continued if it is found to be faulty. Mr. Hussey prefers the investigation of a single bay of a multiple-bay beam; the writer believes that it is extremely complicated to simulate the loading on such a separate bay and rather considers the multiple-bay beam. Instead of groups of concentrated and partial uniform loads on simple beams, the extreme cases of a concentrated load at the center and uniform load over the full length of the beam are considered in Table 1, Cols. 2 to 7.

Mr. Brameld presents some very unusual cases of laterally braced thin-flanged deep plate girders; the writer believes that Mr. Brameld will agree with him on the proposed treatment of such girders. To compute girder flanges as struts is equivalent to applying the l/b-rule and should be avoided.

Professor Gaylord starts with the pure bending formula and, correcting it for top flange load, derives Eq. 104, which is possibly closer to theory, but more involved and as limited in range as Eq. 9. Professor Gaylord's Eq. 102*a* will apply when $l/a < 2$. It is applicable to thin-flanged deep beams with known or computable torsional bending constant a, but for these rare cases the writer would prefer Eq. 4 with Eqs. 131 and 132, respectively. Examples 1 to 3 indicate conservatism of the proposed formula; Table 10, nevertheless, shows that the apparent understress of Eq. 9 for top flange load is false, and that there is really a nearly constant safety factor for the beam.

Mr. Julian gives a thorough investigation of the problem and proposes, instead of Eq. 7, his Eq. 125, the factors of which, if charted or listed in handbooks for rolled beams, would not be available for other sections. The formula is written for pure bending, and the n-values of Table 9 will not make it usable for other loadings, since n, which should be an equivalent of ratios of k, is not as general as indicated in Table 9, but varies with the length of the beam, as can be seen from Table 1. Eq. 7 is not derived from a formula for pure bending, as is Eq. 109, but is derived as an observed approximation to the plotted results of a formula for top flange loading. The limitations stated by Mr. Julian as

necessary to justify passing from Eq. 109 to Eq. 7 do not exist, because no such method of approach is in question. Eq. 12, as proposed in the paper for compound sections, can also be applied to box sections. In computing cantilever beams, the writer uses twice the cantilever as the laterally unsupported length.

The writer wishes to thank the discussers for the interest they have shown in the subject of the paper; he appreciates the many new ideas they have expressed and which have led the writer to additional investigations and to conclusions incorporated in this discussion.

RELIEF WELLS FOR DAMS AND LEVEES

By T. A. Middlebrooks[1] and William H. Jervis,[2]
Assoc. Members, ASCE

With Discussions by Messrs. Henry C. Barksdale, Willard J. Turnbull, Glennon Gilboy, W. A. Wall and C. A. Stone, John R. Charles, Horace A. Johnson, P. C. Rutledge, H. H. Roberts and Carter V. Johnson, Frank E. Fahlquist, Harry R. Cedergren, John S. McNown, Reginald A. Barron, Preston T. Bennett, Charles I. Mansur, S. J. Johnson, Kenneth S. Lane, and T. A. Middlebrooks and William H. Jervis.

Synopsis

Since 1930 a large number of flood control dams and levees have been constructed. Many of them are located on pervious foundations—a practice which would have been considered unsafe in the 1920's. In addition, many of the structures are founded on alluvial deposits which usually grade from fine materials near the ground surface to coarser materials in lower portions of the strata. As a result, the lower parts of the deposits forming the foundations are much more pervious than the upper parts, and deep drainage facilities are necessary for relieving high uplift pressures downstream from the structures to prevent serious and alarming boils and seepage. The writers have studied this problem over a period of years and have developed certain design criteria for systems of relief wells which provide deep drainage. Application of these principles has been quite successful and there has been a rather large demand for information on relief well design. This paper will outline the general method of design, together with the theoretical and empirical background, so that it can be used with full knowledge of its limitations as well as of its advantages.

Danger of Uncontrolled Underseepage

The detrimental effect of the outcropping of underseepage at the toe of dams and levees has long been recognized as a major problem in design. This seepage is most dangerous when it develops in the form of uncontrolled boils

Note.—Published in June, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

at the toe. The uplift pressure beneath concrete structures, low weirs, and masonry dams on sand and the piping of sand have been the subjects of much study. One form of solution consists of relief wells, which, reputedly, were first used by Indian engineers of the Punjab Irrigation District in Punjab, India. Considerable difficulty had been experienced in the prevention of piping beneath low concrete weirs constructed in connection with irrigation projects. After a comprehensive study of seepage pressures, it was found that excessive uplift existed beneath the aprons and that high hydraulic gradients were present near the escape gradients. The first and obvious attempt at a solution of the problem was the installation of sheet-pile cutoffs; but, because of the excessive depth of the sand formation and because of possible leakage through the sheet piling itself, this method was not always effective. After considerable experimentation both in the field and in the laboratory, the method of treatment finally adopted was the relief well, which allowed exit of the water downstream from the weir in such a manner that the uplift pressures and escape gradients were reduced to safe values. It is believed, however, that the application of relief wells to earth dams and levees is new and that, except in unusual cases, these wells will reduce, satisfactorily, the uplift pressures downstream from dams, and on the land side of levees, by providing a controlled exit for the ground-water flow.

In the usual dangerous condition of seepage that may develop, the stratification is such that the over-all horizontal permeability of the foundation is considerably in excess of the vertical permeability. Therefore, it is easier for the water to flow horizontally, and hydrostatic pressures are built up in the foundation of the structure. Although this condition exists most frequently where a relatively impervious top stratum overlies a very pervious foundation, it also exists where the foundation is composed entirely of sands and gravels. Because of the stratification of more pervious and less pervious materials in all natural sedimentary deposits, it is normal for the horizontal permeability to be greater than the vertical permeability. The conclusion that must be drawn, therefore, is that all pervious foundations on which hydraulic structures are built are susceptible to the development of detrimental boils or uncontrolled seepage at the land-side toe.

In a great number of cases on low dams and levees, the relatively impervious material near the ground surface is sufficiently thick to prevent the development of dangerous boils. Theoretically, the thickness of the top stratum necessary to prevent boils represents an effective weight equal to the uplift pressure at the toe. If no seepage is assumed and therefore no loss of head through the foundation, the effective weight of the top stratum, to provide satisfactory protection against boils, must be equal to the total head. However, this case represents an impossible situation, and a reduction in head from the river side to the land side of from 25% to 50% is not unusual. Thus, a top stratum with an effective weight equal to from 50% to 75% of the net head would prevent boils.

Typical conditions conducive to the development of dangerous underseepage conditions are shown in Fig. 1. The relatively pervious stratum is usually stratified horizontally so that its horizontal permeability is greater than its vertical permeability and may vary considerably in thickness. The relatively impervious stratum may be of variable thickness, or it may be non-

existent. Where it is not present, local nonuniformities in the pervious layer are often such that they can cause boils and piping to occur through local concentrations of flow.

All boils are considered potentially dangerous, regardless of size or volume of flow. The discharge from boils is uncontrolled and there is always danger of piping or "quickening" of the foundation material which will result in sufficient movement of material to cause a complete collapse of the structure. However, areas that may probably be considered the most dangerous are those

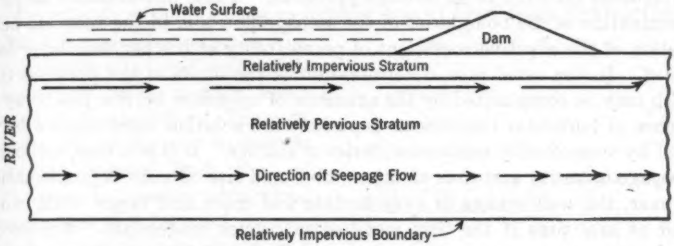

FIG. 1.—TYPICAL CONDITIONS CONDUCIVE TO THE DEVELOPMENT OF UNDERSEEPAGE

which, although they do not seep actively at a low head, still have an insufficient top stratum to withstand the uplift produced by a higher head. Under such conditions a sudden rupture of the top stratum is possible which can lead to extremely violent boiling and even to rapid ultimate failure of the dam or levee. In one case known to the writers, a boil broke out under a levee, removing foundation material in sufficient quantity to cause the levee to settle several feet. This incident occurred during the night and numerous guards and patrols on the levee did not discover it until the next morning.

Another example of the action of a violent boil is the failure of a flood wall during the 1943 flood. In this case the foundation consisted of a relatively impervious top stratum underlain by clean sand. There was no indication of dangerous underseepage until seven o'clock on the morning of the failure. At this time a small boil broke out approximately 10 ft from the wall. This boil was "sacked" (that is, confined by sand bags), and directly thereafter another boil broke out approximately 40 ft from the wall. While the second boil was being sacked, a third boil broke out 100 ft from the wall. The third boil was quite violent and destroyed a small shed under which it had broken out. Observers stated that within a few minutes the ground between the boil and the wall seemed to disintegrate and a section of the wall moved out. It is interesting to note that the flood wall involved had only approximately 6 ft of water against it and that the average hydraulic gradient in the foundation was approximately 1 on 16. Such a value for average gradient has often been considered safe even with uncontrolled outlet, but this case indicates that the average hydraulic gradient is not a true criterion of safety.

DESIGN OF RELIEF WELL SYSTEMS

In view of the potential danger of boils, a rather large research program on the relief of uplift pressure was undertaken by the Mississippi River Commission, the Vicksburg Engineer District, and the United States Waterways

Experiment Station, at Vicksburg, Miss. The research consisted largely of hydraulic models and electric models, both for designing well systems as a whole and for checking well inflow losses. These models yielded certain information concerning relief well design which has been successfully applied to several earth dams and which has been augmented by various experimental observations in the field.

In the design of a well system operating under gravity flow, there are certain fundamental considerations. First, the design is subject to the usual uncertainties involved in all seepage problems. These uncertainties lie in the determination of the boundaries of the seepage flow and in the accurate determination of the effective coefficient of permeability of the pervious layer to be drained. In the usual case, determination of the limits of the pervious layer (which may be complicated by the existence of upstream borrow pits or by the presence of lenticular impervious deposits), the solution often cannot be obtained by a reasonably economical series of studies. If this is true, estimation of seepage quantity and thus of the number and size of wells is problematical. However, the well system is very flexible and more and larger wells can be added at any time if the first installation proves inadequate. The second uncertainty, of course, is one that can generally be solved by sufficient exploration. Several procedures for sampling pervious materials below the water table have been developed, but these are expensive and can be used economically to only a limited extent. Both these considerations require the application of judgment based on experience to obtain reasonable solutions in complicated geological formations.

In view of these conditions, a theoretical design for a simple case will be developed only for the purpose of showing the relative effect of the variables involved. The effect of these variables can then be used as an aid in adjudging the proper solution of more complicated problems.

The first consideration is that there is a definite upper limit to the quantity of water which can be produced by a gravity flow system. This quantity (Q_M), which will be designated as the "carrying capacity" of the pervious layer, can be described algebraically according to Darcy's law as follows:

$$Q_M = \frac{k\,h\,A}{l} \qquad (1)$$

in which k is the effective coefficient of permeability of the pervious stratum; h is the head at source of seepage; l is the length of seepage path measured in direction of flow; and A is the effective area of pervious stratum at right angles to the direction of flow.

To illustrate this quantity, it can be assumed that a condition exists similar to that shown in Fig. 1. If it is assumed that a free outflow face is introduced at the downstream toe of the dam, that a free inflow face exists at the river, and that the top stratum is impervious, the carrying capacity per foot of dam (q_M) then becomes:

$$q_M = \frac{k\,h\,d}{l} \qquad (2)$$

in which d is the depth of pervious stratum. Therefore, Eq. 2 is representative of complete drainage relief and a drainage system should be designed to

carry this quantity plus a reasonable safety factor. Thus, the problem of relief wells is different from the problem usually encountered in dewatering excavations, for instance, where close spacing of a number of short well points or the installation of an additional pump at a lower elevation can be used to lower the ground-water table further by increasing the capacity of the wells. For relief wells to be installed effectively, they must be so placed and so designed that they will either give the desired percentage of relief or furnish the desired percentage of the carrying capacity of the pervious layer without the use of pumps or without excessive outflow loss of head when flowing free.

For the case illustrated in Fig. 1, the purpose of a relief well installation should be to reduce uplift pressure to a safe value. The concept of uplift in the top stratum is somewhat different from that of uplift beneath masonry structures. Consider that a column of the top stratum of unit area is placed in a container such that a head can be applied to its base as shown in Fig. 2 and, furthermore, assume that there is no friction between the soil and the container. Let H be the height of the soil column; h_1 be the head at base of soil column; h_2 be the head at top of soil column; i be the hydraulic gradient; i_c be the "critical" hydraulic gradient (that gradient at which soil column will start to move); γ_w be the unit weight of water; and γ_s be the submerged unit weight of soil. The upward force (p_w) exerted by the water is equal to:

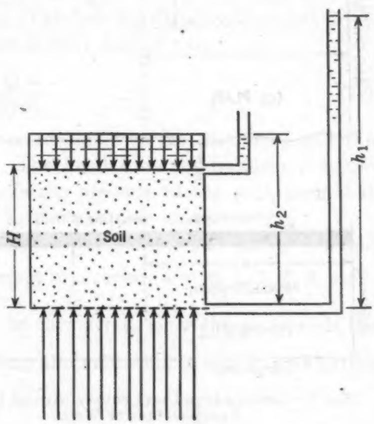

FIG. 2

$$p_w = (h_1 - h_2)\,\gamma_w \qquad (3)$$

The resisting force (p_s) of the soil unsupported at the sides of the container is:

$$p_s = \gamma_s H \qquad (4)$$

The hydraulic gradient is:

$$i = \frac{h_1 - h_2}{H} \qquad (5)$$

and the critical gradient from Eqs. 3 and 4 becomes:

$$i_c = \frac{h_1 - h_2}{H} = \frac{\gamma_s}{\gamma_w} \qquad (6)$$

The design should therefore be made with the idea of so reducing h_1 that the critical gradient will not be exceeded. Normally, values for the critical gradient vary from 0.7 to 1.0, depending on the submerged unit weight of the material under consideration, and it may be that design for a safety factor of 1.5 against developing the critical gradient is satisfactory.

For illustration, the case in Fig. 1 will be considered. This case represents a condition that might be expected along the Mississippi River levees. An infinite length of dam or levee and an infinite line drive source can be assumed without too much error, since the river and levee are parallel to each other, roughly. This condition is illustrated in Fig. 3. The line of wells is considered to be of infinite length. The pervious stratum is likewise assumed to be of infinite extent landward (that is, away from the river), with the pervious stratum completely saturated and the top stratum impervious, so that full riverside uplift acts beneath the land-side top stratum. The last assumption is severe, as the pressure reduction due to seepage, which was previously described, has not been considered. Under these conditions, no seepage is occurring to the landward and a fully static condition exists. To simplify the problem further, it will be assumed that the pervious layer is homogeneous and isotropic. The design of the wells considered subsequently will be such as to prevent the development of the critical hydraulic gradient through the top stratum.

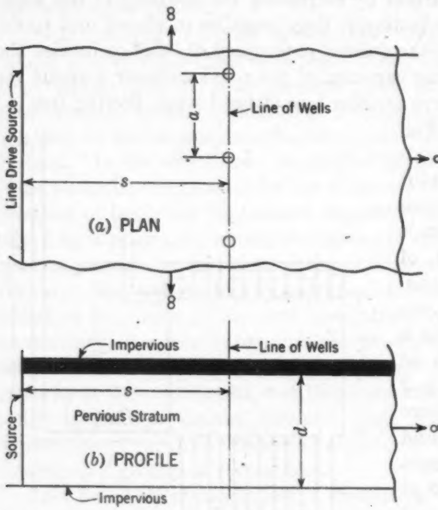

FIG. 3.—INFINITE LINE DRIVE SOURCE WITH AN INFINITE PARALLEL LINE OF WELLS

This well system has been studied by other investigators[3] in so far as wells with strainers completely penetrating the pervious stratum are concerned. If the well is regarded as merely a hole with no clogging on the sides (due to the screen soil contact) and with no outflow friction or velocity head loss, a mathematical solution of the flow characteristics of the system, including head midway between wells and behind the line of wells and the quantity of flow from the wells, can be computed.

Morris Muskat gives a solution of this condition but the form is general with respect to the fluid under consideration and the porous medium. Therefore, it is necessary to convert Mr. Muskat's equation into a more suitable expression for use in studying the seepage of water through sand.

Mr. Muskat gives the following equation[4] (converted to the notation of this paper):

$$p = h_s + c \log_e \frac{\cosh j\,(y - s) - \cos j\,x}{\cosh j\,(y + s) - \cos j\,x} \qquad \text{(7a)}$$

[3] "The Flow of Homogeneous Fluids Through Porous Media," by Morris Muskat, McGraw-Hill Book Co., Inc., New York, N. Y., 1st Ed., 1937.

[4] *Ibid.*, p. 527, Eq. 6.

in which, to simplify typography, $j = \frac{2\pi}{a}$. Furthermore, when a is the well spacing, r_w is the radius of a well, μ is the viscosity of the fluid; and $\frac{K}{\mu}$ is the permeability coefficient k, $\frac{r_w}{a} \ll 1$ and $\frac{2s}{a} \geqq 1$:

$$Q = \frac{\frac{1}{\mu} 2\pi K \Delta p}{\log_e \frac{e^{js}}{j r_w}} \quad \text{(7b)}$$

in which p is the pressure at any point (x, y) and s is the distance from line drive to line of wells. In Eq. 7*a*, c is a flux coefficient defined as:

$$c = \frac{Q\mu}{4\pi K} \quad \text{(7c)}$$

For these formulas the x-axis ($y = 0$) corresponds to the line drive and the y-axis ($x = 0$) passes through a well. The head h_s is the uniform pressure maintained at the "line drive," and h_w is the pressure at the well, such that $p = h_s - h_w$. The thickness, d, of the sand stratum is unity.

For a point in the line of wells midway between two of the wells $y = s$ and $x = \frac{a}{2} \pm n\,a$, in which n signifies a number in a series ($n = 0, 1, 2, 3, 4$, etc.). Only one point ($x = \frac{a}{2}$ and $y = s$) will be considered, since the pressure is the same at all such midpoints. Substituting the values for x and y, and letting p equal the unit pressure at point $\left(\frac{a}{2}, s\right)$, Eq. 7a becomes:

$$p = h_s + c \log_e \frac{\cosh 0 - \cos \pi}{\cosh (2js) - \cos \pi} = h_s + c \log_e \frac{2}{\cosh (2js) + 1} \quad \text{(8)}$$

By equating Q from Eqs. 7*b* and 7*c* and substituting $h_s - h_w$ for p:

$$c = \frac{h_s - h_w}{2 \log_e \frac{e^{js}}{j r_w}} \quad \text{(9)}$$

Therefore,

$$p = h_s + \frac{h_s - h_w}{2 \log_e \frac{e^{js}}{j r_w}} \log_e \frac{2}{1 + \cosh 2js} \quad \text{(10)}$$

and

$$\frac{p - h_w}{h_s - h_w} = 1 + \frac{\log_e \frac{2}{1 + \cosh 2js}}{2 \log_e \frac{e^{js}}{j r_w}} \quad \text{(11)}$$

Working with Eq. 7*b* directly, when $k = \frac{K}{\mu}$ and $h = h_s - h_w$ (since $p = h_s - h_w$):

$$Q = \frac{2\pi k h}{\log_e \frac{e^{js}}{j r_w}} \quad \text{(12)}$$

Curves representing Eqs. 8 to 12 have been reproduced in Fig. 4. With these charts it is possible to determine the flow per well, and the head midway between wells, for an infinite line of wells completely penetrating a pervious stratum fed from a line source parallel to the line of wells. If the effective diameter and the spacing for the wells is assumed and the seepage boundaries and the net head are known, the seepage quantity and the pressure midway between the wells may be found; but, as previously stated, these determinations hold true only for the cases where the actual well points completely penetrate the pervious stratum.

This is a usable solution for such wells. However, if the pervious stratum is very deep, the cost of penetrating it completely with a well strainer is large, particularly as the size of well increases. Larger strainers are very expensive, as is the cost of drilling large wells. Therefore, it was deemed necessary to study partly penetrating well systems. In this connection, the term "percentage of penetration" will be used, referring not to the total percentage of thickness of pervious stratum through which both strainer and riser pipe pass, but only to the percentage of the thickness penetrated by the strainer alone.

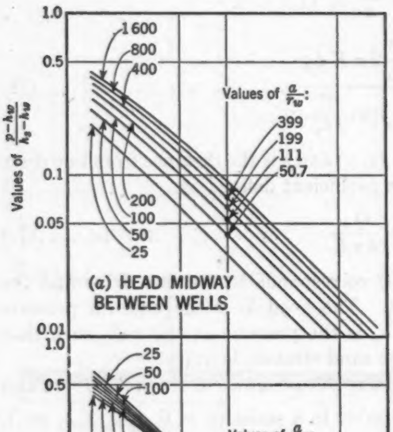

FIG. 4.—CHARTS FOR THE SOLUTION OF EQS. 8 TO 12

No exact mathematical solution is available for studying partly penetrating wells. A series of hydraulic model tests performed at the U. S. Waterways Experiment Station, augmented by electric analogy model tests performed by the Vicksburg Engineer District Laboratory, have yielded empirical data from which design curves were developed. A brief description of the two methods of analysis is pertinent. Hydraulic seepage models are constructed to the same horizontal and vertical scale, and the permeability coefficients of the various materials are so selected that the same ratio of coefficient of permeability is maintained between the various parts of the model as exists between the various similar parts of the prototype. Usually the actual values of the coefficient of permeability chosen are somewhat higher for the model than for the prototype to speed up the action of the model and to reduce capillary effects, which are greatly out of scale in the model. Hydraulic models are

subject to several disadvantages such as the capillary effect, high cost, and the clogging of the voids in the model material by air in solution in the water. Also, a fairly large model must be constructed and the degree of control over the model is sacrificed for size. However, the models have a very definite value in indicating, qualitatively, the effect of various drainage systems; and they give a better visual picture of seepage conditions than any other possible type of study. In addition, the models allow a range of coefficient of permeability which cannot be reached in an electric analogy model. Electric analogy models are based on the fact that Ohm's law governing the flow of electricity and Darcy's law governing the laminar flow of seepage are analogous. Since this condition exists, the flow characteristics of both the seepage and the electricity are the same, and similar results can be obtained from hydraulic models and electric analogy models. A description of the hydraulic electric analogy has been given by L. F. Harza,[8] M. ASCE, and others. Electric models have the advantages of being relatively inexpensive and quickly constructed. They are small and can be accurately controlled. However, attempts by the writers to vary the permeability coefficient over a wide range have not been successful. Furthermore, the only seepage systems that can be readily modeled are those completely enclosed by impervious material or those without a free seepage surface.

Therefore, it is probable that a combination of a few hydraulic models with a larger number of electric models for seepage problems of this type forms the best basis for study, and such an approach was used in the investigations.

Several hydraulic models run at the U. S. Waterways Experiment Station illustrate the effect of partly penetrating wells and well spacing under the aforementioned conditions. However, in this case the conditions simulated consisted of a pervious layer that was more pervious toward the bottom. The top stratum was 10 ft thick with a coefficient of permeability of 0.005×10^{-4} cm per sec. The underlying pervious stratum consisted of two layers—the upper one 18 ft thick with a coefficient of permeability of 220×10^{-4} cm per sec and the lower one 22 ft thick with a coefficient of permeability of 3,700 $\times 10^{-4}$ cm per sec.

The ratio of permeabilities in this case is about 1 : 415,000. The riverside or upstream end of the two pervious strata was exposed directly to the head on the river side of the levee by a pervious bulkhead, arranged so as to simulate the existence of the river at a distance of about 650 ft from the center line of the levee. An impervious bulkhead was provided on the land side or downstream at a distance simulating 1,270 ft from the river as shown in Fig. 5. The levee simulated was 38 ft high and the maximum head was 37 ft above the land-side toe. The cross section was that of a Mississippi River levee. The length of levee simulated, measured along the levee center line, was 190 ft.

The first experiment (Fig. 5(*a*)) was run with no special treatment for control of underseepage. Without drainage, it was found that practically the full head applied on the river side of the levee acted as uplift under the land-side top stratum. This condition is to be expected in the model, since, without

[8] "Uplift and Seepage Under Dams on Sand," by L. F. Harza, *Transactions*, ASCE, Vol. 100, 1935, p. 1352.

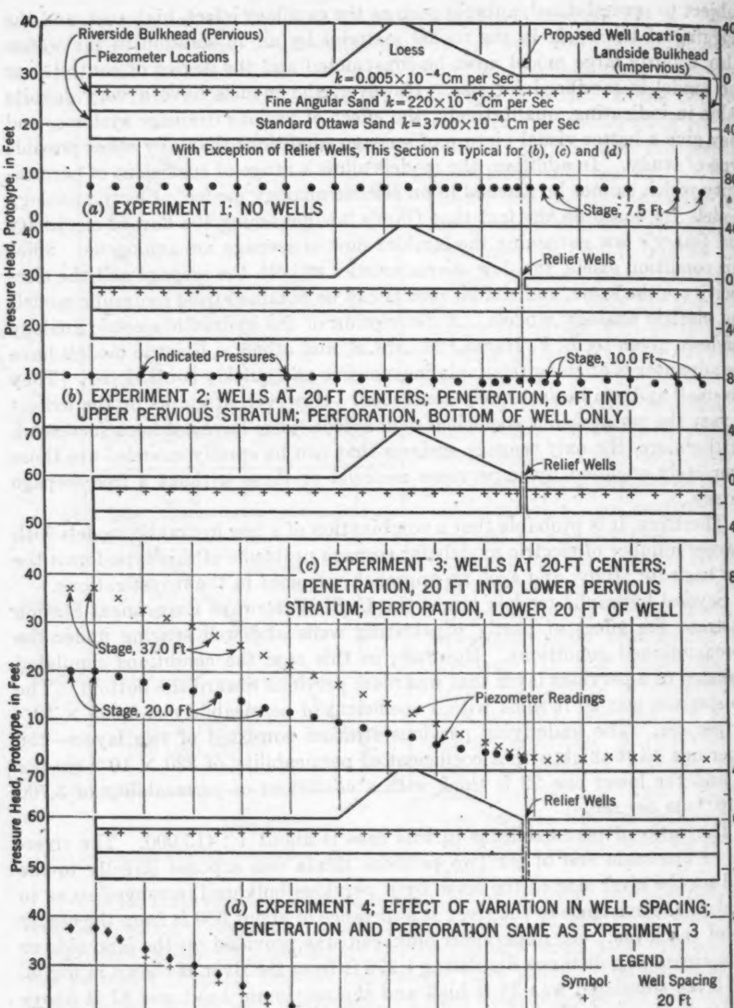

FIG. 5.—DISTRIBUTION OF HYDROSTATIC PRESSURE IN HYDRAULIC SEEPAGE MODEL

movement of water through the foundation material, there can be no loss of head—the pressure drop being caused by the friction loss resulting from flow of seepage water through the sand. The pressure in the model had not appreciably diminished at a distance of 600 ft from the levee. Thus, more leakage would occur in the field and some reduction in pressure would therefore be expected in the prototype. The maximum head shown is 7.5 ft. This head was the highest that could be built up, as a 10-ft head created boils, indicating a critical gradient in the model of approximately 1.

The second experiment utilized wells placed as shown in Fig. 5(*b*). As would be expected, the wells had little effect on the uplift pressure, because they did not penetrate the most pervious material or have sufficient area of well screen.

A third experiment utilized wells spaced at intervals of 20 ft along the land-side toe of the levee. The wells extended through the upper pervious stratum and the effective well point pierced 20 ft of the lowermost pervious stratum. The results of this experiment are shown in Fig. 5(*c*). The major conclusion that may be drawn from this experiment is that a properly designed system of wells will relieve the uplift pressure effectively. If 10 ft of uplift pressure damages the land-side top stratum, this critical pressure corresponding to 10 ft of uplift has been moved back well under the levee by the wells and almost the full height of the levee section is available to resist it. Such a condition is safe. Increasing the percentage of penetration greatly reduced uplift.

A fourth experiment (Fig. 5(*d*)) was run to demonstrate the relatively small effect of varying the well spacing within reasonable limits. In this case the head was kept constant at 37 ft and a safe value for uplift was obtained by using 20-ft, 40-ft, 60-ft, and 80-ft well spacing. The effect of the well spacing on uplift pressure will be discussed subsequently. The effect of varying the spacing is quite small. Wells spaced on 20-ft centers gave 93% relief whereas those on 80-ft centers gave 86% relief.

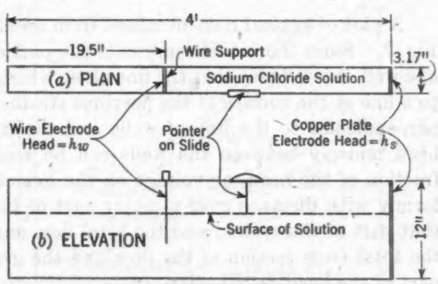

FIG. 6.—SKETCH OF ELECTRIC MODEL SETUP

An attempt was also made independently in the Vicksburg Engineer District Laboratory to obtain similar information from electric analogy models. In the case of the electric models, a homogeneous pervious stratum was used. The first model was set up to simulate the condition computed by Mr. Muskat for 100% penetration. An examination of Fig. 4 will show how closely the model checked curves obtained from the Muskat formulas. Therefore, it was assumed that this check verified the use of the models and the case of partial penetration of wells was studied in the remaining models.

A diagram showing how the models were set up is shown in Fig. 6. The models consisted of a small wooden flume, 3.17 in. wide, 12 in. deep, and 48 in.

long. The inflow region was represented by a solid sheet of copper in one end of the trough and the well by a copper wire, sized to scale, and a series of tests made varying the wire size and the position of the wire to represent values of s/a from 3 to 10 and values of a/r_w from about 50 to 500. Provision was made for adjusting the depth of penetration of the wire. The pervious stratum was simulated by filling the flume to the desired depth with a sodium chloride solution.

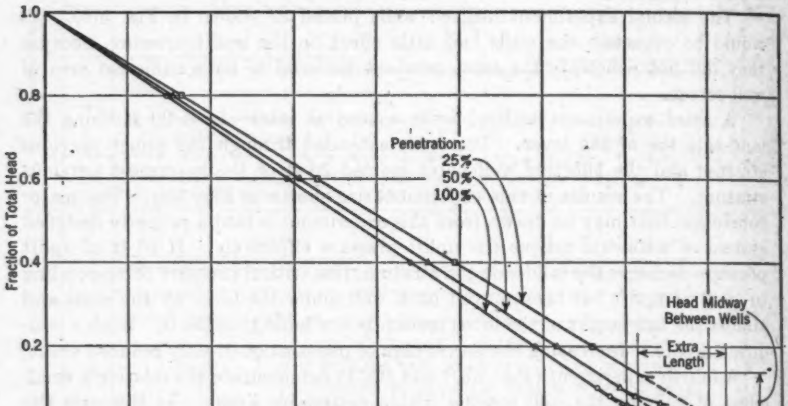

FIG. 7.—REPRESENTATIVE ELECTRIC MODEL TEST RESULTS; PARTIAL PENETRATION OF WELLS; SODIUM CHLORIDE SOLUTION RESISTANCE

A plot of typical data obtained from an electric analogy model is shown in Fig. 7. Since the model represents the part of the seepage system drained by one well, it is evident that the line along which the data were taken corresponds to a line at the surface of the pervious stratum midway between two wells and perpendicular to the line of wells and the line drive source. Therefore, the head midway between the wells can be read directly from the curves as a fraction of the head, or voltage on the model. Since the head decreases uniformly with distance over a major part of the system, the flow is uniform in that part of the system and the total flow per well can be calculated by using the total cross section of the flow and the gradient given by the straight-line part of the head distribution.

To interpret the model studies conveniently, a term called "extra length" is introduced. This term refers to the resistance to flow into the wells. If it is considered that a seepage system is flowing out through a vertical outflow face which offers no resistance to the escape of water, the most effective possible pressure relief is produced. If any other system of outflow is introduced, the system has acquired more total resistance to flow which may be expressed as an additional length of pervious stratum. This additional length will be

designated as "extra length" and can be determined from the model test results as shown in Fig. 7. Also, the head midway between wells can be found in a similar manner.

The important facts that can be gained from a study of the data are that: (1) The length of the strainer has more effect on the effectiveness of the well system than any other factor; (2) the seepage quantity falls off rapidly; and

[a] Midway between wells. [b] In cubic feet per second for stations 100 ft apart.

(3) the head midway between wells rises rapidly as the penetration drops below 25%. An examination of Table 1, which gives results of a numerical example worked out by the writers, shows plainly that well size and well spacing have only minor over-all effects within the limits studied, provided the wells are

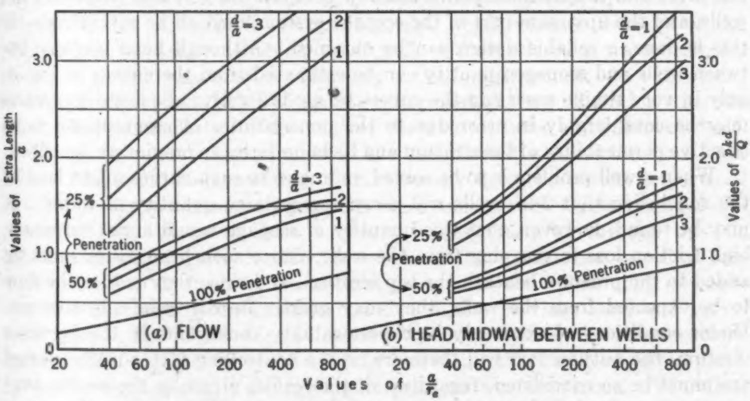

Fig. 8.—Chart for Flow and Head Midway Between Wells for an Infinite Line of Wells Tapping a Pervious Stratum Fed by a "Line Drive" Parallel to the Line of Wells

large enough to carry off the seepage quantity. The curves in Fig. 8, which were plotted from the electric model studies, will readily yield head midway between wells and seepage quantity from a line well system producing from a

"line drive" source for any assumed spacing and for 25%, 50%, and 100% penetration. The curves for flow in Fig. 8(a) are used first. From an assumed well spacing and well radius $\left(\frac{a}{r_e}\right)$, a value of $\frac{\text{(extra length)}}{a}$ can be found (r_e is the effective radius). From this the extra length and Q can be computed, using the formula,

$$Q = \frac{k\,h\,a\,d}{s + \text{(extra length)}} \qquad (13)$$

Then the curves in Fig. 8(b) are entered with the same value of $\frac{a}{r_e}$, and a solution for p is possible. It should be noted, however, that the only criterion is the effect of frictionless wells on a closed seepage system. No consideration has been given to leakage through the top stratum, to losses due to inflow into the well, or to losses due to outflow pipe friction. These factors are of utmost importance, especially when the seepage quantity is large.

The well design curves can be applied in a great number of cases by utilizing the well design in only one part of the seepage system. It can be assumed that there is no further inflow of seepage to the pervious stratum between the line of wells and the upstream toe of the levee or possibly the upstream toe of the core of a dam. A reduced head can be utilized, obtained from the ratio of total resistance to flow on either side of this point, and the assumptions made in developing the curves will then apply quite accurately. The reduced head will depend, of course, on the upstream soil conditions such as width and thickness of blanket and the upstream dimensions of the pervious layer. In considering the system as a whole, the outflow resistance of the wells, the flow between the line drive and the assumed point, the flow between the assumed point and the wells, and the upstream part of the seepage system must all be considered. If this is done, a reliable design can be obtained. Although head midway between wells and seepage quantity can be estimated from the curves in Fig. 8, only in very simple cases can the curves be used directly. Seepage quantities may be considerably in error due to the uncertainties of assumptions as to effective permeability of the stratum and its boundaries as previously described.

When a well problem is to be solved, reference to such curves might lead to the conclusion that 2-in. wells will carry a very large quantity of water. It may be found, however, that this quantity of seepage would entail extremely high friction loss in escaping from the well. Since such head losses must be added to the pressure beneath the top stratum, and since they reduce the flow to be expected from the wells, they may greatly impair relief effectiveness. Under conditions of extremely high permeability coefficients in the pervious stratum, the outflow loss will therefore be the controlling factor in the design and must be so considered, regardless of the results given by the curves concerning the size of well required.

From the foregoing discussion it is evident that the design of the well system is a complicated problem, but one that can be solved reasonably well if judgment is used. However, design by trying various well sizes and spacings can be made on installations of existing structures about which information is

not available in sufficient detail for theoretical study—because a system that is too small will be of some help and the flexible nature of well systems allows additions to be made as required.

Installation of Relief Wells

Whenever possible, well systems should be installed before danger develops, but they may be placed as they were at the Fort Peck Dam in Montana with considerable head against the dam or levee. The wells are placed in cased drill holes. The casing is withdrawn from around the well point and the riser pipe, and the hole is backfilled. Installation of the wells with water behind the dam or levee, however, should be done only with the greatest care and only in cases of extreme emergency when other methods cannot be used.

The part of the riser pipe which penetrates the top stratum should be backfilled and tamped with extreme care. A mixture of sand with about 10% bentonite makes an excellent backfill material and is believed generally preferable to local material since the mix can be used in the form of moist balls to cut off any flow of water into the hole and the mixture can then be tamped in successfully in the dry.

Examples of the Use of Relief Wells

Various methods of controlling underseepage are in general use—trench or sheet-pile cutoffs, upstream blankets, and various types of gravel-toe drains. All these methods have been used with success and have proved satisfactory where foundation conditions were favorable. However, these methods are not effective or economical in a large number of cases, and it is preferable under suitable conditions to install relief wells to provide the necessary pressure relief. Where the loss of water is not an item and where surface drainage of the effluent can be readily achieved, relief wells are considered more economical and more generally satisfactory than any of the foregoing methods. However, in some cases, it is advisable to employ other methods in conjunction with the relief wells, particularly for drainage of the dam or levee embankment itself.

The most outstanding example of the use of relief wells is the Fort Peck Dam. The foundation consisted of an extremely tight, practically impervious stratum of clay overlying very pervious sands and gravels.[6] Although a sheet-pile cutoff was driven to shale, sufficient leakage occurred through the pile cutoff to develop high hydrostatic pressures at the downstream toe that produced a head of 45 ft above the natural ground surface. This uplift pressure was first observed in piezometers installed in the pervious sand and gravel foundation. The first surface evidence of the high hydrostatic pressure came in the form of high discharge from an old well casing that had been left in place. It was recognized that this high uplift pressure was dangerous. Therefore, consideration was given to methods of effecting its release. A board of consultants, consisting of Joel D. Justin, W. H. McAlpine, and Arthur Casagrande, all Members, ASCE, and T. A. Middlebrooks, Assoc. M. ASCE, made a complete study of the problem and recommended the immediate installation of

[6] "Fort Peck Slide," by T. A. Middlebrooks, *Transactions*, ASCE, Vol. 107, 1942, p. 723.

relief wells 100 ft outside the toe on 50-ft centers. Since it was considered imperative that the installation be made as quickly as possible, 4-in. and 6-in. well casings, available at the site, were slotted with a cutting torch and installed in the pervious stratum with solid pipe extending to the surface. To afford some relief over the full length of the affected area, the wells were first spaced on approximately 250-ft centers. After intermediate wells were installed, making the spacing 125 ft, it was evident that satisfactory relief could probably be provided at this spacing rather than at the originally proposed 50-ft spacing.

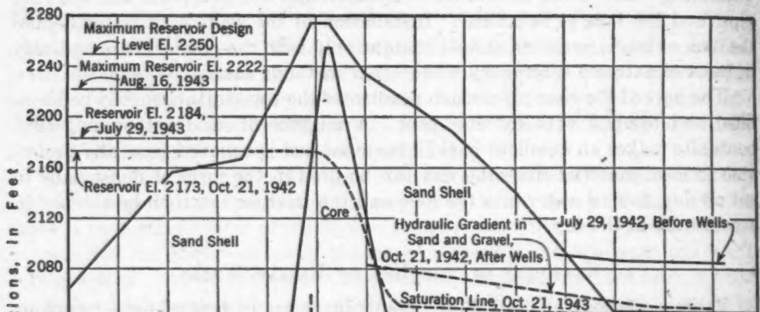

FIG. 9.—RELIEF-WELL INSTALLATION, FORT PECK DAM IN MONTANA

This theory was shown to be true after an extensive testing program, and the spacing was left at 125 ft. The results obtained from this installation are shown in Fig. 9. Special attention is called to the facts that the hydrostatic pressure at the toe was reduced from approximately 45 ft to about 5 ft and that the total flow from all twenty wells averaged around 10 cu ft per sec. It is definitely concluded that the installation is entirely satisfactory.

The foundation for the Great Salt Plains Dam in Oklahoma consisted of approximately 30 ft of pervious sand, varying from fairly fine sand near the surface to medium and coarse sand immediately above the rock. In the design of the structure, it was considered adequate to control the saturation line in the structure and to relieve the seepage, partly, in the foundation by a horizontal drain installed at about the midpoint of the downstream slope. Because of the development of small boils at the toe when the reservoir head reached approximatley 20 ft (maximum 60 ft), it was evident that the foundation

seepage was by-passing the drain in the dam, since the horizontal permeability of the lower stratum was much greater than the vertical permeability. To relieve this situation, relief wells were installed at the downstream toe. Although the maximum head has not yet been experienced, the functioning of the wells at the lower heads indicates entirely satisfactory performance.

Foundation conditions at Sardis Dam in Mississippi consisted of a deep deposit of sand with irregular horizontal strata of more impervious material. In the design of the dam, a relatively impervious blanket was extended from the core 1,000 ft upstream; and a natural blanket, except in the narrow river channel, extended for an unlimited distance in the reservoir. In addition, the top stratum of less pervious material was excavated beneath the downstream section of the dam and backfilled with more pervious material connecting into a horizontal drain. The first filling of the reservoir showed considerable seepage, as was to be expected. However, the existence of hydrostatic pressures downstream from the dam was evidenced by small boils at the toe and by the increase in flow into sides of the dredge borrow area downstream. Relief wells were installed along the downstream toe and have been in operation for several years. In addition to the regular relief well system on this dam, a large number of different types of wells were installed; and their effectiveness, as evidenced by their flow quantities, was studied. It was discovered that porous concrete pipe and even wooden pipe surrounded by suitable gravel filters could be used satisfactorily for this type of installation. It was found that large gravel-filled wells are inefficient.

The installation on the Arkabutla Dam in Mississippi is believed to be the first installation of relief wells included in the original design of a dam. This dam was designed and constructed by the Vicksburg Engineer District of the U. S. Engineer Department and the board of consultants on the dam were Joel D. Justin, L. F. Harza, W. H. McAlpine, and the late O. N. Floyd, all Members, ASCE, and Glennon Gilboy, Assoc. M. ASCE. The wells were installed on 25-ft centers and were approximately 100 ft inside the downstream toe. The foundation of Arkabutla Dam consisted of approximately 30 ft of impervious redeposit loess over a very pervious sand and gravel deposit. The reservoir has not been filled to a high elevation, but low levels indicate that the performance of the wells is entirely satisfactory. In this case, the excavation of an adequate drainage trench would involve excavation from about 30 ft to 40 ft below the ground-water table. The cost was estimated at approximately $300,000. However, the well installation, the cost of which was about $27,000, is apparently serving the same purpose adequately.

An example of an installation for a levee foundation is that at Lawrenceburg, Ind. The levee foundation in the vicinity of Lawrenceburg consists of an overburden of relatively impervious material overlying a deep stratum of water-bearing sand and gravel. The levee practically rings the town; and, as is to be expected, considerable underseepage occurred even at moderately low river stages. When the old levee was enlarged, a system of drainage wells was installed along the inland toe of the new levee. It was the purpose of these wells to insure the stability of the levee and not to relieve all uplift pressures and underseepage completely. This system has been subjected to

two moderately high floods and has been generally satisfactory. Seepage did occur in low areas in the town and at some places along the levee toe, and expansion of the well system will probably be required to provide positive control during higher river stages. At this place, and at other locations where the valley deposit is extremely deep and exposed directly to the river, it may be impossible to take out enough water to relieve all uplift pressures completely and to prevent outcropping of seepage on the land side of the levee. However, it is believed that, in most cases of this type, sufficient water can be released to insure stability of the levee against dangerous boils.

Conclusions

The writers do not recommend relief wells as the most economical and satisfactory drainage system for all dams and levees, but it does appear that they have proved themselves to have definite possibilities and to be especially suited for certain drainage conditions. However, since it takes some pressure (which is represented by the head midway between and behind the wells) to make them operate, their discharge must be placed below the downstream ground surface, to avoid underseepage completely. Likewise, it will probably be only in unusual cases that the wells can be used for drainage of the dam or levee section. However, they can be combined with section drainage which will result in a more economical system. Also, it is doubtful that wells can be made to stop large or channelized boils in areas of thin top stratum, unless they are pumped, or unless they discharge some distance below the ground surface. However, in spite of their limitations, they should prove very effective and economical where deep drainage is required, and in many cases they can be used with great economy in conjunction with the other types of drainage systems. Experience has shown that large wells (6-in. minimum inside diameter) and deep penetration, full where practical, are necessary for highly efficient operation.

Acknowledgments

The assistance of the personnel of the U. S. Waterways Experiment Station and the Vicksburg Engineer District in working up the data on which the design of wells has been based is gratefully acknowledged—especially the contributions of W. M. Snyder, Jr., and A. R. Bourquard, of the Vicksburg Engineer District Laboratory, who did a large part of the work on electrical analogy models and those of W. J. Turnbull, M. ASCE, C. I. Mansur, Jun. ASCE, and William R. Perret of the U. S. Waterways Experiment Station, who did a great deal of research on development of new types of well points for the Sardis Dam installation and who conducted the hydraulic model experiments. Acknowledgment is also made to Brig.-Gen. Max C. Tyler, M. ASCE, formerly President of the Mississippi River Commission, to Gerard H. Matthes, Hon. M. ASCE, formerly Director of the U. S. Waterways Experiment Station, and to Maj.-Gen. Raymond G. Moses, formerly District Engineer, Vicksburg Engineer District, under whose general direction a large part of the experimental work was performed.

DISCUSSION

HENRY C. BARKSDALE,[7] Assoc. M. ASCE.—It seems to the writer that Messrs. Middlebrooks and Jervis are to be commended highly for their careful and intensive studies and for the clarity with which the results have been presented. The note of moderation that permeates the whole paper and prefaces the presentation of the theoretical design is particularly gratifying. Experience with the development of ground-water supplies and studies of their characteristics lead the writer to believe that the uniform conditions and homogeneity of the aquifer, which must be assumed to apply any theoretical methods to the solution of such problems, is the exception rather than the rule. Sound engineering judgment is of prime importance in the application of theoretical equations to ground-water conditions. The following comments are intended to be supplementary rather than critical.

Reference is made in the paper to the difficulty of obtaining accurate samples of material at great depths for the determination of the coefficient of permeability. This difficulty is one that has long confronted students of ground-water hydrology. No inexpensive method of obtaining satisfactory samples has been devised. However, the results of pumping tests for determining the coefficient of permeability are being used increasingly. The several methods of determining permeability from pumping tests have been discussed fully by L. K. Wenzel,[8] Assoc. M. ASCE. They depend upon careful observation of the effect of pumping one well upon the water levels in other wells near by. The coefficient of permeability thus determined automatically averages the irregularities of the formation. It is suggested that, in structures of major importance, test wells and pumping tests on them would be a reliable and not unduly expensive method of determining the permeability of the materials beneath the foundation. Some of the test wells conceivably might later be used as relief wells.

Since relief wells must usually depend for their effectiveness upon natural gravity flow, the reduction of losses of head in the structure of the well itself is, as the authors state, a most important consideration. Both the loss in the well casing and the entrance loss through the screen are important. It is recognized that the rate of flow into a relief well would be slower than that into a well pumped for water supply. The losses would therefore be smaller. Nevertheless, experience with wells for water supply has shown that, in the modern gravel-walled type of well, the entrance losses are less than in wells not so constructed. In formations composed of mixed sand and gravels, the gravel wall may be built up by adequately developing the well. If, however, the formation is uniform and fine grained, it may be advantageous to introduce gravel around the screen at the time the well is constructed.

It seems to the writer that relief wells along a levee might present some special maintenance problems. There would be no flow through them over

[7] Hydr. Engr., U. S. Geological Survey, Trenton, N. J.

[8] "Methods for Determining Permeability of Water-Bearing Materials," by L. K. Wenzel, *Water-Supply Paper No. 887*, U.S.G.S., Govt. Printing Office, Washington, D. C., 1942.

long periods of time. It is conceivable, therefore, that some of the wells in the system might become so clogged by corrosion or by the growth of organisms in the water that they might not be effective when needed in times of flood. Maintenance of the well system would, therefore, become an important part of the maintenance of the levee. Each well should be pumped and tested periodically to assure its continued effectiveness.

Where relief wells are an essential part of a dam, the problem of their maintenance becomes especially important. There is usually a more or less constant head, so that the relief wells will flow continually. It would, therefore, be unnecessary to pump them to determine their continued efficiency if arrangements are made to measure the flow from them periodically. The public and in fact many engineers are inclined to assume that the design of a dam more or less permanently assures its safety. Where the safety of the dam may depend upon the effectiveness of relief wells, the need for competent and continuous engineering supervision of the structure becomes imperative, and the responsibility to the public is greatly increased. Under favorable conditions the life of a properly constructed well might be as much as 40 or 50 years depending largely on the character of the water and the type of materials used in the well. Under less favorable conditions the well might fail within a decade or so. In any event sustained vigilance would be necessary to assure the continued safety of the structure.

In conclusion, the writer believes that this paper deserves the widest publicity and discussion. This relatively new method of increasing the safety of dams and levees should be called to the attention of everyone concerned with the design and maintenance of such structures. In presenting this paper the authors are rendering a distinct service to the profession.

WILLARD J. TURNBULL,[9] M. ASCE.—Information and design data on drainage wells have been presented in an interesting manner in this paper. Drainage wells have been used on structures of any degree of importance only in comparatively recent times, and this particular engineering feature should prove of more and greater importance as times goes on with reference to the relief of detrimental substratum pressures beneath and downstream from dams, levees, miscellaneous embankments, and other types of engineering structures. In the not distant future drainage wells probably will be incorporated as a regular feature in the design of all engineering structures built on pervious foundations which are subject to dangerous exit pressures of seepage water.

The question often arises, particularly with reference to structures already built, as to whether drainage wells are needed for the relief of excessive substratum pressures. An effective method in demonstrating the need of a drainage system is by an installation of piezometers. The piezometer installation should be of such magnitude that true gradients of horizontal and vertical pressures can be obtained. Once the true picture of the pressure gradient is known and the actual horizontal and vertical soil profile established, then the engineer will have sufficient data to indicate whether a pressure relief system of some type is needed.

[9] Chf., Embankment, Foundation & Pavement Div., U. S. Waterways Experiment Station, Vicksburg, Miss.

The authors give a very complete discussion of the critical escape pressure gradients from which boils may result, and state that a pressure head loss of from 25% to 50% is not unusual between the upstream and downstream sides. It is desirable to stress that, in some exceptional instances where the top stratum is quite pervious, the pressure head loss may even be as high as from 70% to 80%. If such a condition exists, it is quite obvious that seepage losses under the structure and through the top stratum behind the structure may dissipate dangerous heads with the result that sand boils could not occur. In these particular cases drainage wells would not be feasible since their effectiveness would be relatively small. Drainage wells also might not be feasible in the case of an extremely pervious and thick foundation where the amount of water from the pervious stratum necessary for adequate pressure relief would require a drainage well system beyond all economical limits of construction. In general, on all ordinary pervious foundations with relatively tight top strata, a properly designed drainage system can be entirely effective and feasible, and in many cases may be a necessity to adequately insure the safety of the structure.

In some instances objections may be raised concerning the additional water that is brought to the surface of the ground by a system of drainage wells. It is true, of course, that any system of drainage brings more water to the ground surface and results in additional drainage requirements. In many cases additional drainage requirements can be easily and economically met. However, in some other instances, particularly behind long levees, the drainage problem may be serious from the practical and economical viewpoint and may have to be handled as an independent project. In these latter cases the increased cost of the well system due to drainage will have to be carefully weighed against the reduced hazards attributed to the drainage well system. As a matter of interest, particularly from the psychological angle, the writer believes that if possible all water from drainage wells should be released into a header pipe beneath the ground surface and collection and disposal should be made in a given sump area. An alternate procedure is to have a properly constructed collection ditch which will carry the water to the disposal sump.

The writer would very much like to indicate a difference between the terms "pressure relief" and "seepage relief." In numerous instances these terms have been used interchangeably although actually there is a vast difference between them. To secure pressure relief—that is, for prevention of boils—an escape pressure gradient of less than 0.6 is certainly adequate in all cases. However, to secure complete seepage relief, a pressure escape gradient of zero is necessary. These facts amply demonstrate why a drainage well system which would give adequate pressure relief may still show considerable free surface seepage. In this connection, the writer wishes to refer to a field experimental installation of pressure relief wells at Sardis Dam at Sardis, Miss. In this installation numerous types of commercial and improvised drainage wells were used. The following is a list of these wells: Improvised—(1) porous concrete (gravel aggregate), bevel joint; (2) porous concrete (slag aggregate), lap joint; (3) cement-asbestos drilled with $\frac{1}{8}$-in. holes on $\frac{1}{2}$-in. centers; (4) square wooden pipe with $\frac{1}{4}$-in. holes on 2-in. centers; (5) perforated concrete pipe with twelve $\frac{1}{4}$-in. holes

per foot of pipe; (6) perforated clay pipe with thirty $\frac{5}{8}$-in. holes per foot of pipe; (7) 10-in. steel casing perforated with $\frac{3}{16}$-in. holes on 3-in. by 5-in. centers filled with sand-gravel; (8) 10-in. steel casing perforated as in item (7) with a perforated collection galvanized sheet-iron pipe in the center of the casing surrounded with gravel filter; (9) perforated galvanized sheet-iron tubes with $\frac{3}{16}$-in. holes on $\frac{3}{4}$-in. centers; and commercial—(10) perforated steel pipe with porous cemented gravel filter; and (11) seven commercial well screens with various type slot openings. In all installations of either commercial or improvised wells, a filter was used around the well if the slot opening was of such size that a filter was necessary to prevent the entrance of the foundation sands into the well. In practically all cases the improvised wells have functioned equally as well as the commercially produced products with the noticeable exception of the 10-in. well which was backfilled on the inside with pervious gravel. In this particular case the frictional resistance of the water through the gravel was such that an excessive head loss resulted and in consequence very little water was delivered by the well and very little pressure relief was accomplished.

The U. S. Waterways Experiment Station at Vicksburg, Miss., had previously done considerable work on the design of gravel filters and had arrived at the general criterion that the ratio of the 15% size of the filter material to the 85% size of the foundation material should not be greater than 5. Laboratory tests in a specially designed pressure tank indicated that this ratio might range from 2 to 5, preferably being around 3 to 4. Furthermore, these special tests showed that the ratio of the 85% size of the filter gravel to the diameter of the screen opening should be greater than 1. All filter gravels used in the placement of the Sardis experimental wells were designed on the preceding assumptions and in every case the filters proved to be entirely successful even though in some cases the thickness of the filter around the pipe was not more than 3 in. The necessity for the ratio of the 85% size of foundation sands or filter (as the case may be) to the slot opening (being greater than 1) was demonstrated by the installation of two metal slot wells without filters. In one case this ratio was 1.1 and in the other 0.7. In the former instance the infiltration of sand into the well did not occur, whereas in the latter instance the well became completely clogged with sand.

In the following paragraphs one of two drainage well installations made along Mississippi River levees is described and discussed briefly. At the site of the installation, excessive underseepage accompanied by numerous small-sized to medium-sized sand boils was observed during the 1937 high water. The sand boils were not considered dangerous and only a few were sacked. Heavy underseepage occurred as far as 1,000 ft to the land side of the levee whereas the boil area was confined mainly within 100 ft of the levee toe. A top stratum of relatively impervious silts and silty clays covers most of the area with a thickness ranging from 4 ft to 40 ft. On one low ridge the surface soil consists of a sandy silt which is relatively pervious, and the earliest and heaviest seepage occurred on this ridge. The top stratum is underlain by a fine sand stratum which is quite pervious, and this in turn is underlain by strata of

medium to coarse sands and sand gravel, all of which are highly pervious. The average thickness of the top stratum along the line of wells is about 10 ft. The river is about 1,800 ft away. However, large borrow pits exist in front of the levee, some areas of which extend into the fine sand stratum. This fact caused difficulty in arriving at a proper assumption of the over-all average distance of the source of the water from the line of wells. The permeability of the pervious strata was based on laboratory tests obtained on disturbed samples of the material in question. The laboratory tests were used because of the lack of more adequate field information on the in-place permeability of the pervious material.

The installation as made was for test purposes. Consequently, the length of the screen was varied to agree with 10%, 20%, and 30% penetrations of the pervious strata. Every fourth well had a 10% penetration screen at the 20% depth. A minimum clear, inside diameter of 2½ in. was chosen for the well screen and riser pipe. On the basis of the assumptions for permeability and length of flow path and well diameter, a well spacing of 50 ft was used. This spacing did not agree, of course, for the various penetrations but represented an average spacing. The wells used were nonmetallic and consisted of screen, riser, and discharge sections. The screen section was composed of a 4-in. inside diameter porous concrete pipe which served as a filter for a core of perforated clay tile, 2½ in. in inside diameter. The riser section was of solid clay tile, 3 in. in inside diameter, which was connected to a solid clay discharge pipe by a T-section. The riser pipe was carefully sealed through the top stratum by a tamped sand-bentonite mixture. Space does not permit further detailed description of the wells. A surface collection ditch was dug near and parallel with the line of the wells for disposal of the water.

A system of piezometers was installed. The system consisted of a single line of piezometers in the line of wells with several lines running transverse both to the land side and river side of the levee.

During the spring flood season of 1943 a relatively low head of about 7.5 ft was experienced against the levee at the location of the wells. A very brief summary of the test findings follows:

a. The piezometers in the line of wells with all wells closed indicated that about 70% of the river-side head was dissipated by underseepage alone and that with the wells open an additional decrease in head of 10% was obtained. These data indicate that the top stratum at the site of the test installation was too pervious to demonstrate the effectiveness of a well system adequately.

b. Test data indicated that the well discharges obtained were about twice those expected for the given head, thus indicating either that the assumed coefficient of permeability was not great enough or that the effective distance to the source of the water chosen was too great. These facts indicate the necessity of designing a well system with a fairly large factor of safety.

c. Test data indicated that the friction losses obtained in the well, from 2½ in. to 3 in. in inside diameter, were too great for the quantity of water produced and that larger clear diameters were necessary.

d. The nonmetallic type of well as installed is highly efficient in the production of water but needs further thought and study to insure that the wells do not develop faults caused by the many joints which are not positively connected.

e. Test data indicated that the 10% penetration well was relatively ineffective but that, if the wall were placed at the 20% penetration depth, it would produce about as much water as the full 20% penetration well. The 30% penetration well is appreciably more effective than the others, showing that a minimum penetration of at least 25% may be desirable in most cases.

f. Test data were not conclusive because of the relatively low head; higher heads are needed for final and conclusive data.

g. Test data indicated that the lack of information on actual field in-place permeabilities is serious and every effort should be made to determine this value. (An excellent method of determining the field permeability is by a large-scale field pumping test and alternate field procedures are the dye or electric methods; however, in general, determination of permeabilities by pumping water into a stratum is not recommended.)

h. The outlet of drainage wells should be as low as possible.

The writer wishes to emphasize a few features of the design and installation of drainage wells. Extreme care should be taken to secure a tight backfill around the well through the top stratum material. This measure is obviously necessary because the higher pressure of the deeper and usually more pervious strata will be brought directly to the surface through the medium of the well and should the well in any manner become plugged, there may be material danger of piping around the well. Thus, every precaution should be taken so that a drainage well is not plugged in any way while in operation. Another feature of extreme importance in the design of drainage wells is adequate insurance that the diameter of the drainage well is sufficiently great that friction and velocity head losses are maintained at a minimum. It is quite possible that the difference between an effective drainage system and one that is ineffective might be a difference of 1 in. in diameter of the wells. To insure the proper functioning of a drainage well system, it is very essential to remember that a properly designed system may be rendered ineffective by a poor installation. The authors have placed needed emphasis on the importance of obtaining the best information possible concerning (1) proper evaluation of the over-all coefficient of permeability of the pervious strata, and (2) the effective distance between the source of the water and the line of wells.

Glennon Gilboy,[10] Assoc. M. ASCE.—A neat summary of the present state of development, both theoretical and practical, of well relief systems is presented in this paper. Although much remains to be learned, such systems have already proved to be of great practical value, and probably they will have an increasingly wider range of application.

Compared with rock toes, gravel drains, and other surface relief measures, the drainage well has outstandingly useful characteristics. Not only does it serve to penetrate a thick impervious blanket at much less expense than trench-

[10] Cons. Engr., South Lincoln, Mass.

ing, but it also serves, in the pervious stratum itself, to intercept a whole succession of layers, thus providing relief where needed and compensating for the inferior drainage characteristics of stratified deposits in the vertical direction.

The importance of these effects can readily be visualized by considering, as an extreme case, a pervious deposit composed of thin layers of sand separated by layers of tar paper. It is obvious that a surface drain would afford practically no relief, whereas a well, punching through the layers of tar paper, would be very effective. The formation of a boil would correspond to a successive tearing of the tar paper layers, beginning at some weak point, as a result of the horizontally transmitted pressures. The surface drain would not prevent this, whereas a properly designed well system would reduce the pressures so that the progressive rupture could never get a start.

Natural deposits do not normally reach this extreme, but the effect is present to some degree in practically all sedimentary materials. Therefore, the applicability of theoretical analyses and model tests based on homogeneous and isotropic media is limited. As guides such analyses and tests are useful, but it is too much to expect that their results will be reflected quantitatively in the prototype. Thus, although wells are peculiarly adapted to drainage of stratified deposits, the existence of stratification throws a considerable element of uncertainty into the design. It is proper to recognize this condition at the outset and to be prepared to modify the installation if the first trial proves inadequate. Fortunately, as the authors state, well systems are naturally flexible, so that the cut-and-try method is not as much of a drawback as it is in other types of drainage installations.

The authors speak of controlled versus uncontrolled drainage. This concept is of prime importance. In certain cases it is desirable, and often necessary, to make a dam as nearly watertight as possible; but there are many instances in which a high degree of watertightness not only is expensive to obtain, but also is not in the least necessary for the functioning of the structure. In structures intended merely to retard, rather than completely stop, the passage of water, a design which contemplates substantial seepage losses can be made entirely adequate by proper drainage control.

Control of seepage through the body of the dam itself is usually provided by a rock toe, a horizontal drainage blanket, or other suitable method. The factors governing the flow pattern and the quantity of seepage are reasonably well understood, so that the drainage system can be planned intelligently. Good modern practice in this respect, however, is by no means universal. Although the subject has already been well reviewed, within the past five years a flood control dam, with normally dry reservoir, has been constructed with a 1-on-3 upstream slope and a 1-on-6 downstream slope—the avowed purpose of the latter being to keep the line of saturation covered up. The fact that this queer concept is still extant shows the need for continued emphasis on the subject of sound drainage control.

Control of foundation seepage is every bit as important, and is frequently much more complicated. Sometimes it is possible to combine the control systems, draining the foundation into the same element which drains the dam.

Sinking an underdrain through an impervious natural blanket and connecting it to the rock toe of the dam is a good example of this practice. On the other hand, there are many cases in which this procedure is impractical, or, if adopted, would prove ineffective. In this region, the drainage well comes into its own. The well should be considered, therefore, not merely as an adjunct or a corrective measure, but as an element in the design, coordinated with the other elements of the drainage system. The Arkabutla installation is an important advance in this field, and there is every reason to believe that future designs will benefit from a similar approach.

The factual material presented by the authors on existing installations is interesting and instructive. The writer has no comment to make, except to suggest that, for those cases which have not as yet been subjected to extreme operating conditions, the authors present a follow-up when those conditions arise, so that the profession may be informed of the final adequacy of the installations and of the additional corrective measures, if any, which the extreme conditions may require.

W. A. Wall,[11] Esq., and C. A. Stone,[12] Esq.—An interesting and comprehensive discussion of the theoretical principles of underseepage control and the relief of subsurface pressures by the use of relief wells is presented in this paper. The writers, having been concerned with the theoretical design of relief well systems for a number of projects, have used these design principles, and those presented by Preston T. Bennett,[13] M. ASCE, as the "Modified Muskat-Jervis Well-Spacing Formula." The formulas thus applied give results that are in close agreement; and the Bennett method simplifies, to some extent, the assumptions that must be made to permit a mathematical solution. In both cases, however, assumptions must be made for the well spacing, well radius, and well losses; only by repeated trials can a theoretically ideal combination of these variables be found which will provide the required subsurface pressure relief most economically.

To simplify the design computations and to facilitate the determination of the most economical design of a well system, the writers suggest a well-spacing chart for the design of pressure relief well systems. Fig. 10 is a further modification of the "Modified Muskat-Jervis Well-Spacing Formula." The intent and purpose of this chart is to provide a reasonably accurate method utilizing fewer initial assumptions in determining the optimum well system design. The writers were unable to eliminate all the assumptions; however, those that must be made are of minor significance, and the chart provides a rapid method for solving for the optimum well spacing for a given set of conditions.

In the usual problems of relief well design, particularly where the design is made in conjunction with the design of a levee or a dam, the maximum permissible head midway between wells is the prime factor governing the design.

[13] "Comments on the Design of Relief Wells," by P. T. Bennett, Rept. on Conference on Control of Underseepage, U. S. Waterways Experiment Station, Vicksburg, Miss., April 1, 1945.

In addition to the head midway between wells, the following factors are known, can be fixed, or must be assumed regardless of the analysis used: (1) The maximum elevation of the impounded water; (2) the maximum allowable pressure in the line of wells; (3) the elevation of the well discharge; (4) the length of path

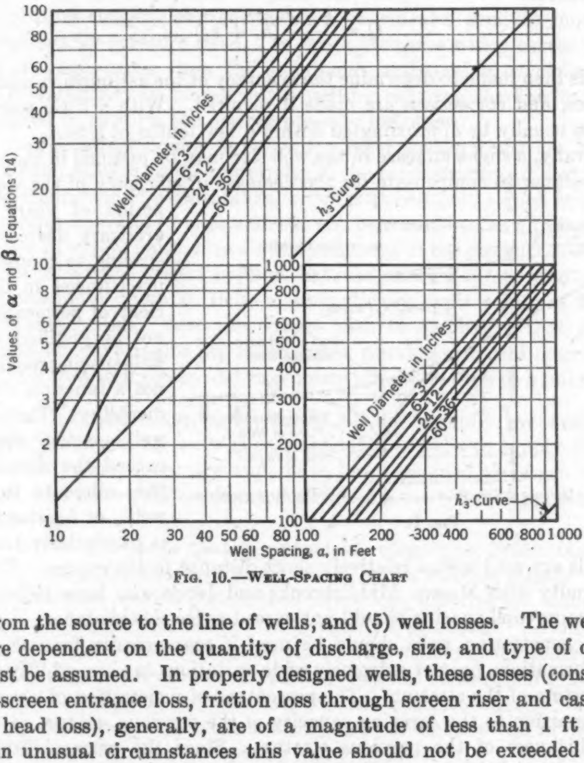

FIG. 10.—WELL-SPACING CHART

of flow from the source to the line of wells; and (5) well losses. The well losses, which are dependent on the quantity of discharge, size, and type of construction, must be assumed. In properly designed wells, these losses (consisting of the well-screen entrance loss, friction loss through screen riser and casing, and velocity head loss), generally, are of a magnitude of less than 1 ft of head. Except in unusual circumstances this value should not be exceeded and can therefore be assumed for the initial computations.

Referring to Fig. 11, let the difference in head h_m between the midpoint of wells and the wells be expressed as

$$h_m = \alpha \frac{h_r}{l} \qquad \text{14}a)$$

or

$$\alpha = \frac{h_m\, l}{h_r} \qquad (14b)$$

Furthermore, let the difference in head h_3 between the midpoint of wells and the average in the plane of wells be expressed as

$$h_3 = \beta \frac{h_r}{l} \qquad (14c)$$

By entering Fig. 10 with value α, obtained by solving Eq 14*b*, the required well spacing a can be determined for the well size selected, and the value of β can be determined from the h_3-curve for that well spacing.

After solving Eq. 14*c* for h_3, the rate of discharge, Q, per well is obtained by the formula:

$$Q = \frac{k\,a\,d}{l}\,(h_r + h_3) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

A check is then made to determine the accuracy of the assumption made for the well losses, and corrections are made if required. With a little practice, the value can usually be approximated within a few tenths of a foot.

Generally, a slight increase in the well size may be justified in the judgment of the designer to compensate for the decrease in efficiency of the well over a period of years; but an arbitrary decrease of well spacing to compensate for inaccuracies in the coefficient of permeability cannot be justified, since the well-spacing requirement is not a function of the permeability. The maximum well spacing should not exceed the distance from the source to the line of wells, or l-distance. This is particularly true where large wells are used with a relatively short distance to the source. This is not in conformity with Messrs. Middlebrooks and Jervis who have indicated that the maximum well spacing should not exceed twice that distance.

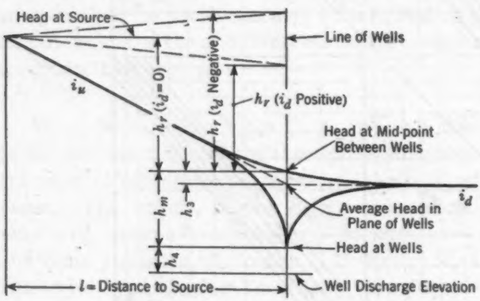

FIG. 11

Fully penetrating wells should be used if economically feasible, as most natural formations present extremely wide variations in permeability from the top to bottom of the stratum. The percentage of penetration of a well should be in proportion to the carrying capacity of the pervious stratum rather than to the thickness of the pervious stratum. Since the permeability usually increases with depth, the economy of the partly penetrating well may be more hypothetical than real. Designs based on partly penetrating wells must, therefore, be very carefully considered on the basis of comprehensive underground data or on actual pumping tests on installed wells.

The theory of pressure relief wells is based on the concept that the well is "a hole with no clogging on the sides." It is apparent that, with present construction methods, an installed well is not 100% efficient. Data pertaining to the relationship of actual production or efficiency of an installed well to the production or efficiency of the theoretical well are very limited or nonexistent. However, since the most open types of well screen have less than 50% open area, it appears that the entrance face area of the well is reduced more than 50% when the well screen is placed in the well to support the formation. Although the entrance face area may be increased somewhat by surging the well to re-

move the fines, or by placing a gravel filter around the well screen, it is doubtful whether the effective entrance face area of the installed wells is more than 50% of that of the theoretical well. For this reason it is considered that the installed well diameter should be at least three times greater than the theoretical diameter. Although the excess well diameter will provide for subsequent loss of efficiency from clogging and encrustation, it will also produce more water than is required for pressure relief. In those instances where excess well discharge is of consequence from the standpoint of pumping or conservation, an orifice or valve may be placed in the well for reducing the flow to that actually required to produce the desired pressure reduction.

Since mathematical design formulas for relief well systems are based on idealized assumptions as to the uniformity of the pervious stratum and blanket, and the determination of permeability, which is at best only a good approximation, the results from the formulas should not be considered as an exact design but rather as an approximation to aid the judgment of the designer. With this thought in mind it is the writers' opinion that reasonably accurate results quickly computed are more desirable than mathematically exact solutions achieved through repeated trials. Also the writers wish to emphasize that generally wells of large effective radius are necessary to provide sufficient entrance face area, and that well screen and riser losses should be kept to a minimum.

JOHN R. CHARLES,[14] ASSOC. M. ASCE.—This carefully prepared report on a relatively new use for wells is commendable. Wells to supply water are as old as history; more recently wells have been designed to return water to the ground; and now wells are being designed for the relief of pressure under dams and levees.

It is interesting to note that the problems concerning determinations of permeability and other factors of water source, which increase specific capacity of the well units and provide materials to assure long life with low maintenance expense, have occurred with each of the foregoing type of well. In the modern water-supply well, the outer casings are sealed with cement grout under pressure to prevent seepage down around the casing. Bronze screens and gravel walls reduce the friction loss of entrance and increase specific capacity; outer and inner casings are constructed with welded joints throughout—all in order that the units will have the desired capacity and long life.

At the first introduction of the return well, it was thought that all these refinements might be superfluous; the first return wells were homemade affairs which quickly clogged up, and permitted the return water to escape up around the outer casings. It was soon found that construction equal to that used for the water-supply well was required to provide a constant operating return well.

Similarly, it will be found that relief wells should be constructed in a manner equal to present-day methods accepted for the construction of water-supply wells and return wells. The use of an outer casing sealed with cement grout under pressure would be superior to casing sealed with bentonite and sand mix. Bronze screens will be found necessary to assure continued life and permanent use of the relief wells; the gravel wall is generally accepted as a means of increasing specific capacity and reducing the number of wells required.

[14] Dist. Engr., Layne-New York Co., Inc., Pittsburgh, Pa.

In 1945, three experimental wells were completed for the Corps of Engineers, U. S. Army, in the Missouri River Valley, to test the type of well best suited for the relief of pressure under levees. Relative specific capacities (in gallons per minute per foot of drawdown) were as follows:

Type	Capacity
Gravel wall (screen C)	224
"Natural gravel pack" (screen C)	68.3
Gravel wall, double cased (screen L)	360

These three wells were located 150 ft on centers in a line along the levee and were provided with 12-in. screens in each case. This test would indicate the variation in specific capacity between the gravel wall well and the so-called "natural gravel pack" as well as between various types of screens.

Relief wells should be constructed in order to provide the highest measure of efficiency in relieving water pressure. They should also be constructed so that there will be the minimum of maintenance and tested at regular intervals. As with most wells, it is to be expected that measures of standard service and cleaning will be required to keep these units in service, and ready for use. Assuredly there would be no time to clean relief wells during the flood period when the relief of pressure is most desperately needed.

Messrs. Middlebrooks and Jervis have cited the uncertainties concerning the boundaries of the seepage flow and the coefficient of permeability. Under the heading, "Design of Relief Well Systems," the authors state: "Both these considerations require the application of judgment based on experience to obtain reasonable solutions in complicated geological formations." Similar experience with water-supply wells proves the accuracy of this statement.

It is possible that some part of the pressure behind a levee may be caused by the increase of water in the natural underground formations. Heavy rainfall on the sides of the valley would result in a ground-water peak moving toward the river. The weight of the levee would help to confine this peak, and the effect of the river rising faster than the ground water would also increase the pressure immediately outside the levee. The combination of these two pressures at the line outside the levee might account, in some part, for the greater-than-anticipated pressure in this area. Similarly, the increase of natural underground water following heavy rainfall, and consequent increase of natural underground pressure, might account for the greater flows beneath dams than would be indicated by the hydrostatic pressure of the water in the reservoir.

The writer can visualize dual-purpose wells constructed to relieve pressure on dams and levees and also to supply this water, which has been filtered and purified by passage through the sands, for use in water-supply systems.

HORACE A. JOHNSON,[15] Assoc. M. ASCE.—It has been assumed in this paper that an infinite line source is paralleled by an infinite line of wells. This

[15] Engr. (Civ.), U. S. Engr. Office, Sacramento, Calif.

is a nearly true condition in many levees and simplifies the problem by making it two dimensional. However, in the design of an earth dam across a V-shaped or U-shaped valley this assumption may be considerably different from the true condition. The purpose of this discussion is to show that by use of the electrical analogy, and by constructing a three-dimensional model, the foregoing assumption may be dispensed with in certain cases, thus broadening the field of application. The authors discuss the use of the electrical analogy, but confine the discussion to a two-dimensional model. In many cases it is practically as easy to construct a three-dimensional model as it is to construct a two-dimensional model and a more exact representation and solution are obtained.

As a case in point, consider a pervious stratum with a very low dip, downstream about 2°, and striking approximately at right angles to the stream bed, which outcrops about 3,000 ft above the proposed dam. At the downstream toe of the dam in the stream bed this stratum is overlain by 100 ft of practically impervious material. With a depth of water of 125 ft in the reservoir, or a head of 225 ft to the bottom of the impervious stratum, the weight of this overlying stratum gives a factor of safety of less than 1 against uplift, assuming no loss in head through flow in the pervious stratum and no flow in the impervious stratum. Fig. 12 illustrates the conditions existing in the example. Permeability of the stratum A was determined by well tests to be 50 ft per day with a hydraulic gradient of 1. Stratum B is very impervious as attested by the fact that an artesian head of approximately 30 ft above river water level exists in stratum A. Stratum B is assumed to be absolutely impervious in the analogue.

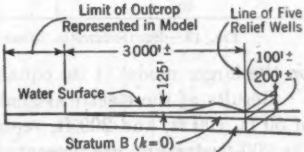

FIG. 12

With these conditions existing it is necessary to reduce the pressure beneath the stream bed and up the abutment slopes until there is sufficient material overlying stratum A to resist the uplift. Five wells spaced at 200-ft centers were tried and gave satisfactory results in pressure reduction.

An electrical analogue was set up on a scale of 1 in. equals 100 ft with 2 in. of water representing the 200 ft of stratum A. The bottom of stratum B was originally represented by the bottom of the electrical analogy tank. The model was thus built upside down, with the wells projecting up from the bottom of the electrical analogy tank. It was found more convenient to rebuild the model right side up for ease in adjusting the well penetration. The wells were represented by No. 22 gage copper wire, which is 0.025 in. in diameter. The source of inflow was represented by a copper plate 8 in. by 12 in. with 2 in. of the 12-in. dimension bent at 90°. The 8-in. by 10-in. dimension was placed at the water surface level with the 2-in. leg projecting down to the bottom of the tank. The area of this plate represented the area of the outcrop of stratum A in the reservoir.

Although the boundary conditions are not exactly represented because of the limitation of the size of the tank (40 in. by 66 in.), the effect of the imposed

boundaries can be estimated by building the model at a smaller scale. In this case another model on a scale of 1 in. equals 200 ft was constructed and tested. Results of this test indicated that the effect of the artificial boundaries

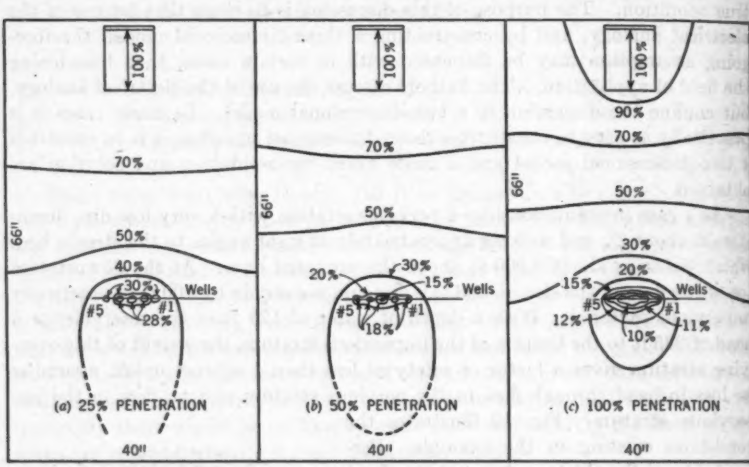

FIG. 13.—EQUIPOTENTIAL LINES FOR DIFFERENT DEGREES OF WELL PENETRATION

on the larger model (1 in. equals 100 ft) were very small.

Results of the electrical analogy tests for three different well penetrations of 50 ft, 100 ft, and 200 ft, representing 25%, 50%, and 100% penetration of the 200-ft stratum, are presented in Fig. 13. In these tests the source was at

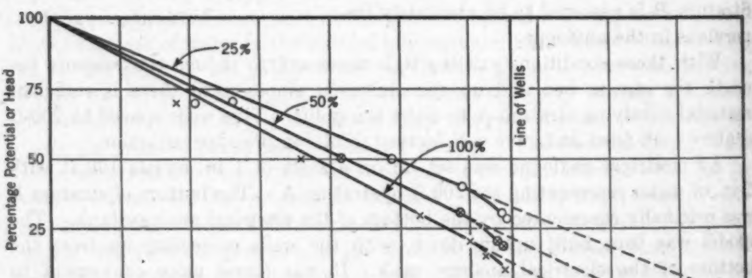

FIG. 14

100% potential and the wells at 0% potential. The other lines marked with percentage figures represent the loci of points having those percentage potentials.

In order to provide a rough comparison with Fig. 7, Fig. 14 is a plot of the potentials along an axis through the center well and the center of the source.

As would be expected, because of the finite number of wells, the "extra length" is considerably greater than that obtained by the authors, but the effect of penetration is relatively about the same.

A further difficulty with a finite number of wells is the computation of flow from each well. The computation of the total flow from all the wells can readily be made by sketching in the flow lines on the potential net. However, it is very difficult to extend this method to an individual well. The flow in individual wells, therefore, was obtained by calibrating the electrolyte and measuring the flow of current into each well. This was done by running individual wires to each well, maintaining all wells at zero potential, and reading the current for each well in turn. Total flow was also measured by measuring the current in all wells simultaneously. The results of current measurements and conversion to flow of water in Table 2 appear to be very satisfactory. The total flow was also checked by sketching the flow net.

TABLE 2.—FLOW MEASUREMENTS[a]

Well No. (Fig. 13)	(a) 25% Penetration; $k' V d' = 140$			(b) 50% Penetration; $k' V d' = 157$			(c) 100% Penetration; $k' V d' = 19.6$

All........	75.5	7.80	....	100.0	9.21	....	13.8	10.2	....

[a] k = 50 ft per day; h = 125 ft; d = 200 ft; $k\,h\,d$ = 1,250,000 cu ft per day or 14.47 cu ft per sec; I (see Cols. 1) = measured flow of electrical current; Q (see Cols. 2) $= I \dfrac{k\,h\,d}{k'\,V\,d'}$ in cubic feet per second (see Eq. 16); and the values in Cols. 3 represent the well flow compared to the average, rated as 100.

The flow of current in the model is easily converted to water flow in the prototype since

$$\frac{Q}{I} = \frac{k\,h\,d}{k'\,V\,d'} \qquad (16)$$

in which Q is water flow in cubic feet per second; k is the effective coefficient of permeability of the pervious stratum; h is the head in feet at the source of seepage; d is the depth in feet of the pervious stratum; I is the current flow in the model; k' is the electrical conductivity of the electrolyte; V is the voltage impressed on the model; and d' is the depth of electrolyte in the model. The product $k'\,V\,d'$ can be determined directly without breaking it down into component quantities by calibrating the electrolyte in a tray of known dimensions. No absolute values of the current flow I, in amperes, were obtained in these experiments; relative values only were obtained.

Two factors proved to be troublesome in the model testing for current flow. The first of these was discovered when a calibration of the electrolyte from a cylindrical surface to a well did not check the calibration using a rectangular

tray. The apparent explanation was that the effective diameter of the model well was considerably smaller than the actual diameter of the wire representing the well. The effective diameter of the well can be computed from the formula:

$$I = \frac{2 \pi k' d' V}{\log_e \left(\frac{r_e}{r_w} \right)} \quad \text{.........................(17)}$$

in which r_e is the inside radius of the calibrating cylinder, and r_w is the effective radius of the model well. All the factors except r_w are known or can be measured; so r_w can be determined. Eq. 17 is analogous to the formula for flow of water into a single well.[16]

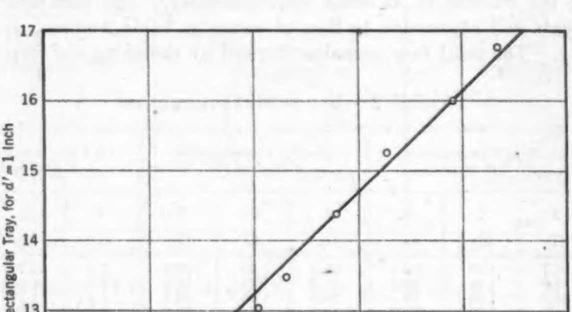

FIG. 15

A further series of tests, run to determine the effective diameter of various sizes of electrodes at several different current concentrations, showed that the effective diameter was only from 5% to 10% less than the actual diameter. Since this represents a difference of actual current flow into the electrode of only 2% or 3%, it was decided to ignore the effect of decrease in diameter as insignificant.

The second factor that must be watched in the measurement of current is the temperature of the electrolyte. It was found that a very few degrees of difference in temperature had an appreciable effect on the current flow. It is

[16] "Methods for Determining Permeability of Water-Bearing Materials," *Water-Supply Paper No. 887*, U.S.G.S., U. S. Govt. Printing Office, Washington, D. C., 1942, p. 79.

necessary, therefore, to calibrate the electrolyte at the temperature at which the experiment is run. Fig. 15 shows the effect of temperature on the conductivity of the electrolyte used which was tap water of unknown analysis.

P. C. RUTLEDGE,[17] ASSOC. M. ASCE.—An outstanding feature of this paper is a prudent use of rather complex theoretical analyses. The authors have emphasized the uncertainties in the field conditions and the necessity for tempering with judgment a design based on their analyses. They claim as a significant advantage the flexibility of relief wells because modifications of an installation can easily be made to meet conditions disclosed by field use for the control of underseepage.

One question which the writer pondered after studying this excellent paper was: "On what can one base one's judgment of a relief well design?" Engineering judgment should be based on accumulated experience and field observations, or on an orderly method of estimating the effects of the several variables involved. Both bases for judgment seem to be lacking for this problem. In particular, the uncertainties in the character and the extent of the pervious soil layer drained by relief wells have effects that cannot be evaluated directly by judgment. Briefly, these uncertainties about the actual pervious soil layer are five:

(*a*) Degree and effects of stratification;
(*b*) Effects of lenticular deposits of silt and clay;
(*c*) Effective depth of the entire layer;
(*d*) Effective distance from the source to the wells; and
(*e*) Effective permeability of the layer.

It may even be argued that these uncertainties invalidate the analyses made by the authors. The writer does not agree with such an argument, however, and will endeavor to show in this discussion that a rational basis for judgment can be formulated and that the effects of the uncertainties previously listed are not serious.

Neglecting for the moment the uncertainties in the pervious soil layer and assuming, in its place, a homogeneous layer of measurable dimensions, the variables that affect the performance of drainage wells are:

1. Length of the pervious layer, s, in feet;
2. Depth of the pervious layer, d, in feet;
3. Effective coefficient of permeability of the pervious layer, k, in feet per minute;
4. Spacing of the wells, a, in feet;
5. Percentage penetration of the wells into the pervious layer;
6. Difference in head between the source and the discharge point, Δh, in feet;
7. Effective radius of the well, r_w, in feet; and
8. Frictional head loss in the well screen and riser pipe.

[17] Prof., Civ. Eng., The Technological Inst., Northwestern Univ., Evanston, Ill.

The inflow into a well is determined by the first seven variables when the difference in head is that between the source and the point of inflow. The effective radius of the well is rarely the actual pipe radius. It may be larger if the well pipe is surrounded by a filter or smaller for a screened well in contact with the soil. The radius of the well pipe governs frictional head losses for flow up the pipe but otherwise has nothing to do with the well inflow.

Eight variables, all of which definitely affect performance, are too many to think about as clearly and concisely as one must in the exercise of judgment. To simplify the problem the authors have introduced two very useful terms:

(1) "Carrying capacity" or maximum possible discharge of the pervious layer under any given conditions; and

(2) "Extra length" which relates well discharge to the "carrying capacity."

The writer will use these two terms to simplify the problem to a greater extent. The authors have shown that the carrying capacity, Q_M, and the discharge of one well in a line of wells, Q_a, both in cubic feet per minute, can be expressed as follows:

$$Q_M = \frac{k\,\Delta h\, a\, d}{s} \qquad (18a)$$

and

$$Q_a = \frac{k\,\Delta h\, a\, d}{s + \text{extra length}} \qquad (18b)$$

Further simplification is obtained if Eqs. 18 are written in terms of

$$\mathbf{W} = \frac{Q}{k\,\Delta h\, d} \qquad (19)$$

in which **W** is a dimensionless number which might be called the "well production number." It can readily be shown that the solution of every problem of steady flow into a well can be expressed in terms of **W** and that, for every problem, **W** depends only on geometrical considerations. Thus, the production number for the "carrying capacity" is

$$\mathbf{W}_M = \frac{a}{s} \qquad (20a)$$

For a single well completely penetrating a homogeneous pervious layer fed by an infinite line source, the production number is

$$\mathbf{W}_1 = \frac{2\,\pi}{\log_e\left(\dfrac{2\,s}{r_w}\right)} \qquad (20b)$$

For a single well on the perpendicular bisector of a line source of finite length, a, the production number is

$$\mathbf{W}_{1a} = \frac{2\,\pi}{\log_e\left[\dfrac{2\,s}{r_w}\left(1 + \dfrac{4\,s^2}{a^2}\right)\right]} \qquad (20c)$$

For one well in a line of wells spaced at a distance, a, on centers and completely penetrating a pervious layer fed by an infinite line source, the production number is

$$W_a = \frac{a}{s + \frac{a}{2\pi}\log_e \frac{a}{2\pi r_w}} = \frac{a}{s + \text{extra length}} \quad \text{.........} (21a)$$

From Eq. 21a it is obvious that the extra length for fully penetrating wells is

$$\text{Extra length} = \frac{a}{2\pi}\log_e \frac{a}{2\pi r_w} \quad \text{.........} (21b)$$

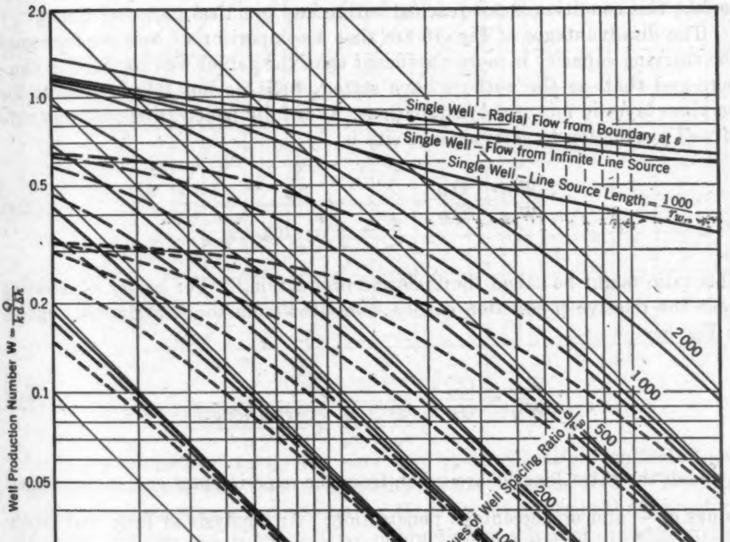

FIG. 16.—WELL PRODUCTION NUMBERS; FOR STEADY FLOW ONLY

The basic solutions for the foregoing cases, and for many others, have been presented elsewhere[18] by M. Muskat. Fig. 16 shows values of the well produc-

[18] "The Flow of Homogeneous Fluids Through Porous Media," by Morris Muskat, McGraw-Hill Book Co., Inc., New York, N. Y., 1st Ed., 1937, pp. 178, 191, and 529.

tion numbers for various values of s and a expressed as ratios of the effective well diameter. This chart shows the dimensional conditions under which fully penetrating wells in a line produce practically the equivalent of the carrying capacity of the pervious layer. As the well spacing is increased, the productions of individual wells in a line approach, but do not equal, the production of a single well fed by an infinite line source or by a line source with a length of the order of 1,000 ft. The production numbers of single wells are indicative of performance but are not numerically significant. The reason is that the solutions for single wells assume that the well has been flowing long enough to have affected the heads in the entire pervious layer. Even with very pervious materials, this condition is not reached within any practical period of time.

The disadvantages of Fig. 16 are that a comparison of well production to the carrying capacity is more significant than the actual well production numbers and that, as the authors have stated, wells do not fully penetrate the pervious layer in most field installations. For fully penetrating wells the ratio of well production to carrying capacity is

$$\frac{\mathbf{W}_a}{\mathbf{W}_M} = \frac{Q_a}{Q_M} = \frac{\frac{s}{r_w}}{\frac{s}{r_w} + \frac{a}{2\,\pi\,r_w}\log_e \frac{a}{2\,\pi\,r_w}} \qquad (22a)$$

This ratio might be called the "relative production." For partly penetrating wells the relative production can be computed from the experimental curves in Fig. 8:

$$\frac{\mathbf{W}_{ap}}{\mathbf{W}_M} = \frac{Q_{ap}}{Q_M} = \frac{\frac{s}{r_w}}{\frac{s}{r_w} + \frac{a}{r_w} \times \frac{\text{extra length}}{a}} \qquad (22b)$$

in which the extra lengths are taken from the experimental curves for various values of $\frac{a}{r_w}$ and of percentage penetration. An analysis of fully and partly penetrating wells, made by replotting the experimental data in Fig. 8, indicates that, within the limits of accuracy required by any practical applications, well spacing and degree of penetration are directly compensating variables in the relative production. Thus relative production depends on a term of the form:

$$\frac{a}{r_w}\,\frac{100}{\%\text{ penetration}} = \text{inflow length} \qquad (23)$$

In other words, the inflow lengths of well systems with 100% penetrating wells 80 ft on centers, with 50% penetrating wells 40 ft on centers, or with 25% penetrating wells 20 ft on centers are identical. Fig. 17 is a plot of relative production in terms of s/r_w and inflow lengths. This one chart summarizes completely the performance of wells penetrating homogeneous pervious layers of measurable dimensions.

Uses of Fig. 17.—The purpose of relief wells is to reduce to safe values the hydrostatic pressures in underlying pervious soil layers on the land side of

levees and the downstream side of dams. A continuous vertical discharge face which completely intersects the pervious layer, the condition assumed for the carrying capacity, limits the head at and on the landward side of the discharge face to the discharge head. The carrying capacity and the discharge of a line

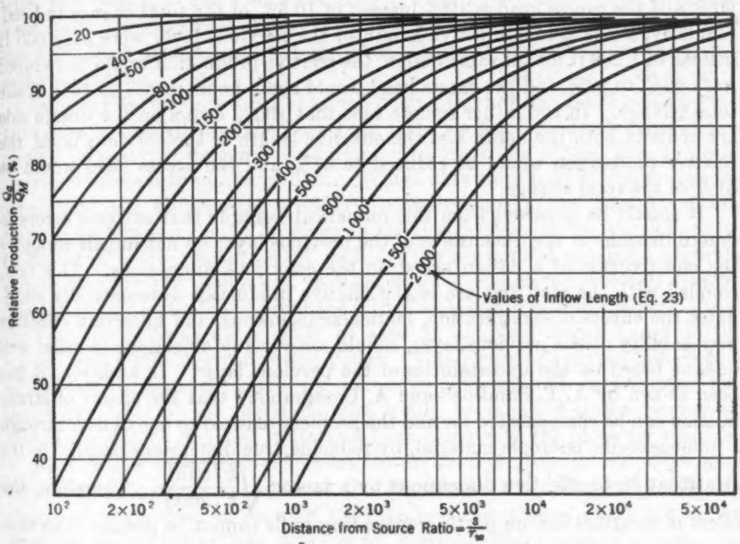

FIG. 17.—RELATIVE PRODUCTION OF RELIEF WELLS FOR DAMS AND LEVEES

of wells are affected in exactly the same way by stratification, lenticular inclusions, and uncertain effective permeability of the pervious layer. Therefore, the relative production is not affected by these uncertainties in the character of the pervious layer and, if the relative production of a line of drainage wells is 100%, they are doing the same job as a continuous discharge face. If the relative production is 90%, computations from the test data in the paper indicate that midway between wells the maximum head in excess of the discharge head will not exceed 20% of the total change in head for any combination of well spacing and percentage penetration. Since the test data presented do not include penetrations less than 25%, this and all other conclusions in regard to effects of partial penetration may not be valid for penetrations less than this value.

Assume that s is 1,200 ft and that wells with an effective radius of 0.25 ft will be used. Taking a relative production of 90% as a design value, the inflow length from Fig. 17 is 800. Since the inflow length is expressed in terms of effective well radius, the ratio of well spacing to degree of penetration is 200. Therefore, 100% penetrating wells spaced 200 ft on centers or 50% penetrating wells spaced 100 ft on centers, or 25% penetrating wells spaced 50 ft on centers could be used. From Fig. 8 the percentage of excess head midway between

wells for these three possible designs will be 13.5%, 10.5%, and 8.3% of the total head change, respectively. Next assume that 50% penetrating wells spaced 100 ft on centers are selected for the design but that the depth of the pervious layer actually is twice that determined from field explorations and used in design. The result will be that relative production is 81% instead of 90% and the excess head is 19% instead of 10.5% of the total change in head. Similarly, if the actual effective length of the pervious layer were only 600 ft instead of 1,200 ft for the same design, the relative production would be reduced from 90% to 82% and the excess head would again be increased to 19% of the total change. In the rather remote case that 100% errors on the unsafe side are made in both the depth and the effective length of the pervious layer, the relative production would be reduced to 67% and the excess head would be 31% of the total change.

It should be apparent from this numerical example that extreme errors in determinations of the dimensions of the pervious layer do not impair seriously the effectiveness of a design based on the erroneous dimensions. This fact, coupled with the fact that use of the relative production automatically eliminates the effects of stratification, lenticular inclusions, and uncertain effective permeability of the pervious layer, should answer any objections to relief well designs based on the uncertainties of the pervious layer. In addition, it has been shown by A. F. Samsioe[19] and A. Casagrande[20] that the effects of stratification can be compensated for and the problem reduced to one of flow through a homogeneous, isotropic material, by reducing true dimensions parallel to the stratification to effective dimensions by a factor $\sqrt{\frac{k\ (\mathrm{min})}{k\ (\mathrm{max})}}$. Therefore, the effect of stratification on partly penetrating wells cannot be greater than that of a change in effective length of the previous layer, by the ratio $\sqrt{\frac{k\ (\mathrm{min})}{k\ (\mathrm{max})}}$.

One word of caution is necessary, however. These conclusions are valid for the primary purpose of relief wells, which is to eliminate dangerous hydrostatic pressures due to underseepage. They do not apply to the actual discharge quantities from the wells. The discharge quantities will vary directly with every uncertainty in the pervious layer. Therefore, variations of 1,000% from the anticipated discharge quantities should not be considered unusual. Since the discharge quantity governs the frictional head loss in upward flow through the well riser pipe, a liberal factor of safety should be used in selecting the size of the well pipe.

Summary.—In conclusion, the writer believes that the authors have made a significant contribution in their development of the use of drainage wells for the relief of dangerous pressures due to underseepage. Their conclusions are valid and they have justly advocated the use of drainage wells only for the specific problem of relieving pressures in underlying pervious layers. Drainage wells usually will have little or no effect on seepage which actually passes through a dam or levee. However, for the specific problem to which drainage

[19] "Einfluss von Rohrbrunnen auf die Bewegung des Grundwassers," by A. F. Samsioe, *Zeitschrift für angewandte Mathematik und Mechanik*, Vol. 11, No. 2, 1931, pp. 124–135.

[20] "Seepage Through Dams," by A. Casagrande, *Journal*, New England Water Works Assn., Vol. 51, No. 2, June, 1937, pp. 151–154.

wells apply, the authors have been modest in their claims and, if anything, have underestimated the flexibility of the system.

H. H. Roberts,[21] Esq., and Carter V. Johnson,[22] Esq.—The pressure-relief well system at the Fort Peck Dam is cited by the authors as being the most outstanding example of the use of such wells. A brief statement regarding the Fort Peck installation and its effectiveness is also given in the paper under discussion.

Information that has been obtained during the period that the relief wells have been in operation at the Fort Peck Dam verifies the effectiveness of this method of relieving excessive subsurface pressure in the critical area immediately downstream from a large dam. Where data from field investigations for a proposed dam indicate the possibility of underseepage, under similar conditions, consideration should be given in the design stage to the immediate installation of a few pressure-relief wells for the purpose of obtaining accurate information for the design and installation of a complete relief-well system. The information obtainable from the initial wells taken during the period that the reservoir is being filled, could be used for the final design based on the criteria and methods given in the paper. This procedure should reduce to a considerable extent the need for extensive underground explorations and laboratory tests of the materials that would be required if the permanent system were to be designed in its final form along with the plans for the dam.

As a matter of interest the equations and charts given in the paper have been applied to the well system at the Fort Peck Dam, using the heads and gradients that existed on July 29, 1946 (highest elevation of water in the Fort Peck Reservoir to that date, 2,232.25 ft), the relief well system discharge, and available data regarding the pervious strata. Correlation of the computed characteristics of the system with the actual was very good.

Data collected since the installation of the pressure-relief wells show that the total discharge of the well system is proportional to the reservoir elevation; it has also been observed that the water elevation in the river downstream from the dam has a material effect on the well discharge. Piezometer pipes both upstream and downstream from the line of wells furnish evidence of the change in well discharge due to fluctuating reservoir and tailwater elevations. Piezometer pipes 50 ft upstream from the line of wells are used to measure the average hydrostatic pressure in the well area; and since the installation of the well system this hydrostatic pressure has never indicated a head in excess of 7 ft above the average ground surface. Maximum and minimum discharges of 12.35 cu ft per sec and 8.5 cu ft per sec, respectively, have been observed for a reservoir fluctuation of 62 ft in which time the reservoir reached an elevation only 18 ft below the maximum level. It has been estimated that the well system discharges from 75% to 85% of the total amount of seepage water that approaches the system. The remainder of the seepage water continues downstream, confined within the pervious strata by the thick overlying layer of

[21] Lt. Col., U. S. Corps of Engrs., Fort Peck Dist., Fort Peck, Mont.

[22] Engr. (Soil Mechanics), U. S. Corps of Engrs., Fort Peck Dist., Fort Peck, Mont.

clay. Consequently, an average hydrostatic pressure can be allowed downstream from the dam which will produce a head that extends above the ground surface without creating a wet and boggy condition.

The present well system at Fort Peck is in excess of the capacity actually needed to relieve the pressure to the required level. This allows a factor of safety for well failures which have occurred due to deterioration of the screen and casing. Several wells have failed because of such deterioration since the original installation; and additional wells have been installed with a more permanent type of screen and casing to assure adequate capacity should too many of the original wells fail. When an individual well fails, the total discharge of the system does not change appreciably and the load is absorbed by all the wells in inverse proportion to their distance from the failed well. When a new well is added to the system the flow in the other wells is reduced in the same manner. Individual wells vary considerably in discharge. The factors that have the greatest effect on the discharge are the effective head producing discharge (which can be varied for individual wells by changing the elevation of flow line), the length of screen, and the type of material which the individual well taps. Since the well system is adequate and the discharge is produced by a very small head, the wells are sensitive to small changes.

In the design of a well system certain fundamental factors enter into the problem; and a thorough understanding of these is necessary in order that a reasonable design may be developed. Furthermore, the effectiveness of the equations and charts for an actual design would depend, of course, on the accuracy of the basic data. The equations and charts in the paper can be used to illustrate the effect of these factors on a system of wells by assuming different conditions and solving for the result. As previously stated, when checking the equations and charts with observed data at Fort Peck, the results checked very well with the actual. This check indicates that, if the fundamental data and tests are reliable, an adequate system of relief wells can be designed by the methods outlined. However, wherever practicable, it is considered desirable actually to install a minimum number of wells and to utilize data from their operation during the initial filling of the reservoir to complete the final design.

Frank E. Fahlquist,[23] M. ASCE.—The design of underground drainage facilities for partial yet adequate control of underseepage pressures is presented by the authors. The paper summarizes the very valuable data of experimentation and experience that was accumulated for several years by the United States Engineer Department. Although the authors have presented the important features of relief well design, it is believed they could also contribute valuable additional data and discussion concerning the fabrication and installation of wells. In particular, comments on the several available types of well intakes, such as metal screens, concrete pipe with porous wall, and perforated tile would be appreciated. Comments as to the preparation

[23] Cons. Engr. and Geologist, Riverside, R. I.

and the stabilization of ground surrounding the well intakes, either by development methods or by placement of graded filter materials, would be in order.

The authors' explanation of Fig. 1 can be further illustrated by the application of two formulas showing the relations of permeability in stratified materials. In general, the permeability in an unstratified or homogeneous deposit is the same in all directions. Geologically, there can be exceptions to this rule but they are not important. If, in an otherwise homogeneous deposit, stratifications of less permeability occur, the permeability in a direction that is across the bedding is much less than that in a direction parallel to the bedding, as shown by the two equations,[24]

$$k_H = \frac{1}{H}\left(k_1\, d_1 + k_2\, d_2 + k_3\, d_3 + \cdots + k_n\, d_n\right) \ldots\ldots\ldots (24a)$$

and

$$k_V = \frac{H}{\dfrac{d_1}{k_1} + \dfrac{d_2}{k_2} + \dfrac{d_3}{k_3} + \cdots + \dfrac{d_n}{k_n}} \ldots\ldots\ldots\ldots\ldots (24b)$$

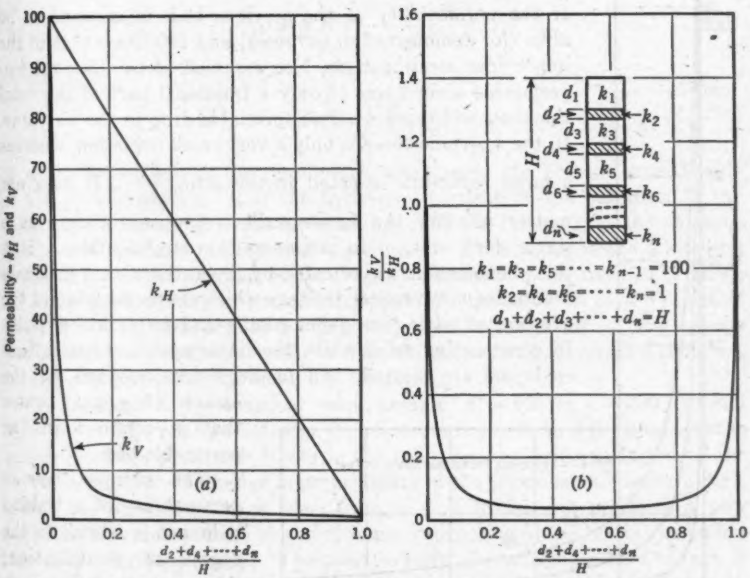

FIG. 18.—HORIZONTAL AND VERTICAL PERMEABILITY IN A PERMEABLE SEDIMENT CONTAINING THIN STRATIFICATIONS OF RELATIVELY IMPERMEABLE MATERIAL

in which k_H is the permeability parallel to bedding or horizontal direction; k_V is the permeability perpendicular to bedding or vertical direction; k_1, k_2, k_3, $\cdots$ k_n represent the permeability of individual layers; d_1, d_2, d_3, $\cdots$ d_n represent the thickness of individual layers; and $H = d_1 + d_2 + d_3 + \cdots + d_n$ is the total thickness.

[24] "Theoretical Soil Mechanics," by Karl Terzaghi, John Wiley & Sons, Inc., New York, N. Y., 1943, pp. 243-244.

The relations expressed in Eqs. 24 are shown graphically in Fig. 18. In Fig. 18 the aggregate thickness of relatively impermeable stratifications is

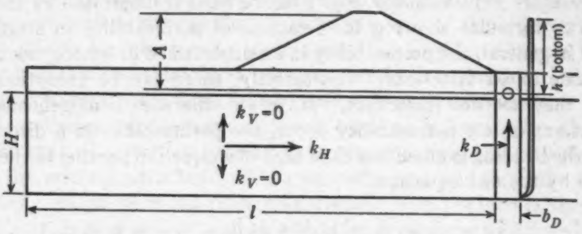

FIG. 19.—FACTORS INVOLVED IN THE DERIVATION OF EQS. 25

indicated by $d_2 + d_4 + \cdots + d_n$, and the fractional part of these thicknesses to the total thickness is $\frac{d_2 + d_4 + \cdots + d_n}{H}$. If the permeability of the pervious beds is assumed to be alike (for demonstration purposes) and 100 times that of the impervious stratifications, also assumed to be alike, the impermeable occurrences of only a fractional part of the total thickness will cause a very appreciable drop in the k_V-value. In the k_H-value there is only a very small reduction, whereas a large reduction is noted in the ratio, $\frac{k_V}{k_H}$. It does not matter whether the impermeable component occurs as a single thick unit, or in numerous thin stratifications. It is this phenomenon, as indicated by the authors, that produces the inadequate vertical drainage which causes flotation of the overburden with consequent piping and formation of boils. In constructing relief wells, the impermeable stratifications or layers are pierced, and facilities are provided for the escape of ground water that is confined in the permeable beds.

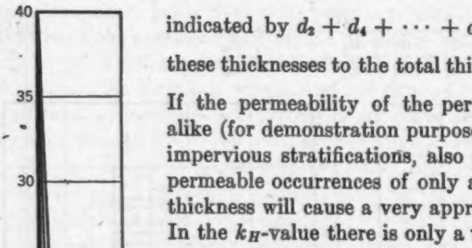

FIG. 20.—RELATION OF PIEZOMETRIC PRESSURE, h (BOTTOM) AT UNDERSIDE OF PERMEABLE STRATA TO REQUIRED RATIO OF PERMEABILITIES OF DRAINAGE ZONE AND FOUNDATION

The average over-all permeability of a bedded sediment is related to the degree of stratification; the amount of fine particles mixed with coarser particles, such as sand and gravel; and the density or porosity of the various beds. The last two factors can be demonstrated easily in the laboratory, and the effect of the first factor has been discussed. Considering these factors and also the manner in which sediments, either fluvial or glacial in origin, are frequently found

in nature, the writer has investigated the theoretical factors involved, and the construction methods required, for creating a continuous and deep drainage zone, in the underground, for the interception of seepage.

The method would involve systematic jetting in a vertical zone, generally less than 10 ft wide, in which, by controlling the jetting process, stratifications could be disrupted, fines floated and washed away, and the entire zone rendered more porous than the adjacent foundation materials. It would not be applicable to all materials or conditions—for example, it would not be practicable to attempt such relief in strata in which sand was predominant. However, there are situations where, because of geologic processes, the deposits are of stratified sand and gravel with varying proportions of fines (silt and clay), in dispersed and concentrated occurrence. For conditions such as these, the relation of the several factors, shown in Fig. 19, can be expressed as:

$$\frac{h\,(\text{bottom})}{A} = 1 - \left(\frac{2\,e^{-\beta H}}{1 + e^{-2\beta H}}\right) \quad \text{(25a)}$$

$$i_0 = \beta\,H \left(\frac{1 - e^{-2\beta H}}{1 + e^{-2\beta H}}\right) \quad \text{(25b)}$$

and

$$\beta = \sqrt{\frac{k_H}{k_D}\,\frac{1}{l\,b_D}} \quad \text{(25c)}$$

in which h (bottom) is the piezometric pressure at the bottom or underside of the pervious strata; i_0 is the hydraulic gradient at the elevation of the drain pipe or ditch; A is the head acting; H is the thickness of the pervious strata; e is the base of Naperian logarithms = 2.71828; k_H is the horizontal permeability of the pervious strata (vertical permeability assumed to be zero); k_D is the permeability of the drainage zone; b_D is the width of the drainage zone; β is a number defined by Eq. 25c; and l is the length of the seepage path. For a convenient solution of Eqs. 25, curves of $\beta\,H$ versus h (bottom) A, and $\beta\,H$ versus $i_0\,H/A$ should be prepared.

To consider a hypothetical case, assume $A = 40$ ft; $l = 300$ ft; and $b_D = 8$ ft. The relation between the piezometric pressure, h (bottom), at the underside of the permeable strata to the ratio, k_D/k_H, is demonstrated by the curves in Fig. 20. A change in permeability of the pervious foundation strata, within the narrow drainage zone, from $k_D = 1$ to $k_D = 4$, produces a very appreciable decrease in the piezometric pressure acting at the bottom or underside of the pervious strata. The practicability of producing such a change in permeability, of course, is the important uncertainty. To the writer's knowledge, such a construction has never been attempted and consequently there is not an experience record by which to judge its feasibility; but by reasoning alone it would appear that, in certain types of material (as previously discussed), a moderate change from $k_D = 1$ to $k_D = 3$ could be produced. The jetting operation would be accomplished by from four to six jets, held rigidly at the same spacing, with provisions for the flexible control of pressure and flow, and operated simultaneously.

The curves in Fig. 21 can be used for determining the width of drainage zone, b_D, required for a length, l, from 100 ft to 1,000 ft. The ratio of permeability of drainage zone to pervious foundation strata is assumed to be unity. If a greater change in permeability is believed possible, the width of zone required is less—for example, if the permeability of the zone is doubled, the width may be reduced by one half.

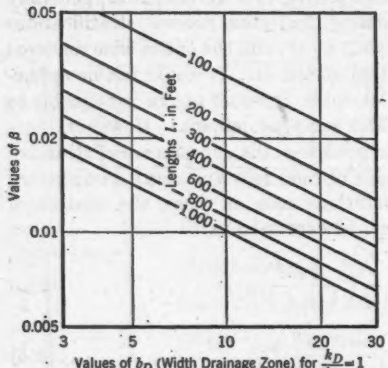

FIG. 21.—REQUIRED WIDTH OF DRAINAGE ZONE

As a further illustration, consider a typical problem of an earth dam, for which $A = 100$ ft; $H = 40$ ft; and $l = 800$ ft. At the downstream toe there is a trench 8 ft deep, and the drainage zone is constructed in such a manner that the h (bottom) at the underside of the pervious stratum is 8 ft. Therefore, $h\,(\text{bottom})/A = 8/100 = 0.08$. From Eqs. 25, or design curves based on them, $\beta H = 0.41$ and $\beta = \beta H/H = 0.41/40 = 0.01$. By reference to Fig. 21, for $\beta = 0.01$ and $l = 800$ ft: $b_D = 12$ ft when $k_D/k_H = 1.0$, and 6 ft when $k_D/k_H = 2.0$.

Considering both the theoretical and practical aspects of the continuous and deep drainage zone, it is obvious that:

(a) All seepage may be intercepted;
(b) The zone can be varied in width to take care of varying amounts of seepage;
(c) The zone is formed in place by modifying the foundation materials; and
(d) The drainage zone can be easily incorporated in other drainage control facilities.

The several uncertainties and disadvantages are as follows:

1. Feasibility of construction depends on the character of foundation materials—the most suitable primary materials being sand-gravel mixtures having dispersed silt and clay, or silt and clay interstratifications;

2. The change of permeability in a drainage zone, relative to adjacent foundations, would be difficult to determine, but the problem is not insuperable; and

3. The cost may be greater, and yet may be less, than that for relief well installations, depending on the number of wells required, and the necessity for placing filters, or stabilizing the ground around well intakes.

Acknowledgment.—The differential equation leading to Eqs. 25 was developed and solved by R. A. Barron, Jun. ASCE.

HARRY R. CEDERGREN,[25] ASSOC. M. ASCE.—The subject of relief wells, in this paper, is presented in a straightforward, yet reserved, manner. The statement (under the heading, "Design of Relief Well Systems") that "* * * the well system is very flexible and more and larger wells can be added at any time if the first installation proves inadequate" is one of the keys to the potential value of relief well systems.

During 1946 the writer was engaged in design studies for a 25-mile system of levees along the Columbia River in Washington. Explorations of proposed sites for levees to protect agricultural and industrial areas revealed extremely heterogeneous deposits of gravelly materials underlying a relatively impervious blanket of fine-grained soils. The overlying blanket varied in thickness from less than 1 ft in isolated areas to 15 ft or 20 ft in others, and averaged about 8 ft. The gravelly formations ranged from well-graded, relatively impervious, silty sandy gravel to extremely open-graded strata of 0.5 in. (+) to 4-in. (+) material with only a trace of fines. The open-graded strata generally did not exceed 1 ft or 2 ft in thickness, and occurred in lenses or pockets of limited extent. The individual lenses or pockets were more or less interconnected, and permitted a relatively free passage of water in the horizontal direction. Underlying the gravelly formations at depths of from 30 ft to 60 ft below the ground surface were beds of clay that were indicated by incomplete explorations to be impervious and continuous.

Complicating the problem, much of the area to be protected was under irrigation, which produced a substantial flow of water toward the river. This flow added to potential construction problems and necessitated even greater seepage protection than would otherwise have been necessary. Where the impervious bed was from 30 ft to 40 ft deep, the use of an impervious cutoff, in combination with shallow drains for the removal of runoff, seemed the most promising solution. Blanketing the riverbank and beaches with relatively impervious soil was considered as the primary control in some areas. In other places, the use of deep relief wells as the principal controls appeared to be the most economical and adequate solution. One of the principal advantages of relief wells on this project is their flexibility. Prediction of the probable seepage quantities, even with the aid of considerable explorations and extensive field and laboratory permeability tests, could be nothing more than a reasonably good guess. Consequently, it was essential that the drainage, or relief system, be of such type that it could be "tailored" to fit the needs of the job as those needs were finally determined by observation of the prototype.

A second advantage of relief wells on this project is their effectiveness in relieving hydrostatic pressures in highly stratified deposits. Shallow drains in such formations are relatively ineffective, since even a thin impervious stratum separating the bottom of a drain from pervious underlying strata can seriously reduce the efficiency of the drain. However, wells drilled into the pervious strata provide a direct means of escape for seepage and can reduce uplift pressures in the foundation substantially.

Should an initial relief well installation not be adequate to control seepage during maximum stages of river or reservoir, this inadequacy frequently can

[25] Cons. Engr., O. J. Porter & Co., Sacramento, Calif.

be predicted by piezometric observations during low and intermediate stages. Such a possibility was demonstrated by the authors under the heading, "Examples of the Use of Relief Wells."

Relief wells should be constructed with considerable care in accordance with specifications prepared by competent soil engineers. When used on important structures, in which their continued functioning over a long period is required, each well should be accessible for cleaning and repairing. If wells are installed beneath an embankment section, vertical riser pipes should extend above the embankment to provide access to the wells. With this provision, and with adequate attention to their design and construction, relief wells can be used with confidence in the most important structure. Periodic observation of seepage pressures within and beneath important earth dams and levees, and requent observation of the effluent of relief wells and drains, should be routine matters for attendants.

JOHN S. MCNOWN,[26] Assoc. M. ASCE.—For some time the writer has been interested in the application of mathematical methods to practical problems of fluid flow, and has contended that many existing mathematical treatments would find wider application if presented in a less obscure manner. It is important from the standpoint of clarity that symbols, wherever used, be clearly defined and used in an entirely consistent manner. Moreover, since the algebraic representation as applied to practical problems is merely a symbolic shorthand, the relationship represented by an equation should be expressed in words wherever the significance of the equation is not readily apparent.

The application of the methods of hydrodynamics to relief well design presented by the authors is an interesting analytical problem leading to worthwhile results. However, the development of the basic equations is exceedingly difficult for the reader to appraise and follow because (1) the explanation of principles underlying the development is far from complete, (2) the symbology is thoroughly confusing, and (3) several inaccurate or inconsistent statements have been included. Since the writer feels that the results obtained by the authors are significant, it seems worthwhile to clarify parts of the development and to reconcile some of the troublesome inconsistencies.

In any development of a highly mathematical nature, it is not the rigorous algebraic transformations which interest the practical-minded engineer, but rather the accuracy of the underlying assumptions and the acceptability of approximations so often essential to the obtainment of useful results. From this viewpoint, the omission of any discussion of the rather surprising analogy which permits the use of hydrodynamic theory for certain problems of viscous motion is regrettable. As presented, the material leaves the reader with no method of evaluating the usefulness of the final equations. Much of the mathematical development is unquestionably beyond the scope of the paper and, furthermore, has been presented elsewhere; nevertheless, the authors might fully as well omit the mathematics and present only the final equations, once they have omitted the initial steps leading to Eq. 7*a*.

[26] Research Engr., Iowa Inst. of Hydr. Research, and Asst. Prof., Dept. of Mechanics and Hydraulics, State Univ. of Iowa, Iowa City, Iowa.

In deriving this basic equation, it is necessary to define and to utilize briefly the concept of velocity potential in relating the flow of a frictionless fluid into mathematical sinks and the laminar flow of a real fluid into relief wells. A velocity potential φ is usually defined as a quantity whose negative derivative in any direction is the component of velocity in that direction—that is:

$$-\frac{\partial \phi}{\partial x} = V_x \quad \text{(26a)}$$

Furthermore, several writers have shown[3,27,28] that the Navier-Stokes equations of viscous motion for flow with negligible acceleration reduce to the form:

$$-\frac{\partial h}{\partial x} = C\, V_x \quad \text{(26b)}$$

in which h is the piezometric head and C is a dimensional constant of proportionality.

A comparison of Eqs. 26 demonstrates the analogy between these two types of motion and indicates that the piezometric head (multiplied by a proportionality factor) will serve as the velocity potential for flow through granular media. Because of this accidental parallel between two widely differing types of motion, many of the results and methods of hydrodynamics may be applied to problems of flow through porous media. Flow into a single well has its exact counterpart in the flow into a mathematical sink, and a number of wells can be studied by utilizing expressions already developed for flow into a comparable number of sinks similarly arranged. Although flow from a river into a line of wells is closely approximated by the corresponding expression for flow into a line of sinks, the condition of a straight line of uniform pressure (the edge of the river) may be exactly reproduced by placing a symmetrical line of sources or supply wells an equal distance the other side of the straight line of uniform pressure. The mathematical expression for the infinite lines of sources and sinks is initially quite complex, but it may be partly simplified to a usable form corresponding to Eq. 7a. Since piezometric heads are of more direct usefulness than pressure intensities, Eq. 7a has been rewritten to give the piezometric head h at the point with general coordinates (x,y) in the following form:

$$h = h_s + c \log_e \frac{\cosh j(y - s) - \cos j\, x}{\cosh j(y + s) - \cos j\, x} \quad \text{(27)}$$

The numerator of the fraction in Eq. 27 is a mathematical simplification giving the sum of the velocity potentials for the sinks along $y = s$ and the denominator for the sources at $y = -s$, s being therefore the distance between the edge of the river and the line of wells. The piezometric head along the edge of the river is designated by h_s. The x-axis coincides with the line of symmetry (the edge of the river), and the y-axis passes through one of the wells. The substitution $j = 2\,\pi/a$, in which a is the well spacing, has again been used to simplify typography. The coefficient c, which reflects both the quantity of flow into

[27] "Fluid Mechanics for Hydraulic Engineers," by Hunter Rouse, McGraw-Hill Book Co., Inc., New York, N. Y., 1st Ed., 1938.

[28] "Hydraulik," by Phillipp Forchheimer, B. G. Teubner, Leipzig and Berlin, 1930.

each well and the characteristics of the medium and the fluid, may be defined as

$$c = \frac{\mu Q}{4 \pi k \gamma} \qquad (28)$$

in which the dynamic viscosity μ characterizes the fluid resistance; and Q is the rate of discharge into each well (the vertical depth of the stratum being assumed as unity). The permeability of the medium k is defined by Mr. Muskat[29] as "the volume of a fluid of unit viscosity passing through a unit cross section of the medium in a unit time under the action of a unit pressure gradient" and is entirely determined by the geometry of the medium. The value of k reflects the ability of the medium to transmit fluid much as a coefficient of heat transfer reflects ability to transmit heat. The unit weight of the liquid, γ, has been introduced to balance the units of Eq. 27. These equations differ somewhat from Eqs. 7 because the writer found it impossible to follow the conflicting definitions and units and still to arrive at a correct equation.

Together with these fundamental relationships, a restatement of the problem in view is essential. Expressions are sought relating (*a*) the well discharge to the drop in head between the river and the well, and (*b*) the head midway between adjacent wells to that at the wells. It is necessary, therefore, to evaluate from Eq. 27 the piezometric head at the edge of the well and midway between wells in terms of known or measurable quantities. If the radius of the well r_w is assumed to be small relative to the well spacing (as it is in any practical case), the lines of constant pressure in the region of the well are essentially circular, and the piezometric head at the well may be evaluated at any point around the periphery. The pressure cannot be evaluated at the center of the well, because the medium is discontinuous in this region in direct contrast to the assumption underlying the derivation. Therefore, if the coordinates (r_w, s) are substituted in Eq. 27, an expression is obtained for h_w, the head in the well:

$$h_w = h_s + c \log_e \frac{1 - \cos j\, r_w}{\cosh 2\, j\, s - \cos j\, r_w} \qquad (29a)$$

In the numerator of the fraction $j\, r_w$ is small, so that $\cos j\, r_w$ may, with good approximation, be replaced by the first two terms of the equivalent series expansion, $1 - \frac{1}{2}(j\, r_w)^2$. Also, since $2\, j\, s$ is considerably greater than unity, $\cosh 2\, j\, s$ may be replaced by $\frac{1}{2}\, e^{2js}$ and $\cos j\, r_w$ may be neglected in the denominator. With these readily permissible simplifications,

$$h_s - h_w = 2\, c\, (j\, s - \log_e j\, r_w) \qquad (29b)$$

If the coordinates $(a/2, s)$, corresponding to a point midway between the wells at $(0, s)$ and (a, s), are substituted in Eq. 27, the piezometric head at this point can also be determined. In the absence of consistent notation, the symbol h_m will be assigned to this head, which can be referred to either the head at the river or the head in the wells by using Eqs. 27 and 29—that is:

$$h_s - h_m = 2\, c\, (j\, s - \log_e 2) \qquad (30a)$$

or

$$h_m - h_w = 2\, c \log_e \frac{2}{j\, r_w} \qquad (30b)$$

[29] "The Flow of Homogeneous Fluids Through Porous Media," by Morris Muskat, McGraw-Hill Book Co. Inc., New York, N. Y., 1st Ed., 1937, p. 71.

Finally, from Eqs. 29*b* and 30*b* the ratio presented as the ordinate scale in Fig. 4(*a*) can be quite simply expressed as follows:

$$\frac{h_m - h_w}{h_s - h_w} = \frac{\log_e (j\, r_w/2)}{\log_e j\, r_w - j\, s} \qquad (31a)$$

For purposes of computation, Eq. 31*a* can be simplified even further by substituting the value of j and changing to decimal logarithms:

$$\frac{h_m - h_w}{h_s - h_w} = \frac{\log_{10}\left(\dfrac{a}{\pi\, r_w}\right)}{2.73\,\dfrac{s}{a} + \log_{10}\left(\dfrac{a}{2\,\pi\, r_w}\right)} \qquad (31b)$$

Also, the combination of Eqs. 28 and 29 yields a relationship between the drop in head from the river to the well and the discharge per well:

$$Q = \frac{2\,\pi\, k\,(h_s - h_w)\,\gamma}{\mu\,(j\, s - \log_e j\, r_w)} \qquad (32)$$

Eqs. 31 and 32 correspond to Eqs. 11 and 12, but are presented in consistent units and in a more readily usable form.

The foregoing development has been included in some detail, in part because the parallel treatment by the authors lacked a systematic and readily understandable order, but primarily because throughout their development the authors have consistently departed from good practice in use of symbols. Although the results of the analysis as embodied in Fig. 4 are correct, it is typical of the confusion confronting the reader that the same quantity is designated as h in one part of Fig. 4 and as $h_s - h_w$ in the other. In fact, four different symbols were used at various points in the authors' development to represent this difference in head—namely, p, Δp, h, and $h_s - h_w$. The symbol p, furthermore, was assigned four distinct meanings, denoting the piezometric head at the point (x,y) in Eq. 7*a*, the difference in head $h_s - h_w$ a few lines thereafter, the unit pressure (actually piezometric head) at the midpoint between the wells in Eq. 8, and the difference $h_m - h_w$ in Fig. 8(*b*). As a result, the reader is forced to use intuitive as well as logical reasoning in following the authors' development.

Although the essential results given by the authors have proved to be correct, several omissions and points of inconsistency further detract from the presentation. It is difficult to obtain a satisfactory interpretation of Table 1 in the absence of specific values for s, h_s, and h_w.

The definition of the quantity "extra length," given as part of the discussion of Fig. 7, is not compatible with its representation in Figs. 7 and 8 and Eq. 13. Neither theory nor electric analogy are suitable for evaluating the effect of a well screen. As presented, this length term is the difference between the length of the direct path from the river to the line of wells and an effective length obtained by dividing the total drop in head $h_s - h_w$ by the piezometric gradient evaluated some distance away from the line of wells. Introduction of this residual quantity leads to the useful plot (Fig. 8(*a*)) which is independent of the variable s (or s/a). However, since Fig. 8(*a*) yields only the extra length and Eq. 13 is necessary for the evaluation of Q, the word "flow" in the caption

of Fig. 8 seems inappropriate. If this extra length is designated as b, it may be defined in relative form as

$$\frac{b}{a} = \frac{1}{2\pi} \log_e \frac{a}{2\pi r_w} \qquad (33)$$

which corresponds to the line for 100% penetration in Fig. 8(a). The equation for the related curve in Fig. 8(b) can be written in a like manner if it is noted that the value p in the ordinate scale is intended to signify the difference in head $h_m - h_w$ and that the porosity factor includes not only the effect of the porous material but the viscosity and unit weight of the water as well. If the writer's terminology and Mr. Muskat's definition of porosity are used, Eqs. 28 and 30b can be combined to represent the 100% line in Fig. 8(b)—that is:

$$\frac{(h_m - h_w)\, k\, d}{Q\, \gamma\, \mu} = \frac{1}{2\pi} \log_e \frac{a}{\pi r_w} \qquad (34)$$

It has been assumed that the effective radius of the well r_e is interchangeable with r_w in the absence of a definition of r_e or a relationship between the two.

The foregoing discussion and the restatement of the analytical part of the authors' paper were undertaken in an attempt to improve and correct the form of presentation. It is hoped that, in so doing, this section of the general discussion has been brought up to the high level of the remainder of the paper.

Reginald A. Barron,[30] Jun. ASCE.—Practical and theoretical requirements for the design of relief wells have been presented in this paper. Of necessity both these requirements must be considered in a design. The general case presented by the authors consists of a semi-infinite pervious layer of uniform thickness covered by an absolutely impervious blanket. In nature the blanket is always slightly pervious and in some cases, such as at Sardis Dam, Mississippi, the downstream blanket is of finite length.

The writer has obtained a mathematical solution for this case that meets the boundary conditions as shown in Fig. 22(b). The hydraulic head h_{xy} measured from a datum plane is

$$h_{xy} = h_p - (h_p - h_T)\frac{y}{L} - \bar{h}_{xy} \qquad (35)$$

in which

$$\bar{h}_{xy} = q \sum_{n=-\infty}^{n=+\infty} \log_e \left[\frac{\cosh \frac{\pi}{L}(n\,a - x) - \cos \frac{\pi}{L}(y + s)}{\cosh \frac{\pi}{L}(n\,a - x) - \cos \frac{\pi}{L}(y - s)} \right] \qquad (36)$$

in which n takes on all integral values between $-\infty$ and $+\infty$ including zero; and

$$q = \frac{\bar{h}_w}{\log_e \left[\dfrac{1 - \cos \dfrac{2\pi s}{L}}{1 - \cos \dfrac{\pi r_w}{L}} \right] + 2 \displaystyle\sum_{n=1,2,3,\ldots}^{n=\infty} \log_e \left[\dfrac{\cosh \dfrac{\pi n a}{L} - \cos \dfrac{2\pi s}{L}}{\cosh \dfrac{\pi n a}{L} - 1} \right]} \qquad (37)$$

[30] Engr., Embankment and Foundation Branch, U. S. Waterways Experiment Station, Corps of Engrs., Vicksburg, Miss.

Approximating $\dfrac{1}{1 - \cos\dfrac{\pi\, r_w}{L}}$ as $\left(\dfrac{2}{\pi^2}\dfrac{L^2}{r^2_w}\right)$, Eq. 37 may be rewritten as:

$$q = \frac{\bar{h}_w}{f\left(\dfrac{L}{r_w}\right) + f\left(\dfrac{s}{L}\right) + F\left(\dfrac{s}{L}, \dfrac{\pi\, a}{L}\right)} \qquad \text{(38)}$$

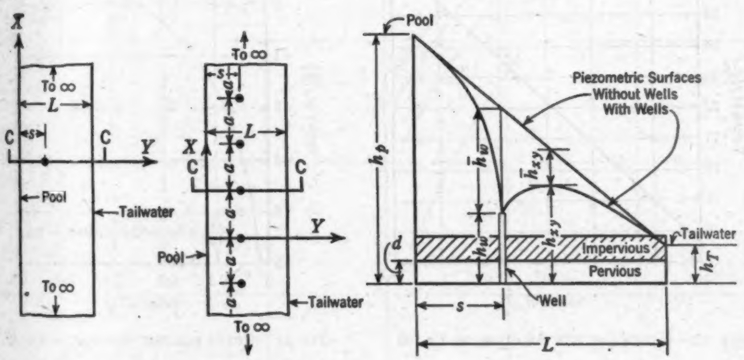
in which

$$f\left(\frac{L}{r_w}\right) = \log_e\left(\frac{2}{\pi^2}\frac{L^2}{r^2_w}\right) \qquad \text{(39)}$$

$$f\left(\frac{s}{L}\right) = \log_e\left(1 - \cos\frac{2\,\pi\, s}{L}\right) \qquad \text{(40)}$$

and

$$F\left(\frac{s}{L}, \frac{\pi\, a}{L}\right) = 2 \sum_{n=1,2,3,\ldots}^{n=\infty} \log_e\left[\frac{\cosh\dfrac{\pi\, n\, a}{L} - \cos\dfrac{2\,\pi\, s}{L}}{\cosh\dfrac{\pi\, n\, a}{L} - 1}\right] \qquad \text{(41)}$$



(*a*) FOR SINGLE WELL (*b*) INFINITE LINE OF EQUALLY SPACED WELLS (*c*) SECTION C–C

FIG. 22.—SINGLE WELL AND INFINITE LINE OF EQUALLY SPACED WELLS FOR CASE OF BLANKET WITH FINITE WIDTH

The individual well discharge is

$$Q = 4\,\pi\, k\, q\, d \qquad \text{(42)}$$

and the head acting on the well is

$$\bar{h}_w = h_p - (h_p - h_T)\,\frac{s}{L} - h_w \qquad \text{(43)}$$

The head above the well discharge midway between wells is $\bar{h}_w - \bar{h}_m$. Of

these two values, $\bar{h}_m$ is expressed as:

$$\bar{h}_m = q \sum_{n=-\infty}^{n=+\infty} \log_e \left[\frac{\cosh \frac{\pi a}{L} (n - \frac{1}{2}) - \cos \frac{2 \pi s}{L}}{\cosh \frac{\pi a}{L} (n - \frac{1}{2}) - 1} \right] \ldots\ldots\ldots (44)$$

in which n takes on all integral values between $-\infty$ and $+\infty$ including zero. The head $\bar{h}_w - \bar{h}_m$ may then be written as

$$\bar{h}_w - \bar{h}_m = \left[1 - \frac{f\left(\frac{s}{L}, \frac{\pi a}{L}\right)}{f\left(\frac{L}{r_w}\right) + f\left(\frac{s}{L}\right) + F\left(\frac{s}{L}, \frac{\pi a}{L}\right)} \right] \bar{h}_w \ldots\ldots (45)$$

In Eq. 45, $f\left(\frac{s}{L}, \frac{\pi a}{L}\right)$ is the quantity within the braces of Eq. 44. Curves for

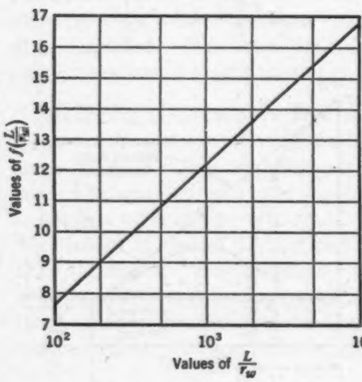


Fig. 23.—Curve for the Solution of Eq. 39

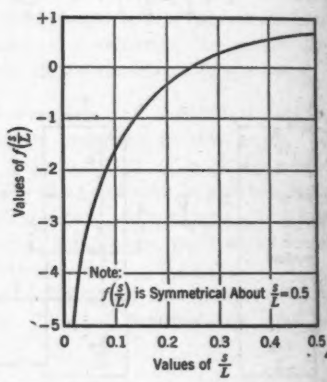

Fig. 24.—Curve for the Solution of Eq. 40

Eqs. 39, 40, and 41 and the quantity $f\left(\frac{s}{L}, \frac{\pi a}{L}\right)$ in Eq. 45 are given in Figs. 23, 24, and 25. For $\frac{a}{L} = \infty$, the values within the summation signs of Eqs. 36, 37, 41, and 44 are zero except for $n = 0$ and the case reduces to that of a single well as shown in Fig. 22(a). The value $\bar{h}_{xy}$ is then

$$\bar{h}_{xy} = q \log_e \left[\frac{\cosh \frac{\pi x}{L} - \cos \frac{\pi}{L} (y + s)}{\cosh \frac{\pi x}{L} - \cos \frac{\pi}{L} (y - s)} \right] \ldots\ldots\ldots\ldots (46)$$

and q may be determined by use of Eqs. 39 and 40 (Eq. 41 being equal to zero).

The average gradients to the well for the case of equal pool and tailwater may be approximated as follows by equating the well flow to that flowing to a continuous slot at s:

$$Q = 4\,\pi\,k\,q\,d = k\,h'\,a\left(\frac{1}{s} + \frac{1}{L - s}\right) d \qquad (47)$$

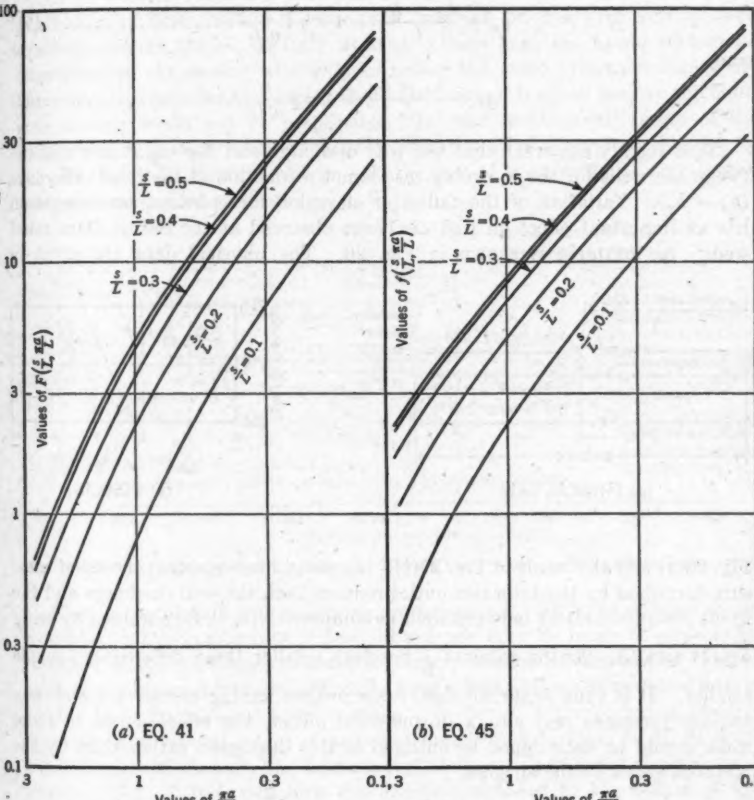

FIG. 25.—CURVES FOR THE DETERMINATION OF $F\left(\frac{s}{L}, \frac{\pi a}{L}\right)$ IN EQ. 41 AND $f\left(\frac{s}{L}, \frac{\pi a}{L}\right)$ IN EQ. 45

The effective head for the slot is

$$h' = 4\,\pi\,q\,\frac{s\,(L - s)}{a\,L} \qquad (48)$$

The gradient out of the pool is then

$$g_p = \frac{h'}{s} = 4\,\pi\,q\,\frac{L - s}{a\,L} \qquad (49)$$

whereas the gradient from the tailwater is

$$g_t = \frac{h'}{L - s} = 4\,\pi\,q\,\frac{s}{a\,L} \quad \text{(50)}$$

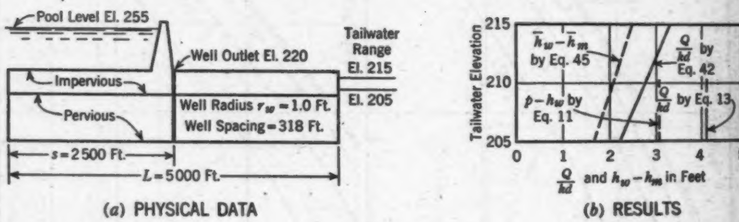
For the case in which pool and tailwater are not at the same elevation:

$$g_p = \frac{h_p - h_T}{L} + 4\,\pi\,q\,\frac{L - s}{a\,L} \quad \text{(51)}$$

and

$$g_t = \frac{h_p - h_T}{L} - 4\,\pi\,q\,\frac{s}{a\,L} \quad \text{(52)}$$

It is readily apparent that the well discharge and the uplift midway between the wells for the foregoing case is not a function of the head difference $(h_p - h_w)$. Variation of the tailwater elevation for constant pool elevation has an important effect on well discharge observed at the Sardis Dam relief wells. An example is shown in Fig. 26. The physical data are given in



(a) PHYSICAL DATA (b) RESULTS

FIG. 26

Fig. 26(a) and the result in Fig. 26(b). As should be expected, the relief measure furnished by the tailwater outlet reduces both the well discharge and the uplift pressure midway between wells as compared with those obtained by using Eq. 11 and 13. As the value of $\frac{s}{L}$ becomes smaller these differences become smaller. It is thus apparent that, for a project having excessive foundation seepage pressures and also a downstream outlet, the effectiveness of relief wells should be determined as outlined in this discussion rather than by the methods given by the authors.

PRESTON T. BENNETT,[31] M. ASCE.—This study of pressure relief is admirably balanced between a general discussion of basic principles involved, and the specific analytical methods that may be used in the application of these principles to the design of an installation.

With regard to the uncertainties concerning the boundaries of flow, permeability coefficients, and the effects of anisotropic permeability, it is believed that extensive field investigations of these factors may or may not be justifiable, depending on the type of installation. If the wells are to be installed at the

[31] Senior Engr., Corps of Engrs., Omaha Dist., Omaha, Nebr.

toe of a dam, flexibility of the system can be insured by placing them in an accessible location, and by omitting any elaborate collection system with a fixed discharge capacity. As the authors have stated in the paper, any deficiency in the original installation can be remedied by the addition of more wells when, and if, actual operation shows it to be necessary.

If, on the other hand, a deep subdrainage system is being considered for prevention of boils behind a levee, the inherent flexibility of vertical well drainage cannot always be fully utilized. Deep drainage would seldom be considered in connection with a levee unless the levee protected highly developed urban or industrial areas, where discharge of the well flow on the landside surface would not be permissible. In such a situation, design of the pressure-relief system involves the determination of the required capacity of the collection and disposal system, and the cost of these facilities may justify fairly expensive field studies.

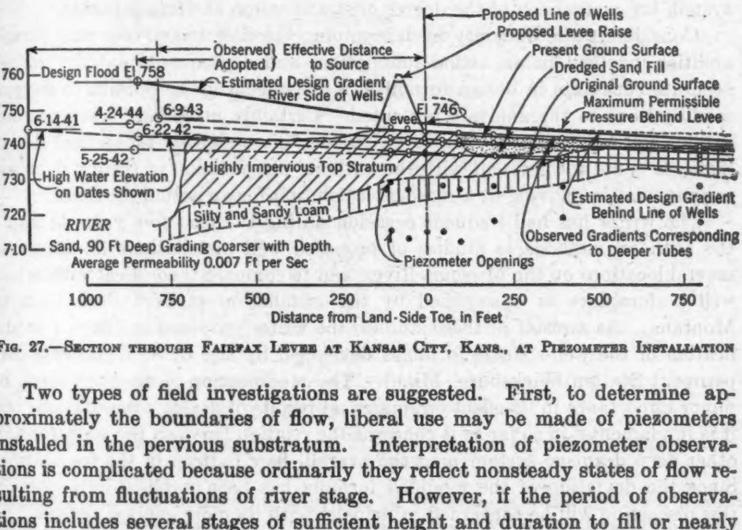


FIG. 27.—SECTION THROUGH FAIRFAX LEVEE AT KANSAS CITY, KANS., AT PIEZOMETER INSTALLATION

Two types of field investigations are suggested. First, to determine approximately the boundaries of flow, liberal use may be made of piezometers installed in the pervious substratum. Interpretation of piezometer observations is complicated because ordinarily they reflect nonsteady states of flow resulting from fluctuations of river stage. However, if the period of observations includes several stages of sufficient height and duration to fill or nearly fill underground storage, the field observations can be of great direct value in design. Fig. 27 indicates how the effective distance to the source of flow may be determined by piezometer observations. It shows data obtained by an installation at Kansas City, Kans., behind a levee constructed by the Corps of Engineers. The general relationship between the foundation pressure gradient, the rate of rise of the river, and the duration of the high stage may also be studied by use of observed data of the type shown in Fig. 27.

For a fairly accurate estimate of foundation permeabilities, deep well pumping tests are considered indispensable. They furnish directly the information needed in design, which is the quantity of water that will move through the entire foundation depth under a given gradient. Existing water-supply wells may be available for this purpose, or it may be necessary to install wells as a

part of the test. In the latter case, the test can be used to evaluate the performance of the type of well screen proposed for the system being designed.

It is also suggested that well pumping tests afford the only means of evaluating the factor of partial penetration in a stratified formation. The authors have shown, by model tests with an isotropic medium, that the percentage of penetration is more important than well size or spacing. In an actual foundation, penetration undoubtedly is of even greater importance, but it cannot be measured solely in terms of screen length versus sand depth, without reference to the comparative water-bearing capacities of the strata penetrated. A series of pumping tests at one location, in which the penetration of the screen is varied by successively filling and plugging off lower sections, will give directly a correction factor for penetration which can be applied to full penetration formulas. The applicability of this factor to other locations would of course be questionable, and should be checked by borings throughout the proposed system for comparison of the degree of stratification at various points.

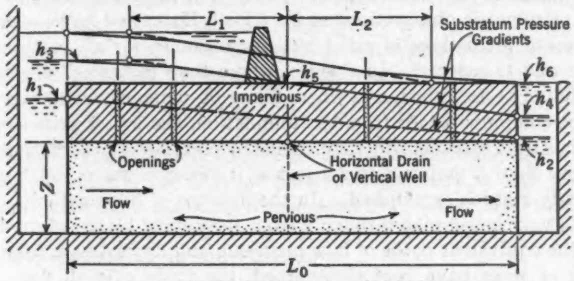
Considering the difficulty in determining the flow boundaries and permeabilities involved in an actual foundation, and consequent inability to use accurate constants in design formulas, it may seem inappropriate to suggest modifications to the analyses presented. Certainly no greater numerical accuracy will be obtained. However, further discussion of theoretical design methods is not inconsistent with the authors' presentation of theory as an aid to judgment in arriving at a reasonable solution for an actual problem.

The writer has had frequent occasion during the past five years to apply the authors' methods to studies of proposed well installations for levees at several locations on the Missouri River, and to compare theoretical with actual well performance as exemplified by the installation at Fort Peck Dam in Montana. As a result of these studies, the writer proposed in 1944[13] a modification of the well-spacing formulas developed by the U. S. Waterways Experiment Station (Vicksburg, Miss.). The modification is, in most cases, of minor importance in its effect on numerical results of design computation; but it is fundamental in so far as it concerns the relation between the wells (or any other deep drainage system) and the over-all flow pattern in the foundation. Since the deviation of the modified formula has been published elsewhere,[13] this discussion will be concerned principally with its more general aspects.

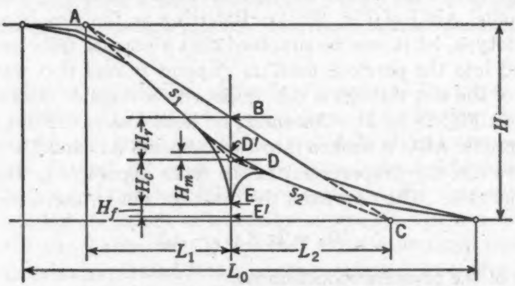
The only basic difference between the writer's analysis and that of Messrs. Middlebrooks and Jervis is that a regional flow landward from the well system is introduced. Perhaps the omission of this flow from the early studies was due to the use of models as shown in Fig. 5, which had an impervious bulkhead a short distance landward from the wells. In an actual installation, the pressure head in the region of the wells that causes them to flow ordinarily also will cause a landward flow away from the wells. This flow may or may not be important in any given case, but should be included in any general theoretical solution.

To simplify the discussion, a very simple model with definite dimensions will be substituted for the actual problem. Fig. 28 represents such a model, and shows the notation used in this discussion. It represents a pervious

medium of depth Z and length L_0, covered by an impervious layer which has a few openings filled with pervious material. These openings in the model represent places in the prototype where inflow or outflow from the pervious sand is relatively easy, as, for example, in borrow pits which partly expose the sand. They may also represent seepage through a surface blanket of low permeability. In this case the foundation pressure profile would become a



(*a*) SIMPLIFIED MODEL SECTION



(*b*) FOUNDATION PRESSURE PROFILES

FIG. 28.—SIMPLIFIED MODEL SECTION (*a*), WITH FOUNDATION PRESSURE PROFILES FOR ASSUMED CONDITIONS

smooth curve which, theoretically, can be determined analytically.[32] Water flows through this system from the reservoir head, h_1, on the left to tailwater head, h_2, on the right. If both headwater and tailwater are below the top of the impervious cover, the effective length of the path of flow is L_0, and the pressure gradient is the straight line connecting h_1 and h_2 on the diagram. Assume that the headwater is raised to h_3, covering the impervious top stratum and causing inflow into the pervious lower stratum through the small openings. The pressure gradient is now broken, becoming steeper below each opening in proportion to the amount of seepage admitted. At this stage, the effective upstream length of the flow path could be determined by measuring the pressure gradient at the toe with several piezometers and dividing the head ($h_3 - h_5$)

[32] "The Effect of Blankets on Seepage through Pervious Foundations," by Preston T. Bennett, *Transactions*, ASCE, Vol. 111, 1946, p. 215.

by the observed gradient. Such a procedure would be identical with that shown by Fig. 27 for an actual piezometer installation.

The space below h_s in the model represents underground storage in the prototype. As this storage fills up, seepage through the impervious cover begins at the outlets nearest the toe, and progresses landward. When the storage is exhausted, the effective land-side length of the model is established as L_2. Dimensions corresponding to L_1 and L_2 of the model have been established by piezometric observations at Fort Peck Dam, and have been used for fairly accurate predictions of relief well performance for all combinations of headwater and tailwater.[33] In a levee, where the "tailwater" elevation cannot be definitely established, and where filling of underground storage involves driving out compressible air from the foundation, the writer knows of no case where L_2 has been satisfactorily determined by piezometer observations. Field observations show a variation in L_2, just as it varies in the model, Fig. 28, before a steady state is established. In the absence of observational data, the distance L_2 may be estimated roughly from theoretical blanket formulas.[32]

After the equivalent paths of flow upstream and downstream from the proposed line of wells have been determined, the basic over-all flow patterns, without drainage relief, may be represented very simply by the foundation pressure profile, ABC of Fig. 28(*b*). Referring to the simplified model, and not the prototype, let it now be supposed that a narrow, fully penetrating slot is introduced into the pervious medium at point B, and that water is allowed to flow out of the slot through a standpipe with a variable discharge elevation represented in Fig. 28 by D. Assuming no head loss in the slot or standpipe, the former profile ABC is broken into two tangents AD and DC whose slopes, s_1 and s_2, are directly proportional to the flows approaching and leaving the pressure-relief slot. The flow from the drainage slot is, therefore:

$$Q_d = k_h Z (s_1 - s_2) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (53a)$$

or, in terms of the pressure reduction H_r,

$$Q_d = k_h Z H_r \left(\frac{L_1 + L_2}{L_1 L_2} \right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (53b)$$

These equations represent the performance of a hypothetical perfect drain, where no loss of head within the drain is involved. Any type of actual drain will involve a loss of head due to concentration of the flow into a drainage surface smaller than the sectional area of the pervious stratum. This loss of head is represented by H_e in Fig. 28(*b*). Suppose that the model flume, Fig. 28(*a*), is provided either with a vertical well or a horizontal drain as indicated by the dotted lines, and that the discharge elevation of the drain outlet is lowered to some elevation E′ (Fig. 28(*b*)) at which the drain discharge is equal to the open slot discharge given in Eqs. 53. The total friction loss in the system is H_f, and the head at the drain surface within the stratum is at elevation E.

The profile AD′C represents pressures along a straight line parallel to the axis of the model flume, and at the maximum distance from the drain. Such a

[33] "Pressure Relief Wells at Fort Peck Dam," by F. B. Slichter, Rept. on Conference on Control of Underseepage, U. S. Waterways Experiment Station, Vicksburg, Miss., April 1, 1945.

line would be midway between vertical wells, or at the bottom of the stratum if a horizontal drain were used. The profile AEC similarly represents horizontal flow gradients along a straight line passing through the drain. Beyond the region of influence of the wells (which from well formulas is not very extensive) the flow is evenly distributed and the pressure profiles AD′C and AEC coincide with ADC for most of their length. Near the drain, water moves laterally from the most remote path to the path through the drain, flattening the profile AD′C and making AEC steeper. Between the extremes AD′C and AEC there are an infinite number of intermediate horizontal flow gradients, but at any plane upstream from the drain the total horizontal flow is:

$$Q_1 = k_h Z s_1 \qquad (54)$$

and, consequently, the average horizontal gradient over the entire area of flow remains s_1. Similarly, the average horizontal gradient at any point downstream from the wells is s_2; and it follows that the average head in the vertical section through the drain is at D, exactly equal to the head in a fully penetrating open slot discharging an equal quantity.

This statement may seem so obvious that the foregoing discussion is unnecessary, but it expresses a basic idea which can be used to simplify the design of any deep pressure-relief system. The recommended procedure is briefly as follows:

(*a*) Establish the permissible subsurface pressure, D, using the criteria given by the authors. If any field comparisons of subsurface pressure with the actual occurrence of boils is available, such data should also be used.

(*b*) Estimate L_1 and L_2, or s_1 and s_2, using actual field observations if possible, by the general methods mentioned earlier in the discussion.

(*c*) Estimate the coefficient of transmissibility ($Z\ k_h$) as closely as possible, preferably using the Thiem tests if the cost of collection and disposal of the drain discharge is an important factor in the problem. At this stage, without going into final details of the type of drain to be used, the pressure relief H_r and the total drainage discharge Q_d can be determined, establishing the general features and cost of a collection and disposal system. It is quite possible that at this stage the economic feasibility of deep drainage can be determined.

(*d*) The location and grade of the collection system will establish the outlet elevations E′ along the drainage system, and the last step of the design procedure becomes the choice of a drain type, size, and penetration which will discharge the required quantity Q_d within the available head ($H_e + H_f$).

If the pervious stratum is deep and has the normal degree of stratification, vertical wells appear to be the best type of drain. A horizontal drain may prove to be more economical if the pervious stratum is thin and homogeneous. In either case, well formulas similar to those given by the authors can be used.

From Morris Muskat's[34] basic solution of multiple-well problems, it has been shown that the head loss H_e can be expressed as:

$$H_e = (s_1 - s_2)\ F\ P \qquad (55)$$

[34] "The Flow of Homogeneous Fluids through Porous Media," by Morris Muskat, McGraw-Hill Book Co., Inc., New York, N. Y., 1st Ed., 1937, Chapter IX.

in which

$$F = \frac{a}{2\pi} \log_e \frac{a}{2\pi r_w} \quad \text{......................(56)}$$

and P is a well penetration factor.

Since F is equal to the "extra length" factor used by the authors, it is evident that Eqs. 53 and 55 are equivalent to Eq. 13 when $s_2 = 0$. Thus, for the special case of no flow past the wells, the only difference involved is that the authors use the maximum pressure between wells as the permissible design value, whereas the writer suggests that the average pressure in the plane of the wells be used. For fully penetrating wells, the difference between maximum and average pressures, D′–D (Fig. 28(*b*)), is

$$H_m = a\,(s_1 - s_2)\,\frac{\log_e 2}{2\pi} = 0.11\,a\,(s_1 - s_2) \quad \text{............(57)}$$

or

$$H_m = \frac{0.59\,H_e}{\log_e \dfrac{a}{2\pi r_w}} \quad \text{......................(58)}$$

The difference between average and maximum pressures is ordinarily so small that either may be used in determining allowable substratum pressures. The writer's preference for the average value is based solely on the fact that it is the "PI" of the tangent gradients s_1 and s_2 which fix the relationship between the drains and the remaining parts of the flow system.

For homogeneous strata, the factor P can be determined from the experimental data given by the authors. For stratified foundations, it should be determined by field tests in which the penetration is actually varied within the limits being considered. In the latter case, the factor would be:

$$P = \frac{\text{well drawdown for partial penetration, discharge } Q_w}{\text{well drawdown for full penetration, discharge } Q_w} \quad \text{.....(59)}$$

Fig. 28 suggests a method for defining the efficiency of a deep drainage system. If the system is designed so that the friction losses (H_f) are negligible, as recommended by the authors, the head E can be lowered to the tailwater elevation C. In this case, the efficiency of the system may be defined in terms of the ratio of head reduction to the head without drainage. It can be shown that the drain efficiency is:

$$\eta_d = \frac{H_r}{H_r + H_e} = \frac{L_2}{L_2 + F\,P} \quad \text{................(60a)}$$

If L_2 is infinite, as assumed by the authors,

$$\eta_d = \frac{H_r}{H} = \frac{L_1}{L_1 + F\,P} \quad \text{..................(60b)}$$

Fig. 29 shows curves which may be used to determine readily the efficiency of a fully penetrating well system if the penetration factor P is known.

Well formulas may be used to evaluate a horizontal drain at the top of the pervious stratum by transposing vertical and horizontal dimensions in the plane

of the wells, and considering the horizontal drain to have half the discharge capacity of wells spaced a distance of $2Z$. If, as usually happens, the stratum is anisotropic, the equivalent well spacing used should be transformed to $2Z\sqrt{k_h/k_v}$, and the corresponding permeability $\sqrt{k_h k_v}$ should be used in computing the quantities of flow.

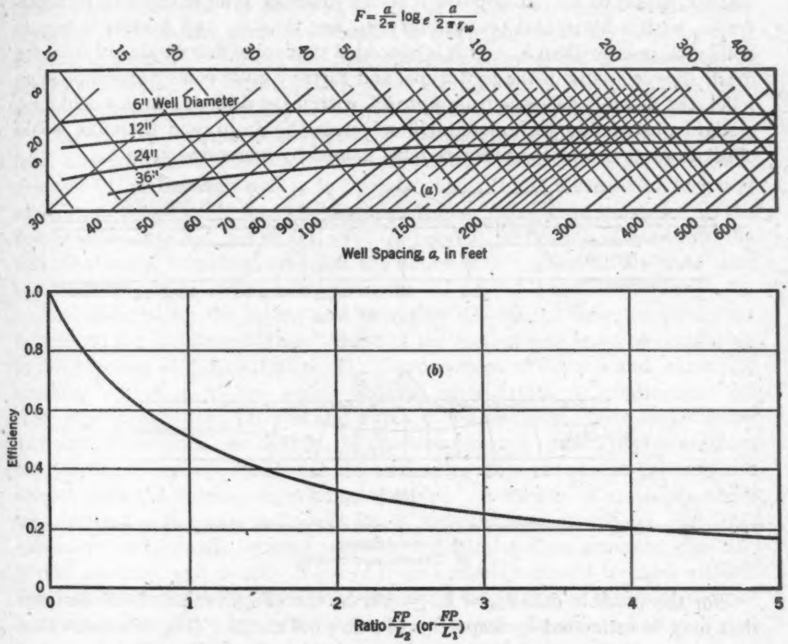


FIG. 29.—CURVES FOR DETERMINATION OF RELIEF WELL EFFICIENCY WHEN PENETRATION FACTOR P IS KNOWN

Eqs. 53 are directly applicable to drainage systems in which a continuous deep drainage zone might be used instead of vertical wells. It should be possible, by model studies or by analytic methods, to evaluate a factor for this type of drain which would be analagous to $F\,P$ in Eqs. 60, thus permitting a comparison in the efficiency of the two types.

It has been proposed to construct continuous deep drainage zones by excavation and backfill with highly pervious material, or by increasing the permeability of the sand by jetting. The writer has no knowledge on which to base any definite conclusion as to the practicability of materially increasing the permeability of the drainage zone. It would appear, however, that washing out any considerable part of the fines would be a very costly and difficult operation. If the jetting should succeed in breaking up the stratification without removing the fines, the maximum possible value of k_d would be the

mean permeability of the original materials, or

$$K_d\,(\max) \approx \sqrt{k_h\,k_v} < k_h \qquad (61)$$

Even if a considerable volume of fines were removed, as would be necessary to make k_d greater than $\sqrt{k_h\,k_v}$, it is difficult to imagine a treatment that would make k_d equal to k_h. It appears that the drainage zone would still be anisotropic, with a horizontal permeability k_{dh} less than k_h, and a vertical permeability k_{dv} greater than k_v. If it is conceded that some flow landward from the drain always occurs in the prototype, and thereby gives some natural pressure relief, the possible decrease from k_h to k_{dh} within the drainage zone would form a slight obstruction to horizontal flow across the drain, and therefore would offset to some extent the pressure relief gained by increasing k_v to k_{dv}.

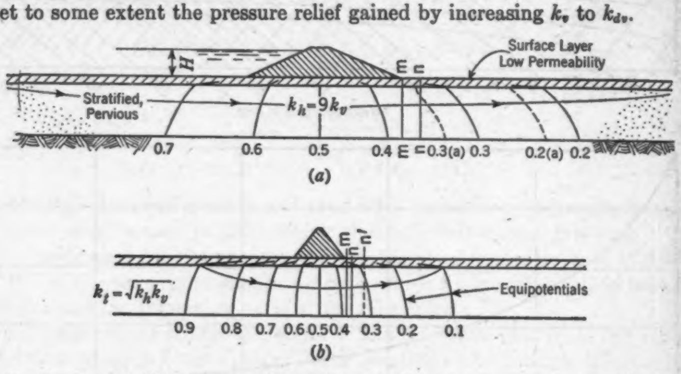

FIG. 30.—COMPARATIVE FLOW NETS FOR DAM OR LEVEE ON PERVIOUS FOUNDATION WITH $k_h = 9\,k_v$ FOR
(a) Natural Section
(b) Transformed Section

For the possible case $k_{dh} = k_{dv} = \sqrt{k_h\,k_v}$, the effectiveness of the drainage zone may be estimated by inspection of a flow net sketch. Fig. 30 represents a dam or levee on a pervious foundation in which $k_h = 9\,k_v$. The lines m-m and n-n represent limits of a potential drainage zone. If Fig. 30(*b*), all horizontal dimensions have been reduced in the ratio $\sqrt{k_v/k_h} = \frac{1}{3}$, and a flow net sketched in. This net has been replotted in Fig. 30(*a*) as shown by the solid equipotential lines, representing conditions without the drain. Foundation pressures in the region of the proposed drain appear to range from 35% to 38% of the total head. If the permeability of the drainage zone were altered to $\sqrt{k_h/k_v}$ the transformation in Fig. 30(*b*) would be accomplished by reducing all distances to the left of m-m and to the right of n-n, but leaving the interval between unchanged in scale, as shown by the line n′-n′ in the figure. Transposing the net back to the undistorted section gives the modified flow net indicated by dotted lines wherever it differs from the original. The pressure in the disturbed zone now appears to be from 30% to 36% of *H*, and the efficiency as previously defined would be about 15%. Actually, some additional pressure relief not indicated by the flow net would be gained by removal of the top stratum resistance, but the relief due to jetting alone is fairly well represented by the sketches.

CHARLES I. MANSUR,[35] JUN. ASCE.—The importance of the control of substratum pressures and seepage beneath hydraulic structures on pervious foundations, as outlined by the authors, cannot be overemphasized. Uncontrolled substratum pressure or seepage has frequently been a direct or contributing cause of the failure of structures that must withstand differential hydrostatic pressures. In addition to the use of pressure-relief wells on the land side of levees and dams as discussed in the paper, wells may also be used to provide pressure relief and drainage beneath other types of structures on pervious foundations. Some examples are stilling basins for outlet and spillway structures, locks, dry docks, weirs, floodgates, and drainage structures.

The primary function of a system of drainage wells is to provide pressure relief and drainage for water under hydrostatic pressure in a pervious substratum. If a drainage well is to operate efficiently as a means of relieving substratum pressures, it must be designed to: (*a*) Offer little resistance to the flow of water into and out of the well; (*b*) prevent infiltration of sand into the well after initial pumping; (*c*) resist the deteriorative action of the water and soil; and (*d*) withstand the earth pressure.

The material for the screen and riser pipe is a special item, which should be selected for each installation. Some of the factors that must be considered in the selection of a material are: (1) Corrosiveness of the soil and water; (2) expected operation of the wells—whether intermittent or continuous; (3) method of installation; (4) size and depth of well; (5) durability under water and alternate wetting and drying; (6) crushing strength; and (7) types of joints for joining the various sections. If practicable, all joints should be flush and smooth with the outside diameter of the pipe. A variety of materials which may be used as drainage wells are: Brass, wrought iron, aluminum, cast iron, galvanized iron, plastic, cement asbestos, bituminous fiber, concrete, clay tile, porous concrete, and wood. None of these materials should be used without first ascertaining whether they will withstand the corrosive action of the soil and water in which they will be placed. General experience has indicated that certain materials, such as brass, stainless steel, cast iron, and special metal alloys, clay tile, and wood, are to be preferred for drainage wells.

The wells, including screen, riser, and discharge pipe, should have an inside diameter which will permit maximum design flow without a head loss (friction and velocity) of more than ½ ft to 1 ft of water, depending on the residual pressure permissible in the design. In no instance should the inside diameter be less than 2.5 in. From hydraulic considerations the screen section of wells up to 6 in. in diameter should have at least twenty-five holes or ten slots with an open area of at least 3 sq in. to 6 sq in. per lin ft of screen. For design purposes it is the writer's belief, based on test data, that the screen openings should be equal to, or less than, the 70% size of the foundation sand or filter gravel.

The joints in the screen and riser sections of the well should be designed and constructed, where practicable, in such a manner that they will support the weight of the pipe as it is lowered into the hole. When not practicable to construct the joints in this manner, the riser should be supported, while being

[35] Engr. (Soil Mechanics), U. S. Waterways Experiment Station, Corps of Engrs., Vicksburg, Miss.

lowered into the casing, by some means which will insure that the joints will not open up. Where the screen and riser pipe consists of numerous loose joints (as, for example, with clay or concrete pipe) the top and bottom of the well should be joined with a brass or wrought-iron rod to eliminate or minimize the opening of any of the joints. All joints should have an overlap of at least ½ in., and should be coated with a good quality asphaltic roofing cement or equivalent plastic.

Experience indicates that wooden pipe is one of the best materials for pressure-relief wells, providing the screen and riser pipe are submerged continuously. The screen of wooden wells may be perforated either with circular holes or slots. It is desirable that circular holes be seared smooth with a hot iron prior to installation. Wooden pipe may be slotted with a small circular saw. Various widths of slot may be obtained by using one or more circular saw blades.

Where metal pipes are used for relief wells, all parts of the screen, riser pipe, and discharge pipe should be of the same kind of metal to minimize corrosion by electrolysis. The results of field and laboratory tests indicate relatively little difference in the discharge efficiency of metallic well screens of the same diameter that have not had an opportunity to corrode or clog. Laboratory tests, using a circular well-tank testing device, on six different new 3-in. commercial well screens, showed well-screen entrance losses of about 0.2 ft to 0.5 ft of water for a discharge of 5 gal per min per lin ft of well screen. A uniform, fine foundation sand was used in these tests.

Where filter gravels are to be placed around the screen part of the well, the perforations should be equal to, or less than, the 70% size of the filter gravel. Gravel filters around a perforated screen pipe should have a thickness of at least 4 in., measured radially from the outer circumference of the pipe. The filter material should be a washed gravel or a crushed stone composed of hard, tough, and durable particles. The gradation of the filter material will depend on the foundation sand being drained. The gravel should be of a size and gradation that will prevent "inwash" of any appreciable quantities of sand into the well, and also of a size and gradation which will be retained by the screen section of the well. The filter should also be considerably more pervious than the foundation sand. These filter requirements may be met by a filter which conforms to the following criteria:

$$\frac{15\% \text{ size of filter}}{85\% \text{ size of foundation}} < 4 \text{ to } 5 < \frac{15\% \text{ size of filter}}{15\% \text{ size of foundation}}$$

In addition to meeting these criteria, filters should be graded uniformly without any lack or excess of particles of any particular size. To minimize segregation during placement under water, the filter should be as uniform as possible and yet meet the aforementioned criteria.

There are many pervious foundations that are sufficiently well graded and which contain sufficient gravel to permit the installation of perforated well pipe without an artificial filter. Following installation, such wells should be "developed" by pumping and surging so as to build up a pervious filter around the well screen. The perforations in the screen for a well of this type should be of sufficient size to permit the inwash of sand within the immediate vicinity

of the well and yet to hold back the larger gravel particles, which thus build up a natural filter.

Porous concrete pipe may also be used as a filter around perforated pipe screens. If porous concrete pipe is used as a filter, it should be fitted closely around the inner pipe and should have a wall thickness of at least 1 in., and preferably greater. It should drain the foundation material freely without inwash of sand (this should be checked by laboratory tests prior to installation). The 70% size of aggregate used in the manufacture of the pipe should be greater than the perforations of the inner pipe.

The efficiency of various types of perforated pipes, with pervious gravel filters surrounding them, is illustrated by the results of tests in a well tank, using a fine, uniform foundation sand (see Table 3).

TABLE 3.—RELATIVE EFFICIENCY OF PERFORATED PIPE (FLOW, 5 GAL PER MIN PER LIN FT)

WELL PIPE		PERFORATIONS		Filter	HEAD LOSS, IN FEET OF WATER	
Inside diameter, in inches	Material	Size and shape (in.)	No. per linear foot		Screen	Screen and filter
(1)	(2)	(3)	(4)	(5)	(6)	(7)
$2\frac{1}{2}$.........	Clay tile	$\frac{1}{16}$ φ	48	Porous concrete[a]	....	0.3 to 0.5
6..........	Wood	$\frac{1}{8}$ φ[b]	36	Gravel[c]	0.12	0.28
6..........	Wood	$\frac{1}{16}$ by $2\frac{1}{2}$[b]	6	Gravel[c]	0.18	0.24

[a] 4-in. inside diameter pipe, 1-in. wall thickness. [b] Holes and slots seared with a hot iron. [c] Uniformly graded gravel from No. 20 sieve to $\frac{1}{4}$-in., filter 8-in. thick.

The casing for drainage wells may be installed by various methods; but the method used should be one which will not cause any excessive disturbance of the foundation sand outside the casing. Where filter materials are to be placed around the well screen, the bottom foot of the hole should be filled with the filter gravel prior to placing the well. The screen should then be properly centered in the casing and held securely in position while the filter is being placed and compacted, and while the casing is being withdrawn.

The filter material should be placed in small increments, so as to permit thorough "rodding" and not to interfere with the removal of the casing. To obtain a continuous filter, each increment of it should be compacted by rodding immediately after placing, and again after each increment of casing has been withdrawn. The casing should be withdrawn in an amount approximately equal to the depth of increment of filter placed. The alternate placing of filter and withdrawing of casing should be continued until the filter has been placed to the elevation of the top of the screen section and the casing has been withdrawn. The riser pipe should then be cut off at the elevation indicated for its termination, capped, and connected to the collector line or ditch in an approved manner. As pointed out by the authors the space around the riser pipe through the top stratum must be sealed carefully.

Promptly on completion of the installation of a well it should be pumped until a clear stream of water is obtained. Sometimes it is desirable to surge the well. When a well continues to produce sand it should be abandoned and a new well constructed near by. Abandoned wells should be plugged, and the riser pipe removed where possible.

Under the heading, "Design of Relief Well Systems," the authors state that a safety factor of 1.5 as applied to the critical gradient, $i_c = \frac{\gamma_s}{\gamma_w}$, may be satisfactory. The adequacy of this factor of safety depends, to a considerable extent, on the completeness of the field exploration of the foundation and top stratum. As illustrated by the authors, sand boils on the land side of dams and levees are the result of excessive hydrostatic pressures in a pervious substratum, which offers communication of pressure and seepage from the river or from borrow pits excavated to sand on the river side of the structure. If this subterranean pressure creates a hydraulic gradient sufficient to cause "flotation" of the soil in cracks, holes, or other thin or weak spots in the top stratum, sand boils will appear. The gradient required to cause such flotation may be considerably less than that theoretically required to cause flotation of the entire top stratum. As the foundation and top strata are usually nonhomogeneous in character, erosional seepage tends to concentrate in paths of least resistance to flow, causing sand boils to appear at localized spots instead of causing the entire foundation or top stratum to become "quick." Because of the foregoing reasons, effect of time on well-screen efficiency, and the other uncertainties of well design, a factor of safety of 2.0 may be warranted. If the flow from the wells is more than necessary to provide adequate pressure reduction, the wells can always be throttled down by valves, orifices, or other means; however, in some cases, conditions or time may not permit the installation of additional wells if the original design is not adequate.

At various times, there has been considerable discussion on the increase of seepage on the land side of levees, occasioned by the installation of pressure-relief wells. The primary purpose of pressure-relief wells is to reduce the hydrostatic pressure on the land side, or the downstream side, of levees or dams. By so doing, the hydraulic gradient from the river or reservoir toward the land side is increased, of course, which therefore increases the landward flow a certain amount. The writer knows of no field observations regarding the amount of such increase of land-side seepage; but the following example, based on the theory of critical gradient as presented by the authors, and on a study of seepage models by the writer, indicates the approximate increase of landward seepage that would be caused by drainage wells. Begin with four assumptions: A water height, H, of 30 ft; a top stratum depth of 8 ft; a critical gradient, i, of 0.9; and a saturated foundation.

The flow through a pervious stratum beneath a levee is directly proportional to the head drop from the river side to the land side. The maximum hydrostatic pressure that can exist land side of the levee would be $h_2 = 8 \times 0.9 = 7.2$ ft. (Any substratum pressure greater than this would raise the land-side blanket.) Therefore, the net hydrostatic head causing landward flow would be $\Delta H = 30 - 7.2 = 22.8$ ft. The flow resulting from this head drop

will emerge somewhere landward of the levee as general seepage, or as flow from sand boils. If a sufficient number of drainage wells were installed to lower the residual pressure on the land side to, say, $h'_2 = 1.0$ ft, the landward flow would be that corresponding to a pressure drop of $\Delta H' = 30 - 1 = 29$ ft. In other words, the drainage wells would increase the landward flow by $\left(\frac{29.0 - 22.8}{22.8} \times 100\right) = 27\%$. The total flow that must be cared for by the surface drainage system land side of levees, during flood time, is composed of surface runoff occasioned by rainfall, general seepage, and the additional flow that would result from the installation of some drainage system. On the basis of the foregoing computations, it may be seen that the additional flow resulting from drainage wells would be relatively small in most instances, considering the total flow that must normally be cared for by the surface drainage system.

The authors have very thoroughly covered the theoretical design of relief wells. Proper design of well spacing, diameter, and penetration is of primary importance in a well system. Of equal importance in the design of a relief well system is the design of the individual wells and their installation because, unless the wells function properly, the best of theoretical designs will not accomplish their purpose. Therefore, some additional discussion of this aspect of well design and installation was considered warranted.

S. J. Johnson,[36] Jun. ASCE.—In bridging the gap between the mathematician and the engineer in a practical manner, the authors have rendered a service to the engineering profession. The design of relief well systems has been greatly simplified by the design curves in this paper, without which the solution of the fundamental design equations becomes a time-consuming operation. Relief well systems are assuming such importance that the presentation of this paper is indeed timely.

The mathematical development presented by the authors is for purely artesian flow. A formula similar to Eq. 7a has been developed by Phillipp Forchheimer[28] for gravity flow in a homogeneous soil, based upon J. Dupuit's assumption that the gradient on any vertical is constant and equal to the slope of the seepage surface in the flow direction. The depth of saturation h at any point is given by:

$$h^2_s - h^2 = \frac{Q_g}{2\,\pi\,k} \log_e \left[\frac{\cosh j\,(y + s) - \cos j\,x}{\cosh j\,(y - s) - \cos j\,x}\right] \qquad (62)$$

in which h_s is the depth of saturation at the line-drive source; Q_g, the gravity flow discharge out of each well, is:

$$Q_g = \frac{2\,\pi\,k\,(h^2_s - h^2_w)}{2 \log_e \frac{e^{js}}{j\,r_w}} \qquad (63)$$

The writer has had occasion to use the gravity equations in studies for a dam that rests on a pervious foundation possessing a natural impervious top layer.

[36] Engr., U. S. Waterways Experiment Station, Corps of Engrs., Vicksburg, Miss.

Over the downstream part of the foundation, this top layer had been removed to permit foundation drainage, which was hindered by foundation stratifications by-passing part of the underseepage. This condition created undesirable uplift pressures at and beyond the downstream toe of the dam. To study the effect of pressure-relief wells, the gravity discharge, Q_g, was equated to the artesian seepage, Q_a, that existed between the upstream end of the natural blanket and the upstream end of the stripped dam foundation, thus:

$$Q_g = \frac{2 \pi k (h^2_s - h^2_w)}{2 \log_e \frac{e^{js}}{j r_w}} = Q_a = \frac{k a d (\Delta H + h_w - h_s)}{L} \qquad (64)$$

—to obtain h_s which is the head at the upstream end of the stripped foundation. In Eq. 64 ΔH is the difference in elevation between reservoir pool and tailwater of the well discharge (head losses in the well considered to be negligible), and L is the distance between the upstream end of the natural blanket and the upstream end of the stripped foundation. With h_s thus determined, the head at any desired location may be determined from Eq. 62. For conditions studied, the head h_s is slightly less, and the heads midway between wells are slightly more (as computed by the foregoing method), than those given for similar points by Eq. 7*a*.

An important item, as the authors have indicated, is the determination of the effective distance from the source to the line of wells. Information on this factor can be determined in advance, when the wells are to be installed behind existing dams or levees, by placing piezometers at various distances from the dam or levee on the water side. Another method is to evaluate this distance by mathematical means[32] after first determining the permeability and extent of the permeable stratum and top stratum. This latter method must be used when piezometer observations cannot be made. The effective distance from the source can also be determined for existing installations if the quantity of flow is known, together with the permeability and the dimensions of the foundation soils. These three methods were used by the writer in analyzing data obtained from a drainage well installation at a flood control dam. The methods gave results which were all the same degree of magnitude, although there were some differences, which probably can be explained by the variations in field conditions which are generally present.

The behavior of the toe drainage provisions at one dam was studied by the U. S. Waterways Experiment Station (Vicksburg, Miss.) in January, 1945. The effect of closing the wells on the piezometric pressures in the line of wells was very pronounced, since the head above ground surface increased from about 1.3 ft with the wells in operation to 6.1 ft with the wells closed. Inasmuch as the natural blanket, or top stratum, was only 8 ft thick at the section where these readings were taken, the necessity of maintaining the wells in good operating condition is evident. Tests such as described herein obviously should be made only under closely controlled conditions.

An important point, not considered by the authors, is the reduction of well discharge rates after installation. The Waterways Experiment Station has studied the reduction in well discharge of the Sardis experimental well installa-

tion. A study of forty-six wells completed in May, 1942, showed that, assuming the initial output as 100%, after two years the average output of all wells had dropped to 35%. However, surging of the wells at that time increased the average well output to 56% of the original output. The comparisons were made at the same net head. These reductions may be caused by one or both of the following: (1) Silting up of the bottom of the reservoir; and (2) clogging of the well screen or filter. Inasmuch as the reservoir is fed by a muddy river some silting probably occurs, although the total quantity of seepage flow has not decreased materially according to other data available. The general improvement of the wells after surging indicates that the major cause of discharge reduction is screen clogging. Such clogging can be caused by imperfect filter action or by chemical deposition.

The experimental wells were pulled during December, 1946, and the screens revealed corrosion and deposition, especially those with fine screen or mesh openings and those that were composed of iron pipes with brass screens or mesh. The ground water at this site has a low pH-value and a sufficient amount of dissolved CO_2 to render it corrosive. The ratio of the 85% size of the sand or gravel immediately adjacent to the screen to the size of screen opening varied from 1.0 to 1.4 for the nonmetallic pipe; whereas the ratio of the 15% size of the filter gravel to the 85% size of the foundation sand varied from 2.3 to 3.0. Some inwash of sand occurred during surging after initial installation. In view of the foregoing satisfactory ratios and the variations of the well discharges, it is evident that there was either a progressive clogging of the well screen, or filters, or both. The surging in June, 1944, materially increased the flow, and thus it probably partly cleared the screen clogging—but not entirely. In general, it is desirable to keep the entrance velocity through the screen openings as low as possible, since the change in pressure head outside the screen to velocity head in the screen releases CO_2 and other gases, thereby increasing corrosion and incrustation.

The useful life of water-supply wells was the subject of six papers presented at the 1946 Annual Conference of the American Water Works Association, and which have been reported in abbreviated form.[37] These papers presented factual data showing that screen clogging and incrustation are common and that a reduction in well output with time is to be expected to some degree. "The average life of screened wells under all conditions seems to be from 25 to 30 years," according to E. W. Bennison, M. ASCE, and "Sufficient length of experience is not available to forecast the life of gravel-packed wells but it is believed one-half of the value is gone in 15 years," according to A. D. Henderson. Although the conditions surrounding the use of water-supply wells may be different from those surrounding the use of relief wells, the data mentioned in this discussion are at least indicative.

The experiences cited herein emphasize the necessity for designing pressure-relief wells oversize to provide for possible reduction in capacity, and to provide for easy replacement of wells at the expiration of their useful life, regardless of whether that be five or fifty years. From the data and experience to date, it appears necessary to consider carefully the materials of which the wells are to be made, and the ground water and soil conditions at the site.

[37] *Journal*, A. W. W. A., January, 1947.

In the experimental well system at Sardis Dam (Mississippi) it was found (as the authors have stated) that wooden wells performed satisfactorily. In this connection, it is interesting to record that slotted wooden wells have been used for water supply purposes for many years in Holland, and with satisfactory results. The wells used in that country are made of hard wood. The wooden wells may be obtained with thin slots parallel to the grain, which are about $\frac{1}{16}$ in. wide, 3 in. long, and spaced at intervals of approximately $\frac{1}{2}$ in. around the outside of the pipe. They may also be obtained with slots perpendicular to the grain but inclined upward, which would tend to minimize the possibility of sand being carried into the well.

One item, which the writer believes to be especially important, is the determination of the discharge elevation of the wells. In general, it is highly desirable that this elevation be as low as possible. Considerable care should be given to this decision, as it may mean the difference between a system which is entirely satisfactory and one which is not.

Gravel filters artificially placed around relief wells are necessary if an adequate natural filter is not developed by pumping and surging of the well. The relative merits of these two types of filter are somewhat controversial; however, the use of one or the other is considered essential.

The writers are to be congratulated for bringing the design of relief well systems to the attention of engineers in a timely and well-prepared paper.

KENNETH S. LANE,[38] ASSOC. M. ASCE.—The authors have presented a worthwhile and timely assembly of theoretical considerations and experimental data which form the basis of design of relief wells. Such wells are among the most flexible of the various types of drains used to relieve seepage pressure by tapping pervious foundation strata, in accordance with the principle that control of seepage pressure rather than seepage quantity is the main factor in avoiding underseepage failures—an important principle which the authors have done well to emphasize. It is rare when uncertainties do not exist about a pervious foundation, especially in regard to chance arrangement of minor geologic layers of widely different permeability, which greatly influence seepage behavior. Hence, it is generally necessary to test the effect of several plausible assumptions of foundation conditions. In certain cases the straightforward charts of the paper will quickly furnish results to guide judgment. For several other common foundation cases, reference could well be made to formulas developed by Preston T. Bennett[32] and William H. Jervis, Members, ASCE, and Reginald A. Barron,[32] Jun. ASCE. These formulas give solutions for the head lost in seepage beneath the structure, and thus indicate whether the resulting seepage pressures in the zone of seepage emergence are likely to be sufficient to cause flotation, warranting relief well or other drainage treatment.

For the condition of flotation (when upward seepage pressure approaches, or equals, downward soil weight), two effects are prone to occur: (1) Emerging seepage concentrated in boils of moderate to large size tending to develop into piping which progresses as an underground channel toward the water source; or (2) flow dispersed over the emergence zone of upward seepage, causing a quick condition over a substantial area, which is often accompanied by many

[38] Chf., Soils and Geology Branch, Garrison Dist., Corps of Engrs., Bismarck, N. Dak.

tiny to small boils. In stressing the fact that boils of all sizes are dangerous, the authors give two examples, of the first effect (piping), and also mention the second effect—a general quickening of the foundation. In the latter state the soil behaves as a heavy liquid and has only minor shear strength; a mat of vegetation or root-bound topsoil will generally weave under foot, and seepage is likely to escape from many small boils.

The writer recalls one instance near West Springfield, Mass., where more than 1,000 small boils were counted in a reach of less than 1,000 ft behind a levee, which was then subjected to about two thirds of the design head. Fortunately, the flood was of short duration and seepage reduced the effective head by building up tailwater so rapidly that the levee escaped failure. Subsequently, a relief well system was designed to meet this condition.

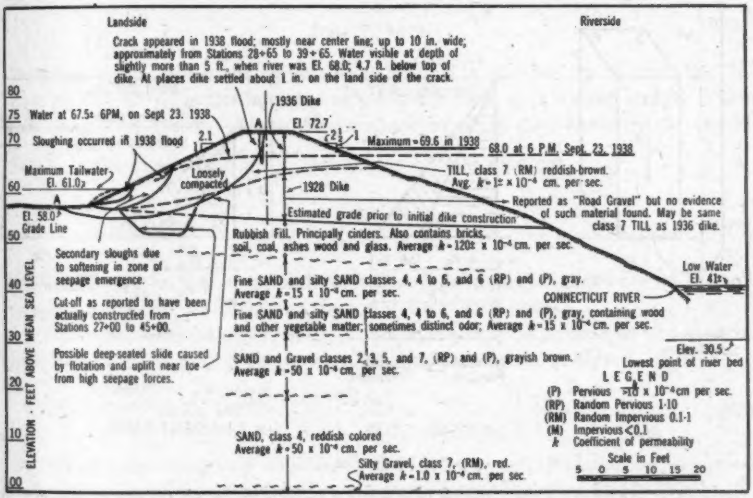

Fig. 31

With such a general quick condition there is real danger that slides may develop on the downstream or land-side slope of the water barrier embankment, from loss of toe support, as the quick condition results in a drastic loss of shear strength of the foundation soil adjacent to the embankment toe. If the slide, or succession of slides, extends back to intersect the water surface, it is followed immediately by overtopping, and a crevasse results.

A partial example of dangerous loss of toe support is the near failure of Springdale Dike during the September, 1938, flood. This levee was built by local interests along the Connecticut River near Holyoke, Mass. Its section is homogeneous, not specially compacted, and contains a shallow cutoff, strangely located near the land side. Fig. 31 shows foundation conditions and behavior observed, except in the land-side area where tailwater prevented observations. During the flood, electric failure occurred within the pumping

station and tailwater was built up rapidly, partly from seepage, but largely from unintentional diversion through an unclosed cross connection from a sewer communicating with the river. As an explanation of surface evidence observed, line AA in Fig. 31 has been drawn as a possible surface of a slide of the land-side slope which may have been in progress until accidental creation of a tailwater pond lowered the effective head, and very likely was a major factor in averting complete failure. To no small degree the unfortunate location of a partial cutoff at the land side, instead of at the river side, would contribute toward such a slide by increasing seepage pressure in the land-side part of the levee to nearly full headwater pressure—shown as having occurred from the water level observed in the center-line crack. Although the Springdale Dike foundation might be treated with relief wells, the reconstruction design in-

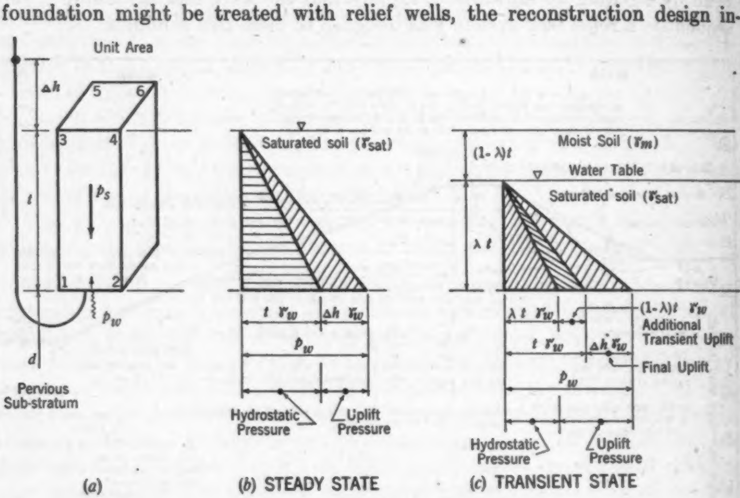

FIG. 32

cluded a continuous pipe drain (extending from 4 ft to 10 ft into the pervious upper layer of fill), which the writer considers as more positive than intermittent relief wells for foundations not too highly stratified, and where the most pervious important foundation layers lie at such depth that they can readily be tapped by a drain.

As indicated by the authors' examples, most of the present relief well installations have been placed behind existing structures as repair measures. From successes in such usage, relief wells are now being designed increasingly as part of initial construction. To aid judgment in determining when pressure-relief treatment is initially needed, it is of interest to investigate the equations of flotation in more detail than is permitted by Eqs. 3 to 6. Figs. 32(*a*) and 32(*b*) show the steady state case usually considered for investigating flotation of a top stratum which is saturated, with the water table at the surface. Seepage is flowing upward and Δh represents the piezometric pressure or uplift head acting at the base of the top stratum, as estimated from computing head lost

in seepage beneath the structure from solutions given by the authors and by others.[32] For the state of flotation, the total upward pressure—

$$p_w = t\,\gamma_w + \Delta h\,\gamma_w \qquad (65a)$$

—equals the total downward pressure—

$$p_s = t\,\gamma_{bs} + t\,\gamma_w \qquad (65b)$$

—assuming no resistance on the sides of the parallelepiped 1–2–3–4–5–6, Fig. 32(*a*). This assumption is substantially correct when flotation occurs, because the soil then acts as a heavy liquid with no shear strength. Accordingly:

$$t\,\gamma_{bs} + t\,\gamma_w = t\,\gamma_w + \Delta h\,\gamma_w \qquad (66a)$$

or

$$t\,\gamma_{bs} = \Delta h\,\gamma_w \qquad (66b)$$

Flotation occurs when the buoyant soil weight is equaled by the uplift. In Eqs. 65 and 66 γ_{bs} is the buoyant or submerged soil unit weight and γ_w is the unit weight of water. When Δh becomes equal to Δh_c, sufficient to create flotation, the gradient, $i = \frac{\Delta h}{t}$, equals the critical gradient, i_c:

$$i_c = \frac{\Delta h_c}{t} = \frac{\gamma_{bs}}{\gamma_w} \qquad (67)$$

which is similar to Eq. 6 and indicates that i_c, being dependent only on the soil density, represents a property of the soil in its natural state.

The factor of safety against flotation is generally expressed as the ratio of unbalanced forces acting (herein termed apparent factor of safety, $(FS)_a$):

$$(FS)_a = \frac{\text{buoyant weight}}{\text{uplift}} = \frac{t\,\gamma_{bs}}{\Delta h\,\gamma_w} = \frac{1}{i}\frac{\gamma_{bs}}{\gamma_w} = \frac{i_c}{i} \qquad (68)$$

For strict correctness it is considered the factor of safety should be expressed as a ratio of total forces acting (herein termed true factor of safety $(\overline{FS})$):

$$(\overline{FS}) = \frac{t\,\gamma_{bs} + t\,\gamma_w}{t\,\gamma_w + \Delta h\,\gamma_w} = \frac{\frac{\gamma_{bs}}{\gamma_w} + 1}{1 + \frac{\Delta h}{t}} = \frac{1 + i_c}{1 + i} \qquad (69)$$

Eqs. 68 and 69 are compared in Fig. 33, which shows that the function $\frac{1 + i_c}{1 + i}$ is not a sensitive one. It has a definite maximum in the vicinity of $(\overline{FS}) = 2$ and has the further disadvantage of not varying directly with Δh which is related directly to total head acting. Since it eliminates these disadvantages, the function $\frac{i_c}{i} = (FS)_a$ is considered the flotation factor of safety in usual practice, with which the writer concurs.

The authors suggest (in the text following Eq. 6) that "it may be that design for a safety factor of 1.5 against developing the critical gradient is satis-

factory." If the authors intend this to be computed as $(\overline{FS}) = 1.5$, it becomes of the order of $(FS)_a = 3.0$ when converted in Fig. 33. However, if the authors intended this to be obtained from the usual equation, $(FS)_a = \frac{i_c}{i} = 1.5$, then the writer is inclined to feel that the suggested value is low for dams, although probably reasonable for most levees except those protecting property of particular importance or value. To a considerable extent the choice of a numerical value for a design objective should depend on the severity of the assumptions used because, in the analysis of flotation, a factor of safety often represents a factor of ignorance to allow for the great influence on seepage behavior caused by discontinuous stratifications of widely different permeability. Fortunately, for decidedly stratified foundations a lower factor of ignorance is applicable to a relief well than to a usual drain treatment because, except for a drain of comparable depth, the relief well treatment is the more positive. Once it has been decided to use relief wells in a levee design, it will often be found that the additional cost of increasing safety to the desired objective by a moderate decrease in spacing is not great.

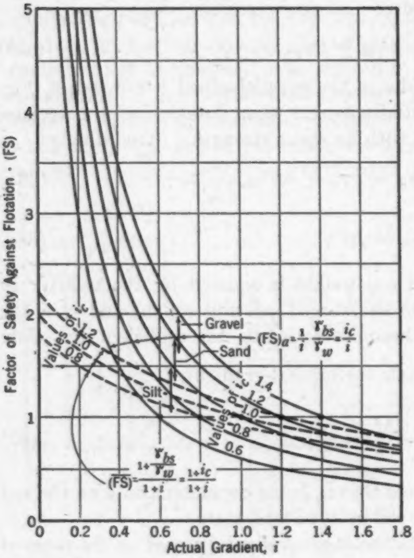

FIG. 33

The most difficult problem is to decide if wells are needed. In studying relief well applications to several levees around built-up areas of moderate property value, the writer has found the following a convenient approach which is advanced here more to stimulate thought than as a proposal for general application. Two flood heights are considered—(1) design flood and (2) top-of-levee flood. The latter equals design flood plus freeboard. If analysis reveals conditions that are considered moderately dangerous for the design flood, and decidedly so for the top-of-levee flood, then pressure-relief treatment is recommended. For less severity, consideration is given to taking a calculated risk by initially omitting extensive treatment and providing for later installation if needed. As the authors mention, the relief well is a particularly flexible tool for such later installation. Once pressure-relief treatment is adopted, an attempt is made to secure definite safety for the design flood and at least a slight margin of safety for the top-of-levee flood.

Greater conservatism is felt warranted in the case of dams, including consideration of the possibility that partial quickening of the downstream

foundation with attendant reduction in shear strength may begin at a gradient below that computed as the critical from Eq. 67. The writer is inclined to the belief that this is a definite possibility from occasional qualitative observations of a quicksand device. In several performances the soil column parted near the middle; the top part lifted a matter of several inches and remained suspended while seepage emerged under a gradient somewhat below a probable value of i_c. Rather similar behavior also has been reported by others.[39] To explore the possibility of such behavior in nature, consider the transient case shown in Fig. 32(*c*) with tailwater rising toward the surface from an initial position of the water table below depth t. When tailwater is rising from point 1 to point 3, the top stratum will tend to lift when the total upward pressure—

$$p_w = \lambda\, t\, \gamma_w + (1 - \lambda)\, t\, \gamma_w + \Delta h\, \gamma_w \ldots\ldots\ldots\ldots\ldots (70a)$$

—equals the total downward pressure exerted by the partly saturated soil—

$$p'_s = \lambda\, t\, \gamma_{bs} + \lambda\, t\, \gamma_w + (1 - \lambda)\, t\, \gamma_m \ldots\ldots\ldots\ldots\ldots (70b)$$

—assuming that the side friction can be neglected around the periphery 3–4–5–6. Although this assumption is too conservative for a small area as indicated in Fig. 32(*a*) (since at least the moist soil above the water table retains substantial shear strength), it becomes reasonable for large areas where the peripheral friction is small in comparison with the weight, p'_s.

For the condition of lifting, equating $p_w = p'_s$ from Eqs. 70*a* and 70*b* and rearranging terms:

$$\underbrace{\Delta h\, \gamma_w}_{\substack{\text{Final}\\ \text{uplift}}} = \underbrace{\lambda\, t\, \gamma_{bs}}_{\substack{\text{buoyant}\\ \text{soil}}} + \underbrace{(1 - \lambda)\, t\, \gamma_m}_{\substack{\text{moist}\\ \text{soil}}} - \underbrace{(1 - \lambda)\, t\, \gamma_w}_{\substack{\text{additional}\\ \text{transient uplift}}} \ldots\ldots (71)$$

$$\text{Final uplift} = \text{net downward pressure}$$

Defining $(i_c)_m$ as the lifting gradient at the time that lifting of the partly moist top stratum begins:

$$(i_c)_m = \frac{\Delta h_{cm}}{t} = \lambda \frac{\gamma_{bs}}{\gamma_w} + (1 - \lambda) \frac{\gamma_m}{\gamma_w} - (1 - \lambda) \ldots\ldots\ldots (72a)$$

Let

$$\beta = \frac{\gamma_m}{\gamma_w} = \frac{S\,(\gamma_{sat} - \gamma_d) + \gamma_d}{\gamma_w} \ldots\ldots\ldots\ldots\ldots\ldots (72b)$$

in which S denotes percentage saturation. Making necessary substitutions of β from Eq. 72*b* and i_c from Eq. 67:

$$(i_c)_m = \lambda\, i_c + (1 - \lambda)\, \beta - (1 - \lambda) \ldots\ldots\ldots\ldots\ldots (72c)$$

or

$$(i_c)_m = \lambda\, [i_c - (\beta - 1)] + (\beta - 1) \ldots\ldots\ldots\ldots\ldots (72d)$$

Expressing the apparent factor of safety against lifting, $(FS)'_a$, as the ratio of net downward pressure to final uplift (see Eq. 71) and using the same sub-

[39] "Cofferdams," by Lazarus White and Edmond A. Prentis, Columbia Univ. Press, New York, N. Y., 1940, p. 13.

stitutions as in Eq. 72*c*:

$$(FS)'_a = \frac{1}{i}[\lambda\, i_c + (1 - \lambda)\,\beta - (1 - \lambda)] = \frac{(i_c)_m}{i} \quad \ldots\ldots\ldots (73)$$

in which $i = \frac{\Delta h}{t}$ is for the final condition when the water table has reached the surface as in Fig. 32(*b*).

An expression can also be derived for true factor of safety against lifting which (omitting the algebra) results in:

$$(\overline{FS})' = \frac{\text{total downward}}{\text{total upward}} = \frac{p'_s}{p_w} = \frac{1 + (i_c)_m}{1 + i} \quad \ldots\ldots\ldots (74)$$

Eqs. 73 and 74 are similar in form to Eqs. 68 and 69; and, using $(i_c)_m$ for i_c, then are solved easily from the curves in Fig. 33.

Eq. 72*c* shows that $(i_c)_m$ varies directly with λ for a given soil and is a minimum for $\lambda = 0$. It is always less than i_c for less than full saturation until $\lambda = 1$, whereupon $(i_c)_m = i_c$. With other variables held constant, $(i_c)_m$ varies directly with β and is a minimum for dry soil. Fig. 34 shows this characteristic for a typical loose sand ($i_c = 1.00$) where the value of $(i_c)_m$ is reduced nearly one half for a dry soil and for $\lambda = 0$. Fig. 35 shows the effect of changes in density with constant saturation, drawn for a common specific gravity of $G = 2.65$ and saturation of $S = 70\%$.

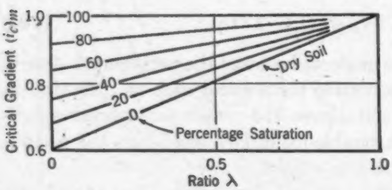

FIG. 34.—EFFECT OF SATURATION, WITH CONSTANT DENSITY ($i_c = 1.00$; $e = 0.65$; $\gamma_d = 100$; AND $G = 2.65$)

The computation of the lifting gradient, $(i_c)_m$, as appreciably less than i_c, is believed to explain the parting and lifting in the quicksand device, which was generally observed at the first beginning of upward flow when the soil was dry to moist. After seepage emerged for some time and was then shut off, successive resumptions of upward seepage did not again cause lifting, presumably as the soil was then saturated and $(i_c)_m$ equaled i_c for all values of λ according to Fig. 34. The quicksand device used was not adapted to close measurement of actual gradients; hence verification of Eq. 72*d* is as yet qualitative rather than quantitative.

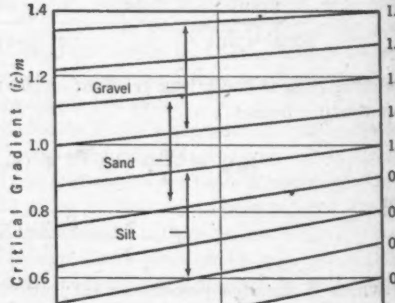

FIG. 35.—EFFECT OF DENSITY, WITH CONSTANT SATURATION ($S = 70\%$ AND $G = 2.65$)

In nature, the case of moist soil with a rising water table is a transient state. Since piping is not likely to start working backward from the seepage outlet

until the steady state has been attained and has established that outlet, most flotation problems should be analyzed for the gradient i_c in the steady state. However, a few cases are visualized where analysis on the basis of the lower gradient $(i_c)_m$ may be of considerable importance. Consider a top stratum of clay, tight and impervious, underlain by a material of such greater permeability that the seepage from it can accumulate rapidly to fill such gaps as might be formed by lifting of the top stratum. With the common case of a sheet pile cofferdam, braced at the top and toed into above top stratum, it is easy to visualize loss of toe support by lifting of the top stratum sufficiently for failure by rotation around the top brace. Another example is that of a dam or high levee, with such a critical condition of downstream slope stability that even a small loss of toe support would be undesirable. Pending the assembly of quantitative data on the possible reduction in shear strength at gradients below i_c, the writer has attempted to allow for this by considering $(i_c)_m$ as the point where reduction starts. For one important dam so analyzed, the result was the inclusion of a few relief wells to relieve seepage pressure in a pervious stratum buried about 130 ft deep under soft varved silt in order to insure against any reduction in strength of the already weak silt foundation.

T. A. MIDDLEBROOKS,[40] ASSOC. M. ASCE, AND WILLIAM H. JERVIS,[41] M. ASCE.—The excellent discussions of this paper have added immensely to the knowledge of relief well design and will be most helpful to engineers who are confronted with this problem.

Mr. Barksdale emphasized the need for careful investigations. In-place permeability pumping tests, mentioned by Mr. Barksdale, are essential for large jobs, where maintenance pumping cost will be excessive. However, in most cases, it is cheaper to install a few additional wells as an added precaution against low discharge estimates than it is to conduct expensive pumping tests. Head loss in the casing and screen, and clogging of wells due to growth, are most important factors, all of which justify larger wells and periodic checks.

Mr. Turnbull's prediction that relief wells will be used on all important engineering structures on pervious foundations is a good possibility as soon as the costs of well installations are lowered by improved techniques. His comment that the foundation may be too pervious for relief wells to remove sufficient water to reduce the pressure to a safe value is a possibility, but a remote one. Collector systems are preferred in most cases; however, they are expensive and should be omitted where it is practicable to do so. The Mississippi River levee installations referred to were experimental and woefully underdesigned. There is no doubt that these installations would have been satisfactory if wells of 6-in. diameter or larger had been used, and if the wells had penetrated deeper into the water-bearing strata. Tight packing around the well is costly and it is not important as long as no provision is made for closing the well during operation.

Mr. Gilboy has emphasized that a wide difference between vertical and horizontal permeability is present in all deposits. This difference is large even

[40] Head Engr., Corps of Engrs., Chf., Soil Mechanics, Geology and Geophysical Section, Washington, D. C.

[41] Cons. Engr., O. J. Porter & Co., Sacramento, Calif.

in seemingly uniform deposits of sand. His comments on controlled versus uncontrolled seepage are important. A boil serves the same purpose as a relief well; but it is uncontrolled and dangerous.

Fully penetrating wells, as shown by Messrs. Wall and Stone, are definitely preferred. Wall spacing no greater than the distance to the source, as they propose, appears reasonable and installation of wells greater than the theoretical is certainly desirable.

The adoption of grouted outer seals, as proposed by Mr. Charles, is definitely preferred to the use of bentonite wherever either is needed. His suggestion of dual-purpose wells is a definite possibility in some locations, such as wells for industrial and irrigation purposes.

Electrical analogy models will certainly be helpful in analyzing dam problems as described by Horace A. Johnson. Fig. 13 clearly indicates the advantage of full penetration over partial penetration.

Professor Rutledge has made an excellent presentation of the variables and the effect of these variables on the design. He further emphasizes the importance of being certain that the well has adequate diameter to reduce friction losses to a minimum. H. H. Roberts and Carter V. Johnson have offered further data on the Fort Peck installation. Their suggestion to install a minimum number of wells initially is sound, and further emphasizes the flexibility of the well system provided the wells installed are large enough and deep enough. The failures mentioned involved the deterioration of the slotted black metal pipe used as an emergency installation during World War II. Recently, permanent installations were completed at Sardis and Fort Peck dams, using a slotted wood pipe.

Mr. Fahlquist has requested data on fabrication and installation of wells. Although experience with water well installations has been most helpful in selecting the general type of design, there is still much to be done in the selection of a well screen that can be depended upon for long life. Experience with relief wells has shown it to be a most serious problem. Usually the water carried by the pervious strata where pressure relief is required is much more highly charged with active salt than water-supply wells in the same area. At Sardis Dam metal well screens, which were giving excellent service in water-supply wells, failed within two years when operated as relief wells. The seepage water was highly acid, whereas in the water-supply wells it was neutral. At Fort Peck the ground water in the pervious strata was highly alkaline and was found unsatisfactory for water-supply purposes before the dam was built. The slotted black pipe used in the temporary installation during World War II started failing because of complete deterioration of the metal in about two years. At both of these dams slotted wood pipes have been used in the recent "permanent" installations. The writers recommend that only noncorrosive materials, such as wood, chemical resistant vitrified clay, stainless steel, monel metal, and other highly resistant metals should be used. Jetting to create continuous drainage is a definite possibility and should be further investigated. In this case the most difficult problem is to obtain a trench wide enough to discharge the required quantity of seepage.

Mr. Cedergren has properly emphasized the importance of exercising considerable care in constructing, and observing the functioning of, relief wells. In connection with the latter, the United States Corps of Engineers has a special research project on relief well design which includes detailed observations of all major relief well installations. A current meter has been designed for measuring the velocity in relief wells by lowering it into the casing. In this manner the total discharge of the well can be quickly obtained; and, in addition, by reading the velocity at different elevations, the quantity of seepage from the various strata can be determined.

Professor McNown has revealed one of the most troublesome factors in the presentation of mathematical solutions—that is, the lack of uniform symbols. The writers regret that the symbols used were not familiar to Professor McNown. Mr. Barron has presented an excellent discussion in which he has obtained a mathematical solution where a blanket of finite length is present. He has modified this solution for seepage through the blanket, which is an important factor in some cases.

Mr. Bennett's discussion should be especially helpful to engineers engaged in the design of relief well systems. He indicates the value of piezometer readings wherever they are available. Field pumping tests, of course, are highly desirable in the case mentioned, and in other cases where the area is highly developed and a large discharge is expected. However, pumping tests are expensive and must be conducted with experienced personnel and extreme care, or the results will be misleading. Where the quantity of seepage is not a major factor, it is usually cheaper to install additional wells than to conduct pumping tests. Modification of the formulas as presented by Mr. Bennett is certainly desirable where there is a definite gradient of flow away from the wells; but this is not often an important factor. As stated, jetting to form an outlet, as proposed by Mr. Fahlquist, may form a block for the more pervious strata and make seepage conditions in levee sections worse.

Mr. Mansur has stressed the importance of the type of well screen used in an installation. He places brass and cast iron in the preferred class. In some cases the use of these two materials may be highly questionable. His minimum diameter of 2.5 in. is considered entirely too small. It is the writers' opinion that this minimum should be 6 in. Quite correctly, Mr. Mansur emphasizes the danger of using dissimilar metals because of the rapid corrosion caused by electrolysis. Surging of relief wells is an essential part of well installation even though the well is gravel packed. Mr. Mansur has shown that wells behind levees will not increase the quantity of seepage by an exorbitant amount. The 27% increase given is reasonable where the pressure head at the land-side toe is reduced to 1.0 ft. Generally this great reduction of pressure is not necessary. Experience with large boils along the Mississippi River levees shows conclusively that a moderate increase in the normal seepage flow will prevent the occurrence of dangerous boils. During high water stages, the writers have seen numerous cases in which one or two large boils were giving adequate pressure release to an extensive area. However, when these boils were sacked (a ring levee built around them) to prevent movement of fines, other dangerous boils

occurred in the vicinity. In these cases one or two large relief wells (which, in effect, are controlled boils) would give permanent relief to such dangerous areas.

Reduction of well discharge rates after installation is a most important factor as shown by S. J. Johnson. The wells referred to by Mr. Johnson were too small and high velocities were a contributing factor in the reduction of flow. This reduction has not been evident on large adequately designed wells. However, clogging is another factor in favor of large-diameter wells and provisions for surging as a maintenance operation. The clogging of water-supply wells is more common because of the high drawdown heads which result in high entrance velocities.

Mr. Lane has added further to the mass of recorded experience in giving a specific example in which the seepage at the toe of a levee has proved dangerous. His discussion of the problem of determining where wells are needed should be most helpful.

Since mathematical design formulas for relief well systems are based on idealized asumptions as to the uniformity of the pervious stratum and blanket and the determination of permeability (which, at best, is only a good approximation), the results from the formulas should not be considered as an exact design but rather as an approximation to aid the judgment of the designer. With this thought in mind, it is the writers' opinion, that reasonably accurate results, quickly computed, are more desirable than mathematically exact solutions, achieved through repeated trials. Also, the writers wish to emphasize that, in general, wells of large effective radius are necessary to provide sufficient entrance face area and to keep well-screen and riser losses at a minimum.

The writers wish to express their appreciation for the most valuable discussions and to express their regrets that they did not have time to compare the various modifications of design with the procedure proposed in the paper, and with the actual installations.

AMERICAN SOCIETY OF CIVIL ENGINEERS
Founded November 5, 1852

Paper No. 2328

THE ENGINEER IN BUILDING FOR PEACE

ANNUAL PRESIDENTIAL ADDRESS

By E. M. Hastings,[1] President, ASCE

Past-President J. C. Stevens,[2] in his Annual Address in 1945, expressed the view that "The engineer will play a most important rôle in the revitalization of the world for peacetime pursuits." How many of the members of our Society today remember that most important statement? I am going to take it up and press forward with it now, two years after it was spoken, in an endeavor to direct attention to the tasks which to my mind are the most important that have ever been given to any people.

The day is here when the creative mind of the engineer must be used for the revitalization of the world if we are to work our way out of the confusion that is almost universal. All too long has the engineering mind been content to channel itself in narrow and, in many respects, selfish ways. There has been much broadening in our public expressions and efforts, reflected to a degree in the activities of the Society in recent years and given impetus in the actions taken by the Society today. We are concerning ourselves about many things outside the purely technical field and gaining for ourselves a large and respectful following in the areas where our profession should make us the leaders.

The mind of the engineer is trained to weigh carefully the important and fundamental elements that inherently are found at the beginning of any great engineering project. Should not that mind be used in leadership to formulate policies for the guidance of men in the pursuit of enduring peace?

Is it necessary that we wait for power politics, so-called diplomacy, or the might of certain nations to declare themselves for this or that solution before we go to work toward the building of the new and better world for which we so recently fought and for which we made so many sacrifices?

Our profession has contributed so many magnificent accomplishments conceived, designed, and constructed for the comfort and welfare of mankind. That same profession also has been used for so many devices that have been concocted to destroy and finally to wipe from the very earth large areas and unnumbered people. Now that we can see the magnitude of the destruction

[1] Chf. Engr., Richmond, R. F. & P. R. R., Richmond, Va.
[2] "Private Enterprise," by J. C. Stevens, *Transactions*, ASCE, Vol. 110, 1945, p. 1605.

wrought by World War II, should we not face the future with a determination that such things shall not happen again?

Although we have destroyed great cities and have in our hands the knowledge and means to destroy greater areas and wipe out nations, please bear in mind that we have one thing that cannot be destroyed, and that is a national ideal. Ideals are indestructible, they will rise out of the debris and ashes of a war-torn world and point the minds and energy of men toward nobler and higher purposes than ever have been known before. That is what we in this nation possess—the ideals of liberty and freedom. They form the rock upon which our nation is founded and have been the banner that has guided us through the trials and dark days of the past; they have been the torch that has lighted the way to victory and today they constitute a searchlight pointing the way to the revitalization of the world.

We engineers here in the United States of America cannot be content to wait for political diplomats to solve the problems; we must put our talents to work and enter wholeheartedly into the tasks of democracy that are now before us.

What is democracy? An American schoolgirl was asked this question. Her answer was: "It is what we have and are." Can you find a better definition than this? Look at what we have and are. I believe that our success as a nation stems from that which, through the years, we have set up in the United States. I am a believer in private enterprise and can find no hope for the world in the philosophy of a Karl Marx. I am a believer in universal military training. We should make our position so strong, so just, and so tempered with realistic generosity that we would gain the respect of the world. Such respect cannot be purchased from foreign nations with dollars.

Let the engineering profession then enter the affairs of the state, the nation, and the world as a profession that creates and revitalizes the factors for a world of peace. With all our resources, our marvelous skill for the production of material things, our creative genius for new and better achievments, our great might, and our power to command respect, it cannot be that we will be willing to let this year of opportunity pass with little or nothing accomplished to that end.

We of the engineering profession need to have for ourselves the inward resources that our young and virile America had when it fought for and won its independence and which our leaders have had in their ensuing struggles to maintain it. If we ever hope to persuade other nations to our way of life we must first recapture for ourselves the zeal, the courage, the eloquence, and the inner spirit of the great men of our history who made it possible. Never for a moment dare we relax our vigilance. Always both from without and within the United States, there are forces at work to destroy it. David Hume said, "It is seldom that liberty of any kind is lost all at once." Our minds must not weakly capitulate to the cynicism which exalts national selfishness, and we must cling hopefully and faithfully to the ideals of our past, so that we shall not lose that precious liberty bit by bit.

I have dealt up to this point with engineers in building for peace—generally and idealistically. In addition, the American Society of Civil Engineers and its membership, as a part of the engineering profession and as the oldest of the

Founder Societies should lead in bringing forcefully before the people of the Unites States and the people of the world the knowledge that engineers must play a most important rôle in the revitalization of the world for peacetime pursuits and economy. Let us no longer hold ourselves within the narrow confines of a purely technical life and of purely technical thinking. Let our members provide the leadership and the financial backing within our Society so that its professional activities will be effective. Let us strike out vigorously into the tasks that are here for us to do in a manner that shall win for us the admiration and the respect of diplomats and of statesmen, as well as of the general public. We can do it. Just because we have not done it before to any great extent is no reason why we should not now resolve to take our rightful place in the thinking and in the building of a new era of peace. As long as we adhere to American ideals, remember that we stand upon the firmest foundation of any nation in the world. We can try, and we can succeed.

MEMOIRS OF DECEASED MEMBERS

GEORGE HERRICK DUGGAN, Hon. M. ASCE[1]

DIED OCTOBER 8, 1946

Although national professional societies in America are young as compared with the European branches of engineering associations, the men who promoted the dissemination of scientific knowledge among early members are, in the nature of things, rapidly passing away. The death of George Herrick Duggan, under the tragic circumstances of an unforeseen motor accident at the age of eighty-four years, is a contingency of this nature which deprived the Society of one of its most valued Honorary Members.

George Herrick Duggan was born in Toronto, Ont., Canada, on September 6, 1862. He spent his early boyhood in Europe on the French Riviera, where his father died and was buried, but returned to Toronto as soon as he was old enough to attend Upper Canada College. From Upper Canada College, Mr. Duggan matriculated at the School of Practical Science, University of Toronto, now the Faculty of Applied Science and Engineering, University of Toronto, from which he was graduated in 1883 at the head of his class in ten subjects out of eleven. The eleventh subject was an essay. That summer he had a job and was able to spend only three days on the essay; yet he received 97%, whereas another chap who had spent the entire six months on the essay received 100%. At Toronto University he specialized in engineering under Prof. John Galbraith. By April, 1884, he had completed the postgraduate course and was awarded the degree of Civil Engineer.

Mr. Duggan's first professional undertaking, in the summer of 1884, was in the Rocky Mountain Division of the Canadian Pacific Railway Company engaged on construction work. For six months he was on the staff of the late Walter A. Doane,[2] M. ASCE, at the summit of the Rockies, designing wooden bridges, tunnels, etc. The year 1885 found Mr. Duggan on railroad location and construction on the west slope of the Selkirks, at the time that the late James Ross, M. ASCE, was the manager for that section of the Canadian Pacific Railway Company.

In 1886 he joined the engineering department of the Dominion Bridge Company which was under the direction of the late Job Abbott,[3] M. ASCE, and in 1891 was appointed chief engineer of that company. He held this position for ten consecutive years and was responsible for the design and construction of most of the important bridges built in Canada during that period—a period which so rapidly developed the science of steel construction. Among others built at that time under his supervision was the interprovincial

[1] Memoir prepared by Frederick P. Shearwood, M. ASCE.
[2] For memoir, see *Transactions*, ASCE, Vol. 105, 1940, p. 1830.
[3] For memoir, *ibid.*, Vol. XXXVI, December, 1896, p. 538.

bridge at Ottawa. In 1901 he was called upon to go to Sydney, Nova Scotia, as assistant to the president of the Dominion Iron and Steel Company and of the Dominion Coal Company and in 1904 was appointed general manager of the latter.

Mr. Duggan returned to the Dominion Bridge Company in 1910 as chief engineer when that company was contemplating the preparation of a competitive design of the Quebec Bridge. With this project in view, the St. Lawrence Bridge Company was formed by a combination of engineers from the Dominion Bridge Company and from the Canadian Bridge Company, with G. H. Duggan as chief engineer. The Quebec Bridge was finally designed and built under Mr. Duggan's supervision.

In 1912 he was appointed general manager of the Dominion Bridge Company, becoming vice-president in 1917, and president in the following year. He relinquished the presidency in 1936 but remained with the company as chairman of the board of directors, which office he held until his death. During the period of his association and largely through his influence, this organization grew from a small fabricating shop into a country-wide, important industry, manufacturing a diversity of steel structures, in the production of which thousands of men are employed and hundreds of engineers are engaged and selected for important executive positions.

Mr. Duggan was also president of the Dominion Engineering Company and of several other organizations allied with the Dominion Bridge Company. The long list of his directorships at the time of his death included the Shawinigan Water and Power Company, the Steel Company of Canada, the Montreal Trust Company, and the Wabasso Cotton Company. He was a former vice-president of the Royal Bank of Canada. In each and all these positions his engineering ability was frequently sought and depended on as of great assistance to his confrères in all their undertakings. He also accomplished much in the service of many professional societies—for example, he served his own Engineering Institute of Canada (which he joined in 1888) as councillor, vice-president, and president (1916); and he was made an honorary life member in 1937 when he presented the Institute with a medal and a prize to be awarded annually which now bears his name. In 1931 the Sir John Kennedy Medal was awarded him by the Institute for great services to his profession.

In 1936 this society conferred upon him an Honorary Membership. He was already a member of the Institute of Civil Engineers of Great Britain, a vice-president of the Canadian Institute of Mining and Metallurgy, and an honorary life member of the Canadian Engineering Standards Association.

The Canadian universities also honored Mr. Duggan: McGill University of Montreal, Quebec, and Queens University of Kingston, Ontario, awarded him the degree of Doctor of Laws; and Toronto University conferred on him the degree of Doctor of Science *Honoris Causa.*

Although the profession of engineering was his chief interest and occupation, Dr. Duggan's devotion to his favorite hobby and sport was remarkable

enough to gain fame for him on two continents. He sailed and designed sailing yachts with exceptional success in many international races, notably those held for the challenge and defense of the Seawanhaka International Cup, which he brought to Canada in 1895. For six years, in spite of the fact that the very best that the professional designers of the United States could produce was lined up against him, his designs and his racing were always successful.

One might think that such a richly endowed mind might portray an austere character, aloof from his associates in his profession and sport, but such was not the case. Many members of the Society will remember him as a genial host, modest and quiet in manner, although his eyes often twinkled while he enjoyed the humor of his fellow engineers. His hospitality in his own home was proverbial among hosts of friends.

On October 13, 1888, he was married to Mildred Stevenson in Montreal. Dr. Duggan is survived by a daughter, Margaret, wife of Senator, the Honorable Adrian Knatchbull-Hugessen, his two sons, both graduates in engineering at McGill University, having given their lives for their country in World War I. He also left three grandsons, Edward Herrick, Andrew, and James; and a granddaughter, Mary Hugessen.

Dr. Duggan was elected a Member on October 2, 1895, and an Honorary Member on October 11, 1936.

ROBERT HOFFMANN, Hon. M. ASCE[1]

DIED MARCH 2, 1946

Robert Hoffmann, the son of Robert and Marie (Treiber) Hoffmann, was born in Cleveland, Ohio, on December 16, 1865.

Mr. Hoffmann received his elementary education in Brownell and Central high schools in Cleveland, and was graduated from Hiram College, at Hiram, Ohio, in 1885, with the degree of Bachelor of Science. Later he entered the Case School of Applied Science at Cleveland, from which he received the degrees of Bachelor of Science in Civil Engineering, in 1893, and of Civil Engineer, in 1896. During his undergraduate days at Case, he was elected to Tau Beta Pi and Sigma Xi. In addition to these academic honors, and in recognition of his "invaluable service to the community," Case School of Applied Science, in 1930, also conferred upon him the honorary degree of Doctor of Engineering.

Immediately following graduation from Case, in 1893, Mr. Hoffmann was employed by the City of Cleveland as a rodman in the paving department, and continued in the service of the city until his death. His advancement in the engineering department was rapid, and, in 1904, he was appointed assistant

[1] Memoir prepared by the following committee: Joseph W. Ellms, Wendell P. Brown, and William L. Havens, Members, ASCE.

chief engineer. Three years later, he became chief engineer and held this position until 1930 although his title was changed to commissioner and chief engineer of the Division of Engineering and Construction. In 1930, in an effort to relieve him of much of the detail work in his department, Mr. Hoffmann was appointed consulting engineer on public works. In 1930, he was also appointed a member of a Special Engineering Commission which reported upon "The Future Development of the Cleveland Water Supply System." In 1939 and 1940, as a member of an advisory board of engineers, he assisted in the preparation of reports on "Sewage Rates" and "Proper Water Rates for Cleveland and Its Suburbs."

For more than half a century, Mr. Hoffmann rendered distinguished public service to the City of Cleveland. Over a span of years matched by few men, and because of character, integrity, and devotion, he held his position, independent of politics, throughout successive administrations. Largely because of his foresight and skill in planning and constructing new streets, pavements, sewers and sewage treatment works, bridges, grade-crossing eliminations, and river and harbor improvements—with expenditures estimated at more than $117,000,000—the city was able to make proper provisions for its rapid development. Illustrative of the esteem in which he was held, and of the public confidence in his honesty, is the fact that, during the construction of the Division Avenue Filtration Plant—which had been designed by another city department—following a dispute between the contractor and the city, he was chosen, by both parties, to arbitrate the issue. The contractor "was willing to let his interest rest on the intelligence and fairness of Mr. Hoffmann."

Behind professional attainment was the man himself. At City Hall, he was distinguished for his modesty, patience, and forbearance. Among those of his own organization he was known affectionately as "The Chief" and his capacity for detail was regarded as amazing. He was a quiet man, intensely interested in his work, and those who knew him well realized that he had a keen sense of humor. Upon one occasion when City Council, in a fit of patriotic fervor, had acted to change the name of Hoffmann Avenue, because of its Teutonic origin, Mr. Hoffmann wrote: "No engineering objections," in approving the legislation and returning it to the Council.

Some twenty years ago, in a press interview, Mr. Hoffmann summarized his own ideas of public service, as applied to younger men, as follows:

> "Like every other occupation, it holds an appeal for certain natures. The youngster is impetuous, impatient. He chafes under delay. Action and rapid advancement is craved. That's why so few young men have a desire for public jobs.
>
> "Patience is the prime requirement for the man who would work for the public. Endless red tape hampers his action. He must wait and wait, seemingly eternally. That red tape has its purpose. A man in private life is careful of his own interests. Serving the public he is inclined to be careless. His mistakes cost him nothing personally. That's why he is bound up with red tape.
>
> "Public jobs offer wonderful opportunity for men of vision, imagination, and energy. It is within their power to perform services for the community far beyond the reach of the average citizen.

"It is from the performance of such services that their satisfaction must come. Pay, as a rule, is not great. Advancement is not rapid. But for a man with an aptitude for such work, social in its nature as it is, the chances for a contented career are unexcelled. Public service provides a good living and it opens the door to information that will widen the outlook upon the world's life.

A former city councilman once identified Mr. Hoffmann to an inquiring press reporter in a single sentence, stating "That is Bob Hoffmann, the city engineer, and a man who comes as close to being entirely honest as you'll ever find any man ever being."

Modest and taciturn, he carried his honors lightly. In 1926 the Cleveland Chamber of Commerce awarded him its distinguished service medal in recognition of his contributions to the growth of Cleveland. The citation on this award read:

"Undisturbed and uninfluenced by partisan considerations or changes of administration, he has steadily pursued a high policy of intelligent, loyal, and effective public service, and has both won the confidence of the people and contributed to the physical reconstruction of Cleveland to make the city more adequate for, and more responsive to, its increasing responsibilities and opportunities."

In 1945, the City Council passed a resolution extending to him the heartiest congratulations of the City of Cleveland, upon the occasion of his eightieth birthday. Perhaps the best tangible evidence of the esteem in which he was held is contained in the following resolution of the City Council, adopted March 4, 1946:

"Whereas, the death of Robert Hoffmann has closed a career of public service to the city of Cleveland commencing in 1893 and paralleling the period of the growth and development of the city from a small struggling community to its present metropolitan status; and

"Whereas, the contribution of Robert Hoffmann to the welfare of this city is inestimable and much of its development is the result of his foresight and skill in planning and constructing the improvements which have so long been taken for granted; and

"Whereas, the engineering profession, the community and civic organizations and this council have bestowed honors upon Robert Hoffmann during his long and distinguished public career, and in so doing they have honored themselves and the city of Cleveland; and

"Whereas, the unimpeachable integrity, the unquestioned ability and tireless energy of Robert Hoffmann commanded the respect of all with whom he came in contact, and his innate modesty, his infinite patience, his unfailing kindliness, and his courteous and considerate manner, won and kept for him a host of friends and endeared him to his associates; now, therefore,

"Be it resolved that this council pauses to pay this final tribute of respect to the memory of Robert Hoffmann, to acknowledge the debt in which his life and services have left this, his native city, to bear testimony to his worth as a citizen and as an individual, and to take just pride in the splendid example of his distinguished public service; to mourn his death and to extend to his bereaved widow the sincere sympathy and condolences of the city of Cleveland; and the clerk of council be and he hereby is requested to transmit a certfied copy of this resolution to Mrs. Robert Hoffmann."

On his vacations Mr. Hoffmann liked to study the engineering achievements of other cities. He found recreation in the Professional Men's Club, a variegated lecture and discussion group of Cleveland. Symphony music was also a delight to him.

He was a member of the Board of Trustees of Hiram College; the Corporation of the Case School of Applied Science; numerous technical organizations—including the American Public Works Association; American City Planning Institute; International Association of Navigation Congresses; Cleveland Engineering Society (past-president and honorary member); and national, state, and county societies of professional engineers. He served as a Director of the American Society of Civil Engineers from 1932 to 1934. He was also a member of the Cleveland Chamber of Commerce, the City Club of Cleveland, and the Cleveland Athletic Club.

Robert Hoffmann was a distinguished engineer, a faithful public servant, and, withal, a gentleman whom everyone was proud to call a friend.

On September 3, 1903, Robert Hoffmann was married to Martha W. Muerman in Cleveland. He is survived by his widow.

Mr. Hoffmann was elected an Associate Member of the American Society of Civil Engineers on June 5, 1901; a Member on September 6, 1904; and an Honorary Member on October 11, 1936.

WILLIAM ANDREW ALLEN, M. ASCE[1]

Died June 27, 1946

William Andrew Allen was born in New York, N. Y., on March 1, 1868, of Irish parentage.

He received his early education in the public schools of New York, from which he was graduated in 1883, and later attended the College of the City of New York. From 1888 to 1891, he attended the Mechanics Institute of the General Society of Mechanics and Tradesmen in New York, receiving a certificate of merit for three years' attendance. In the years from 1891 to 1895, he attended Cooper Union Institute, also in New York, from which he received the degree of Bachelor of Science in 1899 and the degree of Civil Engineer in 1900. From 1888 to 1893, while still a student, he was employed by H. M. Smith and Sons, architects and builders, in New York.

For a period of thirty-six years, from 1896 to 1931, Mr. Allen was employed by the American Smelting and Refining Company and the Guggenheim interests, where he had full charge of construction engineering for steel, brick, and concrete buildings; railroads; railroad trestles; steam and electric power plants; and white lead plants and shot towers. His work also consisted in digging oil wells; coal mining; sinking shafts; building tunnels through rock;

[1] Memoir prepared by Sidney H. Carpenter, Secy., General Society of Mechanics and Tradesmen, New York, N. Y.

and erecting entire town sites of one hundred and fifty houses—complete with stores, churches, and schools and serviced for sewerage, water, and electricity. These operations took place in California; Bayonne, N. J.; Garfield, Utah; Ely, Nev.; Eccles, W. Va.; East Hillside, Mont.; Omaha, Nebr.; Federal, Ill.; El Paso, Tex.; Pueblo and Leadville in Colorado; and Baltimore, Md.

From the fifth to the eleventh of October, 1918, during the explosion of the munitions plant at Morgan, N. J., Mr. Allen was in command of 1,200 men of various military organizations, for six consecutive days and nights, with headquarters at the city hall in Perth Amboy, N. J.

Mr. Allen was initiated as a member of the General Society of Mechanics and Tradesmen of the City of New York on December 19, 1923. He was a veteran of the Seventh Regiment, New York National Guard, and a member of the Cooper Union Alumni Association; the Washington Lodge No. 35 of the F. and A. M. in Elizabeth, N. J.; the New Jersey Consistory, thirty-second degree, of Jersey City, N. J.; and the Islam Temple of the Ancient Arabic Order of Nobles of the Mystic Shrine in San Francisco, Calif. In Perth Amboy he belonged to the Raritan Yacht Club, the International Rotary Club, and the Simpson Methodist Episcopal Church.

Mr. Allen was a man of fine purpose, and his word was his bond. To him, a promise meant that it must be fulfilled. He inherited honesty, integrity, and loyalty. He had many friends, because they found him to be ever faithful.

On August 29, 1931, in Annapolis, Md., he was married to Alva Adelaide Brandt. He is survived by his widow and a son, William McKinley Allen.

Mr. Allen was elected an Associate Member of the American Society of Civil Engineers on February 6, 1901, and a Member on September 6, 1904. He became a Life Member in January, 1936.

URIE NELSON ARTHUR, M. ASCE[1]

DIED SEPTEMBER 13, 1945

Urie Nelson Arthur, the son of John V. and Elizabeth (Clark) Arthur, was born on April 24, 1870, in Erie, Pa.

He obtained his education in the public schools of Erie; Erie Academy; Edinboro State Normal School, at Edinboro, Pa.; and Allegheny College, at Meadville, Pa. He received the degree of Bachelor of Science in Civil Engineering from Allegheny College in 1894. He was a member of the Phi Kappa Psi fraternity.

Mr. Arthur's first professional endeavors were in the railroad field. Beginning as rodman, he was employed by the Pennsylvania Railroad at Erie and at Renovo, Pa., from 1895 to 1898. For the next three years he served as assistant engineer for the Pittsburgh and Lake Erie Railroad at McKeesport, Pa. When plans were being prepared for routing the Wabash Railroad

[1] Memoir prepared by Louis P. Blum and Ray S. Quick, Members, ASCE.

through Pittsburgh, Pa., Mr. Arthur served as assistant engineer under the late George T. Barnsley, M. ASCE,[2] from 1901 to 1904, in charge of much of the construction between Pittsburgh and Jewett, Ohio. His next professional work was with the Western Maryland Railroad Company, as division engineer in charge of two hundred miles of surveying and location in western Pennsylvania and West Virginia.

His long service with the City of Pittsburgh began in 1907, when he became assistant engineer in the Bureau of Surveys; he was promoted to principal assistant engineer in 1910, becoming chief engineer in 1916. During this period, he planned and supervised the collection of an extensive history of every street in Pittsburgh and the annexed territory. This work, involving abundant research in old municipal records, has proved of great value and has been consulted extensively by municipal engineers, title insurance examiners, and others interested in early land titles. During Mr. Arthur's term as chief of the Bureau of Surveys, he supervised the establishment of a system of precise bench marks and survey monuments in a large area of the city.

When the Pittsburgh City Planning Commission was formed with the late Morris Knowles,[3] M. ASCE, as chairman, Mr. Arthur became the first chief engineer. The first project of this commission, done under the supervision and direction of Mr. Arthur, was the preparation of zoning ordinances and maps of the entire city area. Although the original ordinance has been amended from time to time and changes of zone boundaries have been revised to fit changing developments, Mr. Arthur's work still forms the fundamental basis of Pittsburgh zoning.

During this time, he was associated with R. H. Randall, M. ASCE, in the topographical survey of Pittsburgh. After Mr. Randall's retirement, the survey was directed by Mr. Arthur—to the extent allowed by councilmanic appropriation. This phase of his work is preserved in a joint publication by Messrs. Randall and Arthur, "The Geodetic and Topographic Survey of Pittsburgh and Allegheny County."[4] After his retirement from the city service in 1936, Mr. Arthur was associated in general engineering and surveying practice with the McCully Engineering Company of Pittsburgh.

He was the ideal public servant: Hard working, painstaking, and clear thinking; inspiring his associates to greater earnestness and zeal; and with little use for the diplomatic expression of opinion. Having made up his mind, as the result of study of an engineering proposition, he asserted his opinions directly and unequivocally, not hesitating to differ with his colleagues and superiors.

On April 26, 1914, Mr. Arthur joined the Smithfield Street Methodist Episcopal Church, under the ministry of Dr. J. T. Pender, by certificate of transfer. He was an active member of the Board of Stewards (later the Board of Trustees) and of the Board of Directors of the Church Union of the Methodist Church, then affiliated with the Smithfield Street Church. When the

[3] For memoir, *ibid.*, Vol. 98, 1933, p. 1567.

[4] "The Geodetic and Topographic Survey of Pittsburgh and Allegheny County," Pittsburgh, Pa., December, 1925.

church was being remodeled during the pastorate of Dr. Daniel L. Marsh, Mr. Arthur was quite interested in the architectural changes and improvement. During his later years he was not quite so active, but he will always be remembered by his church as a Christian gentleman of distinctive and unusual qualities.

Mr. Arthur was married on September 12, 1907, to May E. Ryan of Renovo. He is survived by his widow and son, Robert L.

Mr. Arthur was elected a Member of the American Society of Civil Engineers on October 1, 1928.

CHARLES DWIGHT AVERY, M. ASCE[1]

DIED FEBRUARY 1, 1947

Charles Dwight Avery was born at Galesville, Wis., on July 29, 1877. His parents were Henry N. and Catherine S. (Fowler) Avery.

At an early age he moved with his parents to Minneapolis, Minn., where he received most of his schooling including three years at the University of Minnesota. He then entered the Michigan College of Mines and Technology in Houghton, and was graduated with the degree of Engineer of Mines in 1903. At college he belonged to the Beta Theta Pi fraternity.

From 1903 to 1908 he was engaged in coal and metal mining, principally in Utah, and superintended some construction work in Oregon. In 1908 he was appointed a mineral and Carey Act inspector by the United States General Land Office of the Department of the Interior, with headquarters at Salt Lake City, Utah, and later at Cheyenne, Wyo. He remained with the General Land Office (later the Bureau of Land Management) from 1908 to 1920, doing field work in the states of Utah, Montana, Wyoming, and Colorado. In 1920 Mr. Avery transferred to the United States Geological Survey as a mining engineer, and later was appointed a senior geologist, remaining with the Geological Survey until his death.

While employed by the General Land Office, he examined and reported on the Carey Act irrigation projects, as to the adequacy of the water supply, the facilities for irrigating the land, and the estimated cost. He also reported on the feasibility of proposed projects from an engineering and financial viewpoint.

Mr. Avery's transfer from the General Land Office to the U. S. Geological Survey in February, 1920, antedated by about two weeks the approval, by the late Woodrow Wilson, then President of the United States, of the general leasing law for nonmetalliferous minerals in lands owned by the federal government. To the adoption of sound policies and expeditious procedures in the administration, particularly of the oil and gas provisions of this important legislation, the remaining twenty-seven years of Mr. Avery's public

---

[1] Memoir prepared by Benjamin E. Jones, M. ASCE.

service were devoted. His personal knowledge of men and conditions throughout the states west of the 100th meridian was an invaluable asset to the Geological Survey in the discharge of its responsibilities under the mineral leasing law, and a never failing source of aid and inspiration to his associates. His remarkable record during these twenty-seven years included basic determinations made and reported to administrative agencies on the structural situation and the relation to other holdings of the same applicant, of the lands described in more than 57,000 applications for oil and gas prospecting permits on public lands, and of the more than 35,000 applications for oil and gas leases on such lands. He made determinations of the bona fide potential value for oil and gas of more than 34,500 land parcels affected by conflicting applications for homestead and mineral prospecting rights. All this was accomplished with less than one hundred appeals from his findings in the entire period. This achievement is in itself an eloquent tribute both to his judgment and to his capacity for constructive work and it contributed to the highly successful venture of the government in the field of oil and gas leasing.

It is only a part, however, of his contribution, which also included most of the spadework involved in defining the "known geologic structure" of producing oil and gas fields containing federal lands, as an administrative basis for distinguishing between land parcels to be leased for oil and gas by competitive bidding, and others that might be leased to the first applicant therefor. The record of 250 outstanding definitions of such structures on January 31, 1947, aggregating more that 4,326,000 acres in nine public land states, is mostly of his making, and constitutes a lasting monument to the utility of his unpublished but invaluable public service.

In the field of conservation he was an ardent advocate, from its inception, of the policy of unit operation for oil and gas fields containing government lands.

He participated actively in the conferences and discussions leading to the amendment of the oil and gas provisions of the federal leasing law in 1930, 1931, and 1935, to authorize and encourage unit or cooperative development of such fields or pools. His only literary contribution in the period of his Geological Survey employ, aside from the thousands to his credit in the files of the Interior Department and its agencies, was as senior author of a paper on this subject, presented at the Dallas (Tex.) meeting of the American Association of Petroleum Geologists on March 23, 1934.[2]

Although Mr. Avery was primarily a mining engineer, his early work involved civil engineering, and it was then he became interested in the Society. He was President of the District of Columbia Section in 1927 and 1928. Throughout his twenty-seven-year residence in Washington, D. C., he was one of the most active members of the Section, and at his death was chairman of a committee engaged in revising the constitution, for which he was largely responsible.

In addition, he belonged to the American Association of Petroleum Geologists and to the Geological Society of Washington, D. C. He was a

[2] "Relationship of Geology to Unit Operation of Oil and Gas Fields, Involving Government Lands," by Charles D. Avery and John C. Miller, *Bulletin*, Am. Assn. of Petroleum Geologists, November, 1934, p. 1454.

member of the F. and A. M., the Scottish Rite in Cheyenne, and the Korein Temple Shrine in Rawlins, Wyo.

On December 6, 1917, he was married to Myra K. Graham of Greeley, Colo., at Storm Lake, Iowa. He is survived by his widow; a daughter, Nancy (Mrs. Charles A. Kuhl); and two grandchildren, Nancy Louise and Barbara Jean Kuhl, of California, Pa.

Mr Avery was elected an Associate Member of the American Society of Civil Engineers on January 2, 1912, and a Member on January 16, 1917. He became a Life Member in January, 1947.

HOMER GAGE BALCOM, M. ASCE[1]

Died July 3, 1938

Homer Gage Balcom, the son and only child of Mahlon Balcom and Frances (Gage) Balcom, was born in Chili, N. Y., on February 16, 1870.

He received his primary education in the grade school at Morton, N. Y., and was graduated from the Brockport (N.Y.) State Normal School. After teaching for two years in Stone Church, Kendall, N. Y., he entered the College of Civil Engineering at Cornell University in Ithaca, N. Y., from which he was graduated with the degree of Civil Engineer in 1897. He was elected to the honorary society of the Sigma Xi.

After being graduated from Cornell, Mr. Balcom entered the employ of the Berlin Iron Bridge Company in Berlin, Conn., as a draftsman. In 1900 when the American Bridge Company was formed, inclusive of the Berlin Iron Bridge Company, he was appointed to one of the designing engineer positions of this new company and, in January, 1902, was put in charge of design for the New York (N.Y.) and Pittsburgh (Pa.) districts.

In 1905 he became structural engineer of Reed and Stem, architects for the Grand Central Railroad Terminal in New York, in charge of steel design for the station and the many terminal buildings. On these projects he mastered the difficult structural and foundation problems and also insulated the building framework against the transmission of vibration from the track and street by independent foundations, vibration absorbing mats in footings, and vertical separation between building and traffic carrying framework.

In 1908 he formed a partnership with Wilton J. Darrow, M. ASCE, and opened an office of consulting engineers in New York. This partnership continued until 1916 when Mr. Darrow retired from the firm. Mr. Balcom continued the office under his own name until a few years before his death, when he was joined by his fellow workers in the firm of H. G. Balcom and Associates.

His practice grew rapidly from the start, and before many years he was recognized as the leading structural engineer, for buildings, in the metropoli-

---

[1] Memoir prepared by George E. J. Pistor, M. ASCE.

tan area. A list of the structures for which he designed the steelwork would include buildings in practically all the large cities of the United States and also many in foreign countries.

A few of the more prominent structures are recorded: The Empire State Building, the Chrysler Building, most of the Rockefeller Center buildings, the Waldorf-Astoria Hotel, the Grand Central Terminal buildings, and the Federal Reserve Bank Building, all in New York; the Mellon Art Museum, the Archives Building, and the Department of Commerce Building in Washington, D. C.; the Cathedral of Learning in Pittsburgh; the Library of Louvain University in Louvain, Belgium; the Young Men's Christian Association Building in Jerusalem; and the Devonshire House in London, England. He was responsible for the structural design of buildings costing close to a billion dollars, an outstanding accomplishment.

Mr. Balcom found time and energy to serve the engineering profession on many technical committees, in matters on which he was considered an authority. He was president of the New York Chapter of the New York State Society of Professional Engineers and was earnestly interested in promoting public recognition of the engineering profession.

On January 3, 1912, Mr. Balcom was appointed a member of the Board of Education of Hastings-on-Hudson, N. Y., and served continuously until 1933. From 1921 to 1933, he held the office of president of the board and, as such, exercised a great influence in developing a modern suburban school system for Hastings. His aim was to create a centralized school plant where children from all sections of the village, both industrial and residential, would receive education and training in a democratic way of life.

During World War I he contributed his services as chief structural engineer of the American International Corporation in fabricated ship construction at the Emergency Fleet Corporation Yard at Hog Island, Pa. His knowledge of fabricating shop practices enabled him to design the frames and hull plating of the ten thousand-ton freighters so that the steel could be fabricated both rapidly and economically at scores of fabricating shops throughout the United States with such precision as to permit direct assembly and riveting at the shipyard without fitting and drilling.

Mr. Balcom was always glad and ready to assist his fellow engineer with advice whenever he was approached.

On October 24, 1900, he was married to Gertrude McCrum of East Berlin, Conn. Besides his widow, he is survived by their only child, Gertrude Marie (Mrs. John Moon) and three grandchildren, Barbara Joan Moon, Lois Gage Moon, and John Andrew Moon, Jr.

He belonged to the Cornell Society of Engineers and the American Society for Testing Materials; he was an honorary committeeman of the American Institute of Steel Construction, a director of the New York State Society of Professional Engineers, a past-president of the New York Chapter of that society, and past-master of the Fernbrook Lodge of the F. and A. M.

Mr. Balcom was elected a Member of the American Society of Civil Engineers on April 18, 1916.

WESTERN RADFORD BASCOME, M. ASCE[1]

DIED JUNE 14, 1940

Western Radford Bascome, the son of Western and Ellen (Kearny) Bascome, was born in St. Louis, Mo., on April 15, 1867. He came from a long line of American ancestors that reached back to Colonial times. Outstanding among these were: William Nicoll, member of the Council of New York from 1691 to 1698, speaker of the Colonial Assembly from 1702 to 1718, and Attorney General from 1687 to 1690; Matthias Nicoll, secretary of the Province of New York from 1664 to 1680, member of the King's Council from 1667 to 1680, speaker of the Provincial Assembly in 1683, and Mayor of New York in 1672; Jeremias Van Rensselaer, second patroon member and speaker of the Colonial Assembly in 1664; Stephanus Van Corlandt, Colonel of the Kings County Regiment from 1671 to 1693 and twice Mayor of New York; and Olaff Stevensen Van Cortlandt, Colonel of the Burgher Corps in 1649 and the last Burgomaster of New Amsterdam (1655 to 1664) before the English conquest. He was the grandson of Gen. Stephen Watts Kearny, the centenary of whose entry into Santa Fe, N. Mex., was celebrated in 1946 by the issuance of a commemoratory United States postage stamp.

Western Bascome was graduated from Washington University at St. Louis, with the degree of Bachelor of Engineering, in 1888, and the degree of Civil Engineer in 1889. His professional career began immediately after graduation. From June to November, 1889, he was employed by the Department of Bridges in St. Louis, engaged in drafting, designing, and field work.

From November, 1889, to May, 1893, he was with the St. Louis Merchants' Bridge Terminal Railway Company as assistant engineer during the construction of the elevated steel viaduct (about 8,000 ft long) with terminals and connections. This position included office work, drafting, designing, field work, and inspection.

From May, 1893, to May, 1896, he was employed as assistant engineer with the St. Louis Water-Works Extension (under the late M. L. Holman,[2] M. ASCE) in charge of field work on construction of four settling basins (each 400 ft by 700 ft) with connecting conduits, and gate chambers, at Chain of Rocks, Mo. He also did work on foundations and buildings for a high service pumping station at Baden in St. Louis. From May, 1896, to July, 1897, Mr. Bascome engaged in private business with his father in St. Louis.

On July 8, 1897, he entered the Department of Bridges of the City of New York (which became the Department of Plant and Structures in 1916), as assistant engineer on the construction of the Williamsburg Bridge across the East River, engaged on office work, drafting, computing, designing, and also on field work and inspection. From January, 1902, to June, 1903, he inspected the construction of main cables and suspenders, of that bridge. His next position,

[1] Memoir prepared by Theodore Belzner, Affiliate, ASCE.

[2] For memoir, see *Transactions*, ASCE, Vol. 89, 1926, p. 1630.

from June, 1903, to December, 1904, was assistant engineer, in charge of field work and construction of the Vernon Avenue Bridge, across Newtown Creek, between Brooklyn and Long Island City (center span of 172 ft, two side spans of 80 ft each, and about 1,400 ft of masonry and steel approaches).

For a short period in early 1905, Mr. Bascome again took charge of his father's business in St. Louis. Then, in April, 1905, he became assistant engineer on the Manhattan Bridge across the East River in New York City, designing plans for cables, towers, and superstructure, as well as plans for a subway terminal station for the Williamsburg Bridge. From March, 1906, to March, 1907, he was resident engineer in charge of construction of the Manhattan anchorage of Manhattan Bridge and, until June, 1910, was resident engineer in charge of all Brooklyn construction of this bridge, including anchorages, steel towers, side span, one half of main span, and approach. In the latter position, he was also in entire charge of construction of main cables and suspenders for the whole suspended structure.

Mr. Bascome was then assistant to the late E. A. Byrne,[3] M. ASCE, chief engineer in the Department of Plant and Structures, in charge of all correspondence, reports, and general executive work, until August, 1924, when he was transferred to the Department of Public Markets in New York City, as engineer in charge of construction of the Bronx Terminal Market (under the late J. O. Eckersley,[4] M. ASCE, chief engineer of design and construction). From December, 1926, to February, 1927, Mr. Bascome was again in charge of his father's private business.

He then became engineer in charge of the reinforcement and reconstruction of the Pines (highway) Bridge across Croton Lake, a part of the New York City water supply until March, 1931.

On March 18, 1931, he was transferred from the Department of Plant and Structures to the Department of Parks (New York City); and until May, 1933, he was resident engineer in charge of construction of the West Side Express Highway, along Riverside Park from West Seventy-Second Street to the Harlem River. From this date until June 16, 1935, when he retired from the Department of Parks, he was assistant to the chief engineer of parks in charge of general construction work. After his retirement until his death, he was a consulting engineer.

Mr. Bascome held the esteem and affection of his friends and associates, and the respect of all with whom he came in contact. He was a quiet, unassuming man, diplomatic and considerate in his dealings with all who came to know him. During the construction of the Williamsburg Bridge, there developed a lifelong friendship between Mr. Bascome and the late Holton D. Robinson, M. ASCE. In tribute to Mr. Bascome, Isidore Delson, M. ASCE, who had frequent contact with him as engineer of design during the reconstruction of the bridges in the Croton Watershed wrote:

> "He certainly was a gentleman in the true traditional sense of the word with whom courtesy and considerateness were innate, and not assumed mannerisms. In that sense he was not unlike his friend, the late H. D. Robinson."

[3] For memoir, see *Transactions*, ASCE, Vol. 104, 1939, p. 1890.
[4] For memoir, *ibid.*, Vol. 103, 1938, p. 1785.

Mr. Bascome was a licensed professional engineer and land surveyor of the State of New York. He was also a member of the Society of Colonial Wars. His hobby was photography.

On August 10, 1904, Mr. Bascome was married to Shelley Barriger of Louisville, Ky. He is survived by his widow and a son, Western Radford Bascome, Jr.

Mr. Bascome was elected a Junior of the American Society of Civil Engineers on December 3, 1891; an Associate Member on May 5, 1897; and a Member on September 11, 1917. He became a Life Member in January, 1932.

JAMES EVERETT BESWICK, M. ASCE[1]

DIED APRIL 15, 1946

James Everett Beswick was born on May 18, 1882, in Hermon, N. Y., the son of William Everton Beswick and Eva (Kelly) Beswick. His earliest known ancestor was William Beswicke, Alderman of London, who died May 5, 1567, and was buried in St. Lawrence, Poultney, London, England. Mr. Beswick was named James Everton Beswick, but in early youth the family changed his middle name to Everett, by which he was thereafter known. The name, Everton, was carried by eight of his direct ancestors.

His earliest ancestor in America was George Beswick who resided at Wethersfield, Conn., in 1672. From there the family migrated to West Bridgewater, Scituate, and Chesterfield in Massachusetts, and thence to Warrensburg and Morley in New York, where his father was born. His direct ancestor Lt. Everton Beswick of Chesterfield was one of the forty-eight minute men who, under Capt. Robert Webster, responded to the Lexington alarm and marched to that battle on April 21, 1775.

Mr. Beswick's early education was obtained in the grammar and high schools at Hermon. He attended Clarkson College of Technology at Potsdam, N. Y., and was graduated in 1903 with the degree of Bachelor of Science in Civil Engineering.

His first engineering work was with Waring, Chapman and Farquhar, Consulting Engineers of New York, N. Y., where he was engaged on the construction of sewers and sewage disposal systems. This was followed in 1904 by the position of transitman with the Rapid Transit Subway Construction Company on the first subway from New York to Brooklyn, N. Y. From 1905 to 1907, he was with the Rapid Transit Commission of the City of New York as assistant engineer on the construction of the Battery Tunnel to Brooklyn and the Fulton Street Subway in Brooklyn.

In 1907 he transferred to the Board of Water Supply of the City of New York, where he was engaged on the Catskill Aqueduct, on topographic, real

[1] Memoir prepared by Charles A. Pohl, M. ASCE.

estate, rights of way, and alinement surveys, and on both opencut and tunnel construction. Later he was in charge of all work on shaft No. 17 at 42d Street and Sixth Avenue in New York City, including the shaft sinking and the complete tunnel construction.

For three years, from 1913 to 1915, he was with the New York State Highway Commission as special assistant to the late George A. Ricker,[2] M. ASCE, first deputy commissioner, on progress and final inspections of highway contracts and other special and confidential work. For a period he was resident engineer of Erie County, New York, in charge of all construction and maintenance.

From 1915 to 1920, he supervised all field work and construction of a section of subway for the Public Service Commission of New York, First District work, that cost about $3,500,000, and that included three stations with both opencut and twin-tube, shield driven tunnels.

During the years from 1920 to 1922 he was engaged in a comprehensive investigation of all existing power generation and transmission in the State of New York for the late Gen. William Barclay Parsons,[3] Hon. M. ASCE, and under the general supervision of Col. John P. Hogan, Past-President ASCE. This work also included collection of data on stream flow and rainfall and complete studies of stream characteristics and potential water-power developments.

His next work was as resident engineer in charge of construction of sewers and a sewage treatment plant at Rye, N. Y., from 1922 to 1924. He then built many miles of distribution lines, wells, and pumping plants for the Hicksville (Long Island) water district, during 1924–1925, after which he returned to Rye as chief engineer for about five years, from 1925 to 1929, engaging in extensive enlargements of the sewer system, and improvements and enlargements in the disposal system.

He served with the Water Policy Commission of New Jersey, compiling population studies and forecasts with particular reference to future water requirements for many of the most populous areas of the state. Stream studies that included frequency and magnitude probabilities were made, as well as some on water storage and distribution requirements.

He also made many studies of buildings adjacent to construction projects in connection with liability insurance against damage which might arise by reason of construction activities. This was followed by the position of resident engineer for the Public Works Administration in charge of a number of projects mostly in connection with the water supply of the City of New York which had an aggregate cost of about two million dollars.

From 1936 to the time of his death he was assigned to the Bureau of Claims of the Board of Water Supply of the City of New York. He worked in close cooperation with the Law Department in engineering settlements for property and rights-of-way claims arising from the acquisition of lands and rights for water supply purposes. He gave engineering assistance and advice in preparation for the trial of claims including the securing of expert witnesses. He

[2] For memoir, see *Transactions*, ASCE, Vol. 99, 1934, p. 1501.
[3] For memoir, *ibid.*, Vol. 98, 1933, p. 1485.

also acted as an engineering expert in many technical cases involving water powers, special manufacturing processes, and similar enterprises affected by the city's acts. His department head said of him:

> "Of the highest integrity, he was most dependable for an accurate opinion upon an engineering problem with which he was confronted. He never ventured an expression unless he was fully informed of his facts."

Throughout his life Mr. Beswick was an assiduous student of engineering and mathematical subjects. Completely trustworthy in every particular, he was always loyal and helpful to his associates and friends.

He was a licensed professional engineer in New York State, and a member of the Sons of the American Revolution and the F. and A. M.

On July 3, 1915, Mr. Beswick was married to Cecilia Agnes Farren of Albany, N. Y., who survives him.

Mr. Beswick was elected a Junior of the American Society of Civil Engineers on July 1, 1909; an Associate Member on October 1, 1913; and a Member on January 16, 1928.

ROBERT WRIGHT BOYD, M. ASCE[1]

DIED MARCH 22, 1946

The career of Robert Wright Boyd as an engineer and builder was in a period of great advancement in the development of modern structural design and in the standardization of building codes. An early interest in the design and use of reinforced concrete as a structural material greatly influenced his future achievements.

Robert Wright Boyd, the son of Robert W. and Mary (Ballantine) Boyd, was born in New York, N. Y., on July 14, 1879. He was graduated from the College of the City of New York with the degree of Bachelor of Science in 1899. His technical education was continued at New York University from which he received the degree of Bachelor of Science in 1900 and the degree of Civil Engineer, in 1901. His scholastic achievements brought him the Duryea Fellowship and the Hoe Engineering Prize. Because of Bob Boyd's sound common sense, pleasing personality, and ability to get along with others, in later life he was able to apply this thorough technical training in a very practical way.

After his graduation in 1901, he was employed by W. F. Whittemore,[2] M. ASCE, a civil engineer of Hoboken, N. J., and, for five years, he gained experience in drafting, surveying, and designing. Later he became general office assistant, supervising in the field construction work on sewers, water supply systems, waterfront development, and railroad track. In 1906, he

[1] Memoir prepared by George E. Horr, Vice-Pres., Turner Construction Co., New York, N. Y.

[2] For memoir, see *Transactions*, ASCE, Vol. 106, 1941, p. 1696.

went with Rudolph P. Miller, M. ASCE, consulting engineer of New York, as principal assistant and later associate, specializing in the design and supervision of construction of structural steel and reinforced concrete buildings and foundations. From 1910 to 1918, Mr. Boyd was in private practice—maintaining his own office in New York City as consulting engineer. His work covered not only the design and supervision of structural steel and reinforced concrete buildings, but also the broader field of special examinations and reports.

By this time, he was recognized as an outstanding authority in reinforced concrete construction, so it was not surprising that in January, 1918, he was made advisory engineer, then assistant head, and finally head of the concrete ship section of the United States Shipping Board Emergency Fleet Corporation. In this capacity he directed, designed, and supervised construction of concrete ships and barges needed by the United States Government to replace the vessels destroyed by the ravages of World War I. When this emergency program was completed, Mr. Boyd joined Turner Construction Company as engineer and later became chief engineer in charge of many important projects. His wide experience made him not only an able engineer but also an administrator and executive of real ability.

In November, 1934, the Turner Construction Company granted him leave of absence to head the depression-born Temporary Emergency Relief Administration of the City of New York. He continued in this work, later becoming assistant executive director and finally director of New York State Employment Service (until May, 1940). These difficult jobs were ably and efficiently handled and his administration was always free of the taint of political influence that so often hinders the efficient operation of government departments. On January 6, 1942, Mr. Boyd returned to Turner Construction Company and gave unstintingly of his great knowledge and ability to help in the execution of a huge war program. He was associated with that company until his death.

With all his many engineering and construction interests Robert Boyd still found time for activities outside his profession. He was for many years president and director of Roxmor Colony, Inc., a community built up by a group of summer home owners in the Catskill Mountains. He was a director of the United States Life Insurance Company, and for a long time an Elder in the First Presbyterian Church in New York. Each year he gave a talk at the New York University School of Engineering on "An Engineer's Relations with the Public." He also belonged to the American Society for Testing Materials, the honorary engineering fraternity Tau Beta Pi, and the Engineers Club of New York.

In both his private and business life, he was admired for his kindness, thoughtfulness, and unfailing willingness to help others. His one great hobby was his family.

On May 29, 1906, in New York he was married to Elsie Grace Bushong. He is survived by his widow; two sons, Robert W., Jr., and John B. Boyd; a daughter, Helen Bushong Boyd (Mrs. Laurence Duggan); seven grandchildren, Stephanie, Laurence, Robert, and Christopher Duggan, and Nancy,

Robert W., III, and John Murray Boyd; a brother, William B. Boyd; and a sister, Virginia T. Boyd.

Mr. Boyd was elected an Associate Member of the American Society of Civil Engineers on January 8, 1908, and a Member on June 20, 1922.

WALDO EMERSON BUCK, M. ASCE[1]

DIED APRIL 6, 1945

Waldo Emerson Buck was born in Stoneham, Mass., on February 21, 1856. He was graduated from the Massachusetts Institute of Technology at Boston as a civil engineer in the class of 1876.

After following his profession for several years, and after gaining experience as an agent of the Lake Company in Laconia, N. H., he became a special inspector and chief adjuster for the Associated Factory Mutual Fire Insurance Companies on January 1, 1889.

In 1897 Mr. Buck was elected vice-president, secretary, and director of the Worcester Manufacturers Mutual Insurance Company and three years later became president and treasurer of that company. The latter offices were held by him until March 12, 1942, when he retired from active service as president emeritus. He continued as a member of the company's board of directors and as a member of the advisory board of the Boston Manufacturers Mutual Group until February, 1945, when ill health forced him to retire from that service.

Mr. Buck was a director of the United States Envelope Company and of the Merchants and Farmers Mutual Fire Insurance Company. He was a member of the Boston Society of Civil Engineers as well as of this Society.

His life was a full one which, because of his character and ability, enriched the lives of those with whom he came in contact. As a friend and associate he will be greatly missed.

On June 6, 1894, in Woburn, Mass., he was married to Frances Sherwood Jones. He is survived by his widow and a daughter, Eleanor (Mrs. Harry R. Davis), both of Worcester, Mass.

Mr. Buck was elected a Member of the American Society of Civil Engineers on July 3, 1889. He became a Life Member in January, 1924.

---

[1] Memoir prepared by Otto F. Hauck, Secy., Boston Mfrs. Mutual Fire Insurance Co., Boston, Mass.

NEIL STANLEY BUCKBEE, M. ASCE[1]

DIED APRIL 10, 1946

Neil Stanley Buckbee, the son of William Doane and Kate (Brown) Buckbee, was born on September 21, 1883, at French Mountain, near Glens Falls, N. Y. He was graduated from Dartmouth College, in Hanover, N. H., in 1906, and from the Thayer School of Civil Engineering at Dartmouth in 1907.

Throughout his entire life, after leaving college, Mr. Buckbee practiced the profession in which he was educated in his native state and in the State of Pennsylvania, except for a brief period in Youngstown, Ohio. The first half of his business life was devoted constantly to reinforced concrete design and construction, with manufacturers or contractors in Buffalo, N. Y., Rochester, N. Y., and Niagara Falls, N. Y. The second half of his career was spent as designing engineer and then chief engineer on varied work with Gannett, Fleming, Corddry and Carpenter, Incorporated, of Harrisburg, Pa., an organization which he joined in 1929.

"Buck," as he was called, was a careful and accurate designer, an earnest worker, and a good teacher of the young men under him. He was greatly respected and appreciated by those closely associated with him, but, because of his refusals to attend conventions or to write engineering articles or speeches, he was not as widely known as he would otherwise have been. In his drafting room, he usually had several young Dartmouth men in whom he naturally took a particular interest.

The design and supervision of earth dams became Mr. Buckbee's specialty over the last fifteen years of his life. The largest jobs, those in which he took an active part, were three water storage reservoirs and pipe lines for the Lehigh Coal and Navigation Company and the cities of Harrisburg and Lebanon, Pa.

Mr. Buckbee was married in Canton, Ohio, to Alice May Loud, by whom he had three sons— Donald M., Neil S., Jr., and John A. Buckbee. He is survived by his widow; one son, John A.; four grandchildren; his mother; and two sisters, Mrs. Blanche Townsend and Mrs. William Edmunds. Mr. Buckbee died suddenly of unsuspected heart trouble on April 10, 1946, at the age of sixty-three. He was a licensed professional engineer in the states of New York and Pennsylvania.

During recent years the Buckbees lived in a very attractive house filled with the antiques which he and Mrs. Buckbee had collected over many years. He designed this house to meet their desires and needs and was exceedingly fond of it, as well as of his flower and vegetable gardens.

Mr. Buckbee was elected a Member of the American Society of Civil Engineers on June 16, 1919.

[1] Memoir prepared by Farley Gannett, M. ASCE.

SAMUEL JEFFERSON CHAPLEAU, M. ASCE[1]

DIED FEBRUARY 25, 1947

Samuel Jefferson Chapleau, the son of Maj. S. E. Saint Onge Chapleau and Caroline Kirby (Patten) Chapleau, was born at Atlanta, Ga., on January 1, 1869. Between 1873 and 1917 his father was, successively, secretary of the Department of Public Works of Canada, sheriff of the Northwest Territories, clerk of the Crown in Chancery, and clerk of the Senate.

After the usual elementary education, Samuel Chapleau entered Rensselaer Polytechnic Institute at Troy, N. Y., in 1887, being graduated with honors and the degree of Civil Engineer in 1891.

He began his career, most of which was spent in Canada, in 1892 as assistant to the division engineer, Eastern Division, Canadian Pacific Railway Company in Montreal, Que. Between January and August, 1894, Mr. Chapleau was in private practice in Ottawa, Ont. Then he was appointed engineer in charge of a topographic party on a hydrographic survey of the Fraser River in British Columbia for the Department of Public Works. In 1895 he was a structural draftsman in connection with the construction of the Soulanges Canal in Quebec. He then became assistant engineer on the adjustment of the final estimates for the Canadian Ship Canal at Sault Sainte Marie, Ont. From 1896 to 1900 he was assistant engineer in the Department of Railways and Canals, in charge of design, construction, and estimates on the Soulanges Canal construction.

From June, 1900, to March, 1901, Mr. Chapleau was assistant engineer on the New York State Barge Canal Survey, in charge of the design and estimates of locks and equipment on the proposed 12-foot canal between Buffalo and Albany, N. Y. He then returned to Canada and the Department of Public Works, being appointed engineer in charge of hydrographic investigation of the middle channel of the Saint Lawrence River in Ontario between Kingston and Brockville, and also of surveys and improvements of harbors and channels in the upper Saint Lawrence District. He left the department to become principal assistant engineer of the Department of Marine on the organization of the Canadian Hydrographic Office and was in charge of the district extending from Montreal, Que., to the Great Lakes.

In 1904 he again returned to the Department of Public Works as district engineer in charge of the Nipissing District of the Georgian Bay Ship Canal Survey, remaining until 1908, when he was appointed district engineer of the Upper Saint Lawrence District with headquarters at Ottawa.

In 1922 when this district was merged with the Ottawa District, Mr. Chapleau was promoted to engineer grade two at headquarters. With the reorganization of the headquarters staff in 1937, he became superintending engineer and chairman of the Board of Engineers, which position he held

[1] Memoir prepared by Fred G. Smith, Supervising Office Engr., Dept. of Public Works of Canada, Ottawa, Ont., Canada.

until his retirement from the public service on Jaunary 1, 1939, after more then forty-three years.

Among the outstanding engineering works for which Mr. Chapleau was responsible are the international bridges between Clair, N. B., and Fort Kent, Me.; Edmundston, N. B., and Madawaska, Me.; and Saint Leonard, N. B., and Van Buren, Me.; the Lasalle causeway between Kingston and Barriefield, Ont.; and the two control dams on Lake Nipissing at the head of the French River in Ontario. He also devised and completed the middle channel, 300 feet wide and 16 feet deep at low water, on the Saint Lawrence River between Kingston and Brockville through the Thousand Islands.

As a member of the Board of Consulting Engineers of the International Commission of the River Saint John in New Brunswick, he carried out an investigation of the River Saint John watershed. From 1908 until his retirement in 1939, he had direct control of all matters in connection with the French River watershed, Rainy River, and Lake of the Woods and of all international bridges between New Brunswick and Maine, and was engaged in studies of all engineering projects of major importance undertaken by the Department of Public Works.

Mr. Chapleau became an associate member of the Canadian Society of Civil Engineers in 1896 and attained full membership in 1909. He was chairman of the Ottawa Branch in 1911 and 1912 and councillor of that society in 1913, 1914, and 1915. Early in 1918 when the Canadian Society of Civil Engineers became the Engineering Institute of Canada, the "Institute" became the possessor of a case containing two beavers, one a pure albino. These were the gift of Mr. Chapleau and are highly prized by all members. In his letter to the institute at that time, he stated:

> "Some years ago I had occasion to arrange the distribution of flow in the Rainy River past the Fort Frances, Ontario—International Falls, Minnesota Section, in order that the Canadian Side would receive the benefit of its share, or one-half of all power generated there by the operating Companies, and during my stay at Fort Frances I greatly admired a pair of stuffed beavers, one black and one white, that I thought, if properly arranged together, would look well as a group illustrating 'The First Engineers,' after a picture that I had seen of like nature. I tried to buy the beavers at the time with the idea of sending them to the Main Society at Montreal, but was unable to do so, and expressed my ideas in that regard to Colonel D. C. McKenzie, then Mayor of the town.
>
> "About one and a half years afterwards, much to my surprise, Dr. McKenzie sent me down two mounted beavers which are now in the case, asking me to accept them as a gift from himself and other friends of the town, so I turned them over to our Branch with the request that they be sent on to Headquarters.
>
> "On enquiring for a mounted white beaver Dr. McKenzie found none were to be had, but learned from an old trapper that there was one on a lake in the Atikokan District, who trapped the same next Winter at Dr. McKenzie's request.
>
> "The 141st Battalion, the 'Bull Moosers,' which was raised for Overseas Service by Dr. McKenzie as its Colonel, wished to take these specimens with them to England and present them to the King, but the Doctor preferred to carry out his original intention.

"They were mounted here by Mr. Petch, who does all that kind of work for the Dominion Museum."

As a result of this typical generous act, the institute's crest shows "a beaver at work" which typifies the engineering profession in general and Mr. Chapleau in particular. On October 18, 1935, he became a life member of the institute.

He was a member of Saint John's Anglican Church; Civil Service Lodge, A. F. and A. M.; Carleton Chapter, Royal Arch Masons; Ottawa Preceptory, Knights Templar; and Karnak Temple of the Mystic Shrine.

On October 21, 1897, Mr. Chapleau was married to May Edith Gouin, who predeceased him in 1944. He is survived by a son, Jefferson, and a daughter, Mary Louise (Mrs. L. Clare Moyer).

The funeral service was conducted by the Venerable Archdeacon C. G. Hepburn on February 27, 1947, and interment was at Beechwood Cemetery, Ottawa.

In Mr. Chapleau's death the engineering profession has lost an outstanding and brilliant engineer, a gentleman, and a friend.

His associates have paid him the following tribute:

"Life held you fast—
And how you loved it, too.
You found it good to touch
And see and smell the things of earth.
But came a day when Life,
With wistful fingers, beckoned you away.
You did not halt, nor fear, nor fail,
But straightway followed that strange lead
Into a world so full of life and joy,
That could we call you back with one quick word,
We would keep silent.
Yours is the gain,
And ours the blessing, too.
The world of things unseen, unfelt, unheard
Is strangely friendly now,
Because you walk where we have never trod
And sing the songs, the melodies of God."

Mr. Chapleau was elected an Associate Member of the American Society of Civil Engineers on May 1, 1901, and a Member on January 31, 1905. He became a Life Member in January, 1936.

JOHN ABELL CLEVELAND, M. ASCE[1]

DIED APRIL 17, 1946

John Abell Cleveland, the son of Charles and Lizzie (Houston) Cleveland, was born in Linden, Ala., on March 8, 1876. He entered the United States

[1] Memoir prepared by a Committee of the Miami Section consisting of Lynn Perry, M. ASCE, and Herbert J. Morrison, Assoc. M. ASCE.

Military Academy at West Point, N. Y., in 1898, but resigned three years later to work with Archer Harmon, engineer, of New York, N. Y.

In May, 1901, he became associated with the Guayaquil and Quito Railway in Ecuador, South America, under Mr. Harmon who was then the engineer in charge. Mr. Cleveland began as leveler, topographer, transitman, and in charge of party, surveying bridge sites. From December, 1901, to March, 1902, he was assistant to the bridge engineer and in charge of bridge abutments and erection of steel bridges, and later that year, he was placed in responsible charge on the same work His next position was as acting resident engineer, and in March, 1903, he became resident engineer. By December, 1903, he had advanced from assistant engineer in charge of stadia survey to engineer in charge of assembling and erecting steel bridges. From January, 1904, to October, 1905 (during which time he was granted a seven-month leave of absence), he was resident engineer and also locating engineer. He worked as general roadmaster and inspecting engineer until October, 1906, after which he became resident engineer in charge of all construction. In May, 1907, he was made chief engineer of the railway, and in September, 1907, he held the positions of vice-president and chief engineer. In December, 1907, he became general manager of the entire railway.

The Government of Ecuador employed him, from November, 1909, to September, 1911, as chief engineer in charge of engineering and public works. In October, 1911, he was consulted in connection with a proposed steel custom house for the City of Guayaquil on estimates, specifications, and plans. He then became chief engineer and general director of Ferrocarril de la Costa for the Government of Ecuador serving from October, 1912, to April, 1920. During 1918, he was also consulting engineer on a new line and projected viaduct for the Guayaquil and Quito Railway. For three years, beginning in May, 1920, he was consulting engineer for that railway and other organizations, after which he was on location and in charge of construction of a plantation narrow-gage railway on a banana farm in Ecuador.

Mr. Cleveland returned to the United States in 1919 to place his son in school. He returned again with his family in 1926 to make Miami, Fla., his permanent home. There he continued to engage in an active business and civic life.

He was vice-president of the Filer-Cleveland Company which engaged in mortgage loans and investments, and which subsequently engaged in apartment and hotel property management. He became the first president of the Miami branch of the Mortgage Bankers Association. In various capacities, he served the American Red Cross, the Boy Scouts of America, the Children's Home Society of Florida, and other local civic, religious, and charitable organizations. He was a Thirty-Second Degree Mason and a member of Mahi Temple, Ancient Arabic Order of Nobles of the Mystic Shrine. For fifteen years prior to his death he served as Senior Warden of the Miami Trinity Episcopal Church.

For the last nine years of his life from 1937 to 1946, he was consul ad honorem for the Government of Ecuador at Miami.

Although Mr. Cleveland's career was varied, particularly in his later years, his basic and fundamental background was that of civil engineering. This profession gave to him that incisive, clear cut, and unswerving approach to civic problems for which he was well known in the Miami area. His work was characterized by thoroughness and his judgment, by broad vision and keen insight. During a long and successful career he enjoyed a wide acquaintance both in the United States and in South America. His vast experience as a civil engineer in Latin America was a valuable factor in initiating and developing a smoother and more understandable relationship between the United States and South America. As testified to (*Miami Daily News*) by the community in which he lived,

> "* * * he did much to cement neighborly relationships, and he was always acutely conscious of the things Miami should do, as a community, to fit itself better for the role of bridge between the Americas."

In 1908, Mr. Cleveland married Maria Teresa Valdez of Guayaquil. He is survived by his widow and their four sons, Charles B., John A., Jr., Rafael, and Houston H.

Mr. Cleveland was elected an Associate Member of the American Society of Civil Engineers on March 14, 1916, and a Member on January 17, 1927.

ALBERT SEARS CRANE, M. ASCE[1]

Died August 25, 1946

Albert Sears Crane was born on May 30, 1868, in Addison, N. Y., where he spent his boyhood. His ancestry was mostly English; the first Crane in America was said, by Mr. Crane, to have arrived on the *Mayflower*. A great-grandmother, on his mother's side, Abigail Ayrault, was a French Hugenot who settled in Rhode Island.

He prepared at the Addison Union School for Cornell University, at Ithaca, N. Y., from which he was graduated with the degree of Civil Engineer, in 1891. During one of his summer vacations he was chosen as secretary by the late Rudolph Hering,[2] M. ASCE, whom he accompanied on a study and inspection trip of sewerage systems in Germany and other European countries. Mr. Crane was always particularly proud of this association.

His first job after graduation was as assistant engineer of the City of Newton, Mass., a position he held for four years. Following this employment, he went to Brooklyn, N. Y., as assistant engineer in the department of sewers. While in Brooklyn he became a charter member and was active in the formation of the Brooklyn Engineers Club, and in the establishment of its library.

---

[1] Memoir prepared by Henry A. Lardner, Vice-Pres., The J. G. White Engineering Corp., New York, N. Y.

[2] For memoir, see *Transactions*, ASCE, Vol. LXXXVII, 1924, p. 1350.

From 1898 until 1902, he was associated with the power companies at Sault Sainte Marie, Mich., and, during the last two years of residence there, he became chief engineer of the Lake Superior Power Company at Sault Sainte Marie, Ont., Canada. For three years, beginning in 1902, he was principal assistant engineer of the Chicago Drainage Canal, in Illinois, then under construction.

With this background of valuable experience, he was prepared to undertake his major lifework—he became hydraulic engineer with the J. G. White interests in New York, N. Y. During his active association with the White companies, he was a vice-president and director of The J. G. White Engineering Corporation until his retirement in 1928, when he became a valued consultant until his death.

His splendid technical knowledge and skill in design commanded the respect, and his fine personal character the love, of his associates and many friends. He was a man noted for his high integrity. His skill in the design of large earth dams, masonry dams, hydroelectric power stations, and irrigation projects was widely recognized in the profession. His advice was sought both by engineers and by investment bankers.

He never married. He maintained his residence at the Engineers Club, in New York City, continuously, from the time of its completion. In addition to his membership in the American Society of Civil Engineers, he was a member of the American Institute of Electrical Engineers, the Western Society of Engineers, the Boston Society of Engineers, the Brooklyn Engineers Club, and the Cornell and Lawyers clubs of New York.

Mr. Crane was elected a Junior of the American Society of Civil Engineers on September 3, 1895; an Associate Member on May 4, 1898; and a Member on May 1, 1901. He became a Life Member in January, 1933.

FRANK TERENCE DAVIS, M. ASCE[1]

DIED JANUARY 7, 1947

Frank Terence Davis was born in Evanston, Ill., on January 9, 1900. His parents were John J. and Jane Davis.

He received his early schooling in Chicago, Ill., and spent two years at the University of Havana in Cuba, later doing postgraduate work in civil engineering and engineering law at the University of Tennessee in Knoxville.

His first professional engagement was as project engineer for the Standard Construction Company in Havana. He became a partner in the firm in 1930. Mr. Davis' work involved the construction of heavy bridges, docks, and sugar mills. In 1934 he was engaged by the Cerro de Pasco Corporation where he was in charge of a large hydroelectric power station at Malpaso, Peru.

[1] Memoir prepared by Stewart S. Neff, M. ASCE.

During 1940, he returned to the United States and was engaged by the Federal Housing Administration in Washington, D. C., to supervise several large housing developments in Tennessee and Kentucky. In 1942 Mr. Davis was transferred to the Reconstruction Finance Corporation (R.F.C.), and assigned to responsible charge of a large nickel extraction plant and mining development in Cuba. On completion of this assignment, he was recalled to the United States and appointed division engineer and senior division engineer for plant clearance in the Pittsburgh (Pa.) division of the R.F.C. In 1945 he returned to Washington, D. C., as the principal engineer and administrative assistant in the office of the vice-president of R.F.C., where he was busily engaged until his death.

Affable and of an engaging manner, and with an untiring capacity for work, Mr. Davis had many friends and associates in the United States and the tropical countries. All mourned his passing. His engineering and administrative ability were of the highest standard, and he had the respect and confidence of his associates.

In 1926, in Cuba, he was married to Cleo Gonzales, who survives him.

Mr. Davis was elected a Member of the American Society of Civil Engineers on March 12, 1945.

HENRY DIEVENDORF DEWELL, M. ASCE[1]

DIED MARCH 20, 1946

Henry Dievendorf Dewell, the son of William Henry and Maria J. (Dievendorf) Dewell, was born in Springfield, Ohio, on October 24, 1881. He came to Fresno, Calif., with his parents at an early age. There he received his grammar school and high school education, being graduated with honors from Fresno High School, in 1900. His boyhood experiences at Fresno, when that city was in its period of rapid pioneer development and when it was becoming the center of one of the most intensively developed, irrigated areas of the West, made a deep impression on him.

He entered the University of California at Berkeley, in August, 1901. In the following year, however, circumstances required his return to Fresno, where he spent an active year in the lumber industry. During that period he acquired an interest in, and a knowledge of, timber which was later to aid him in becoming an authority on timber construction and an author on the subject.

He resumed his college course in 1903, and was graduated from the College of Civil Engineering of the University of California in 1906. At the time of his graduation, San Francisco, Calif., had been largely destroyed by the earthquake and fire of April 18, 1906. He at once entered into problems of reconstruction as a member of the staff of Howard and Galloway, Architects and

---

[1] Memoir prepared by a Committee of the San Francisco Section consisting of Walter L. Huber, Chairman, Austin W. Earl, and the late L. H. Nishkian, Members, ASCE.

Engineers, and, indeed, had a responsible part in many important design problems. When his employers were commissioned supervising architects of the Alaska-Yukon Pacific Exposition at Seattle, Wash., he became the designing structural engineer in their Seattle office, where he designed the frames of some of the principal buildings for the exposition, and some of the buildings for the University of Washington.

He returned to San Francisco in 1909, and, until 1911, was principal assistant engineer for Galloway and Markwart, Consulting Engineers. His work included design of hydroelectric power plants, bridges, water-supply systems, and buildings, and also involved appraisals. From February, 1911, to January, 1912, he was employed by the Oro Electric Corporation, under the supervision of Galloway and Markwart, in direct charge of surveys for reservoirs, conduits, powerhouses, and transmission lines. On completion of this service, he returned to Galloway and Markwart to design a steel drawbridge spanning the Sacramento River.

The next three years were spent with the Panama Pacific International Exposition at San Francisco, where he was, successively, chief structural engineer, assistant superintendent of building construction, and engineer of domestic water supply and distribution. His connection with the exposition gave him wide experience in timber design, a subject which had long interested him. Later he was the author of "Timber Framing,"[3] and was associate editor of the following textbooks edited by George A. Hool and W. S. Kinne: "Handbook of Building Construction," "Structural Members and Connections," and "Steel and Timber Construction."

After 1915 he was engaged in private practice as a consulting engineer with offices in San Francisco. From 1932 to 1940, he was associated with Austin W. Earl, M. ASCE, as Dewell and Earl, Consulting Engineers; and, from 1944 until his death, he was with his son Robert D. Dewell, Assoc. M. ASCE, as Dewell and Dewell, Consulting Engineers.

His practice covered a wide range of important projects that included, among many others, additions to the water supply of the City of Sacramento (Calif.), involving the design and construction of three elevated reinforced-concrete water towers of three-million-gallon capacity and involving some unusual features. His advice on design problems was widely sought, as for instance in connection with the great cableway head tower which was the master feature of the concrete plant at Shasta Dam. Perhaps his best remembered work will be his intensive studies on earthquake resistant construction, which resulted in many assignments of special design problems.

In 1919 and 1920, he lectured at the University of California. He was a member of the California State Board of Registration for Civil Engineers, from 1931 to 1945, and was long president of the board. He served the Seismological Society of America as its treasurer and was a member of the publication committee. He was a member of the Advisory Committee on Vibration Research at Stanford University, Stanford University, Calif.; the Structural Engineers Association of Northern California; the American Con-

[3] "Timber Framing," by Henry Dievendorf Dewell, Dewey Pub. Co., San Francisco, Calif., 1917.

crete Institute; the American Society for Testing Materials; and the National Committee on Wood Utilization. Mr. Dewell was also the northern technical editor of the "Uniform Building Code" (California edition), which was adopted in large measure as "Appendix A" of the "Rules and Regulations" of the Division of Architecture of the California State Department of Public Works, governing the design and construction of school buildings.

He was a member of Sigma Xi, Tau Beta Pi, and Chi Epsilon, honorary scholarship societies. In addition he was a member of the Engineers Club of San Francisco and the Commonwealth Club of California.

In Society affairs Mr. Dewell was most active: He served as a Director, from 1925 to 1927, and a Vice-President in 1934 and 1935. He also served on many of the Society's committees and was particularly active as Chairman of the Committee on Local Sections while serving as Director. He was President of the San Francisco Section in 1930.

He was married on June 30, 1909, to Manie Ola Harrell at Fresno. He is survived by his widow; three children, Robert D. Dewell, Henry D. Dewell, Jr., and Jane (Mrs. Frank Reanier); and by his sister, Jessie W. Dewell.

A man of brilliant mind and steadfast purpose, he never spared himself in his professional work, whether it was in his endeavor to provide his clients with the best possible solution to their problems; in his willingness to do his share, and more than his share, of work for the profession as a whole; or in his helpfulness to the younger men of the profession. Although his chief characteristic was earnestness—indeed, he took a very serious view of professional affairs—he had a droll sense of humor which appeared even at times of serious discussion. He was very much respected and liked by all who knew him, both inside and outside the profession. His life was enriched by many loyal friendships.

Mr. Dewell was elected an Associate Member of the American Society of Civil Engineers on May 2, 1911, and a Member on June 12, 1917. He became a Life Member in January, 1946.

GILBERT COLFAX DOBSON, M. ASCE[1]

DIED DECEMBER 29, 1945

Gilbert Colfax Dobson was born in Philadelphia, Pa., on February 27, 1881. He was the son of James Wrigley Dobson and Rachel (Walsh) Dobson, who were natives of England.

James Wrigley Dobson emigrated to America in 1870, when he was nineteen years of age. Finding the United States much to his liking, he returned to England to claim as his bride, Rachel, daughter of John and Margaret Walsh, of Hooley Bridge, Lancashire. The couple was married on June 9, 1874, and, on the same day, they sailed for America on the maiden voyage of

[1] Memoir prepared by Victor H. Cochrane, M. ASCE.

the *Pennsylvania,* the first "iron steamship" to cross the Atlantic. With true pioneer courage and faith in their adopted land, they established their home in Philadelphia and reared their sons and daughters in accordance with high Christian ideals. In 1881, the year in which Gilbert Colfax Dobson was born, his father became a naturalized American citizen.

In 1886 the Dobson family moved to St. Louis, Mo., later settling in the town of Mexico, Mo., where the father was engaged in pioneer work in industrial insurance. His duties in connection with the establishment of district offices necessitated several moves by the family, and Gilbert received his grammar school education in various places. By the time he was ready to enter high school, the family had taken up residence in Columbia, Mo. Here, he demonstrated his ability as a student, and particularly his talent for mathematics, by completing three years of high school work in two years.

About this time because of failing health, his father decided to return to Philadelphia with his family to be near all the relatives who had followed him to America. Gilbert remained in Columbia and there entered the University of Missouri, receiving the degree of Bachelor of Science in Civil Engineering in 1905. (The university awarded him the postgraduate degree of Civil Engineer in 1909.) He supported himself during his college years by working in a real estate office after school hours, which often necessitated his studying most of the night. He started as office boy and, during his last year in school, became a member of the firm. He had charge of rentals, insurance, and instalment purchases, in addition to taking part in other activities of the firm.

In the fall of 1905 he received an appointment for service in the Philippine Islands, and he proceeded to his station in Manila, remaining there until June, 1909. His first assignment was as surveyor to the Court of Land Registration, in which capacity he was responsible for surveys of city and province lands in title investigations. In connection with this work, Mr. Dobson had to develop control methods and prepare instructions for field operations.

In the wilderness remote from adequate library facilities, his ability in mathematics stood him in good stead. He carried on research work on the direct solar observation for azimuth, and handled the coordinate computations for several very large surveys, one having more than five thousand courses. He carried the astronomical triangle through all its differential variations, plotted the probable error curves for all locations and conditions in the Philippines, and complied mathematical tables based on these computations. During the last two years of his stay in the Philippines, Mr. Dobson served as assistant city engineer of Manila, supervising many designs for streets, bridges, and canals. He also had full charge of the emergency drainage of infected swamps in the fight against the Asiatic cholera epidemic.

Mr. Dobson returned to the United States in August, 1909, to accept an appointment with the United States General Land Office in Sante Fe, N. Mex. He served for nearly a year as special agent, in charge of investigation of violations of public land laws. In addition, he prepared a topographic map of 160 square miles of mountain country and mapped by reconnaissance methods several hundred square miles of illegally enclosed land.

In July, 1910, Mr. Dobson accepted an appointment with the Isthmian Canal Commission, and he remained in the Canal Zone during the next five and a half years. Here he had a wide range of experience and great responsibility in the design and construction of locks, dams, buildings, and other structures. He had charge of the field engineering for the Gatun Spillway, including the control gates and appurtenant hydroelectric plant and later of installing the mechanical equipment for the Gatun Locks. For a period of two and a half years he supervised the engineering design of all permanent buildings, and structures costing several million dollars were built from his designs.

On his return to the United States in April, 1916, Mr. Dobson worked for the Kansas City Terminal Railway Company, in Kansas City, Mo. During the following thirteen months he was engaged in making an economic study of column spacing, the rearrangement of tracks, and other factors relating to the design of a five-mile elevated railway through industrial areas and complicated railway yards in Kansas City.

Upon completion of this work in May, 1917, he was commissioned a Captain in the Corps of Engineers, United States Army. He remained in the Army for three and a half years, rising to the rank of Major. Before serving in France with combat troops, the 314th Engineers, he had charge of the construction of the drainage system of Camp Funston at Fort Riley, Kans. Following the Armistice, he was assigned to the post of professor of military science and tactics at the Colorado School of Mines in Golden, where he remained until he resigned his commission in October, 1920, to become a member of a firm in Tulsa, Okla., specializing in special hazard insurance. Here Mr. Dobson made examinations of fire hazards in oil refineries and gasoline plants and investigated methods of reducing fire risks. The firm was dissolved in February, 1925.

Mr. Dobson's next professional engagement was as a representative of the Portland Cement Association, with headquarters in Tulsa, from February, 1925, to July, 1928. He was responsible for the promotion of the use of cement and for the dissemination of data relating to concrete technology. During the next seven months he was a consulting engineer in Tulsa, engaged chiefly in structural design.

The remaining years of Mr. Dobson's professional career were spent in the service of the federal government. From February, 1929, to November, 1935, he was in the United States Engineer Office in Memphis, Tenn., and subsequently, was with the Soil Conservation Service until his retirement on July 31, 1943. During the period of his service with the U. S. Engineer Office in Memphis, he made engineering and economic investigations on the Arkansas River and its tributaries for flood control, navigation, and other uses. He served both as field engineer and specialist in mathematical investigations. His most notable technical contribution during this period was a review of the mathematical processes employed by M. P. du Boys in his "Study of the Regime of the Rhone and the Action Exercised by the Water on an Indefinitely Shifting Bed of Gravel."

His first position in the Soil Conservation Service was as hydraulic engineer of the Sedimentation Section in the Office of Research. He supervised investigations of bed load movements in natural streams, and he guided the design and construction of the experimental stations on the Enoree River near Greenville, S. C., and at other locations. In October, 1936, he became the head of the Sedimentation Section, serving in that capacity until August, 1942, in charge of a wide range of investigations pertaining to reservoir silting, stream and valley sedimentation, and bed load transportation, as well as to related laboratory work. His last year of service was spent at the Greenville station, winding up the work of this project which had been under his supervision from its inception.

Mr. Dobson contributed to the literature on sedimentation and related problems. He collaborated with others in the preparation of papers and reports dealing with sedimentation, published by the United States Department of Agriculture and by the Society. The most notable of these was "Some Principles of Accelerated Stream and Valley Sedimentation." [2]

After Mr. Dobson's retirement from federal service, he returned to his home in Tulsa, and served as a member of a board of consultants appointed to study the sedimentation problems of the river basins comprising the Southwestern District of the U. S. Engineer Corps.

He was greatly esteemed by all who knew him. He was an engineer of the highest principles, and his close friends believed that at least one important move during his career was made to avoid the violation of professional ethics. He was a pleasant and agreeable companion, and his friends and associates gained much from the sound philosophy of life which he represented. His hobby was mathematics; he would sometimes spend most of the night on an intriguing problem, even if it were unrelated to his regular work. Mr. Dobson's associates gained from him many useful mathematical tricks and processes.

He was a member of the American Geophysical Union; the F. and A. M., Thirty-Second Degree; and the Shrine. If he had lived but three days longer his life membership in the Society would have become effective.

On October 26, 1905, at Columbia, he was married to Dee Lake. He is survived by his widow and a son, Gilbert Lake Dobson.

Mr. Dobson was elected an Associate Member of the American Society of Civil Engineers on May 2, 1911, and a Member on March 11, 1919.

JOHN STEPHEN DOYLE, M. ASCE[1]

Died March 11, 1947

John Stephen Doyle, the son of John I. Doyle and Adelaide (Ruff) Doyle, was born in Baltimore, Md., on December 26, 1873. He received his early education in Baltimore at Calvert Hall and Rock Hill College. He was graduated from Johns Hopkins University, also in Baltimore, with the degree of Civil Engineer in 1900 and, subsequently, in 1921, he received the degree of Doctor of Philosophy.

Mr. Doyle was employed by the Baltimore District of the Corps of Engineers from August 2, 1897, to May 16, 1900, as inspector on fortifications and on sea-wall, road, and electrical construction, also designing military structures. From May 17, 1900, to January 15, 1910, he was with the Street Repair Department of the Baltimore City Engineering Department, as assistant engineer. In 1904 he was in charge of wrecking dangerous structures standing after the fire of that year. As engineer of parks, he designed reinforced concrete bridges, two skewed arch bridges, a 167-foot steel truss bridge, and a large bridge over Gwynns Falls. In private practice he designed a highway bridge and timber piers, and was examining engineer and appraiser on masonry bridges, road and culvert work, and other large bridges.

During his tenure of office with the Corps of Engineers, he was responsible for the design and construction of many river and harbor, flood control, and national defense works. He wrote many reports on river and harbor and flood control projects relative to the Chesapeake Bay and its tributaries, and, also, relative to the Susquehanna River Basin in Maryland, Virginia, Pennsylvania, and New York.

In 1910 he returned to the Baltimore District Office, Corps of Engineers, where he remained until his retirement on January 25, 1943. In 1914 he enrolled in the officers' training course at Plattsburg, N. Y., and studied there for two years. During World War I he became District Engineer with the ranks first of Captain and then of Major for the period from June 6, 1918, until January 17, 1919. He always retained his interest in the Reserve Corps, attending annual encampment whenever his duties permitted, and rose to the rank of Lieutenant Colonel in the Engineer Reserve Corps. During the last years of his service with the Corps of Engineers, he was consultant to the District Engineer. He died in St. Petersburg, Fla., where he had gone in November, 1946, to recuperate from an illness.

Mr. Doyle was a strict disciplinarian of both himself and those who worked with him. At the same time he took a great interest in new employees and young men and at all times insisted that they come to him with any problem that might be troublesome. He took great pleasure in showing others how to

[1] Memoir prepared by C. C. Neher, Assoc. M. ASCE.

overcome their difficulties. He was a very capable, energetic man of high character.

Mr. Doyle was married to Mary Frances Doyle in 1905. She died in 1929. He is survived by a son, J. Stephen Doyle, Jr., a special assistant to the Attorney General in Washington, D. C.

Mr. Doyle was elected an Associate Member of the American Society of Civil Engineers on November 7, 1906, and a Member on May 3, 1910. He became a Life Member in January, 1941.

FRANK KEYS DUNCAN, M. ASCE[1]

DIED FEBRUARY 20, 1946

Frank Keys Duncan, the son of George H. and Mary Louise (Keys) Duncan, was born at Warren, Baltimore County, Md., on March 10, 1874. He attended the public schools of Baltimore, Md., and the Maryland Institute in Baltimore where he studied mechanical drawing.

Upon graduation he entered the employ of John Laing, a civil engineer. A year later he went to work in the engineering department of the Baltimore and Ohio Railroad Company.

Mr. Duncan's long and diversified career in the engineering service of the City of Baltimore began in 1894, when he was twenty years old, with the Topographical Survey. Three years later, he transferred to the city commissioner's office. His civilian engineering activities were interrupted the following year when he volunteered for naval duty in the Spanish-American War. At the conclusion of the war, he returned to the city commissioner's office. In 1900 he was transferred to the city engineer's office; and, in 1911, he was promoted to office engineer. With the creation of the Paving Commission, in 1911, he became engineer in charge of design and then engineer in charge of construction.

During World War I, almost singlehanded, he conducted the operations of the Paving Commission resigning, in 1921, to enter the contracting business as a member of the firm of P. G. Ligon and Company. The firm's name was later changed to Ligon and Duncan.

After an absence of two years, in 1923, he returned to municipal service as assistant highway engineer. In 1925, when the engineering bureaus of the city were coordinated under the Department of Public Works, headed by the chief engineer of Baltimore, he became the first assistant chief engineer and, in 1938, chief engineer. He retained this, the highest engineering position in the city government, for a little more than a year before retiring to private life.

During his long career of municipal service, in which he served the City of Baltimore almost continuously for forty-five years, Mr. Duncan was at all

---

[1] Memoir prepared by George A. Carter, and Nathan L. Smith, Members, ASCE.

times a conscientious and energetic public servant. Under his guidance and direction, many public improvements were completed. His ability to analyze and solve a problem was unusual. Possessed of an underlying sense of humor that won him many friends, he nevertheless exhibited uncompromising firmness when the occasion demanded.

Mr. Duncan was married to Lucy Amelia Wright, in Suffolk, Va., on December 10, 1907. He is survived by his widow; five sons, Gerald (by a previous marriage), Donald Wright, Frank Keys, James Robert, and Louis Edward Duncan; two daughters, Dorothy (Mrs. D. M. Muth) and Eleanor (Mrs. C. A. Eisenhauer); four grandchildren; three brothers; and two sisters.

In addition to his membership in the Society, Mr. Duncan was a member of the Engineers Club of Baltimore, the Maryland Association of Engineers, and the Masons.

Mr. Duncan was elected a Member of the American Society of Civil Engineers on August 9, 1920. He became a Life Member in January, 1945.

ROBERT PURL EASLEY, M. ASCE[1]

Died June 10, 1945

Robert Purl Easley, the son of Robert Alexander and Edith Barbara (Schramm) Easley, was born on January 24, 1887, in Boise, Idaho. At the age of fourteen he moved with his parents to California, where the remainder of his life was spent. He received his high school education in Santa Cruz and San Francisco.

His career as a contractor began in 1906, on small brick work jobs, following the San Francisco earthquake and fire, when he was only nineteen years old. Then for two years he was employed in the rebuilding of San Francisco, as a draftsman and inspector. During this period he also obtained his engineering training in the Humboldt Evening Engineering School in San Francisco. Beginning in 1907, he spent two and a half years on railroad work—much of the time in charge of rail and terminal construction—with the Western Pacific and the Oakland-Antioch railroads, followed by a year and a half on the installation of water and sewer systems in California and Nevada.

In 1913 Mr. Easley entered private practice and for the remainder of his career followed a combination of engineering and contracting. For a part of that period he acted as assistant city engineer for Daly City, Calif., and as city engineer for Antioch, Calif. His contracting and construction work covered the building of city water systems, sewers, and streets; large earth-fill dams; and irrigation, drainage, levee, and other reclamation projects. Since 1933, in partnership with L. P. Brassy, he held a contract with the City

[1] Memoir prepared by Edward Hyatt, M. ASCE.

of San Francisco for disposing of all the city's garbage and refuse by covering in trenches excavated in the tidelands of San Francisco Bay.

Unlike most engineers, Mr. Easley took time from his professional activities to devote to public affairs. He was elected to the Assembly of the California State Legislature, serving from 1925 through 1933. During those years he was active in connection with legislation and in other ways affecting California's water problems. He was a member of the joint committee of the senate and assembly, appointed in 1929, which reported to the legislature of 1931 on the water problems of the state. He was vice-chairman of a legislative water resources committee, appointed at the 1931 session, which submitted to the legislature in April, 1932, a "Report of the California Joint Legislative Water Committeee Dealing with the Water Problems of the State of California."

Other public activities included membership on the Water Conservation Committee appointed by James Rolph, Jr., then Governor of California, in 1931, to confer with Herbert Hoover, Hon. M. ASCE, then President of the United States, and representatives of federal agencies on California's State Water Plan; the State Water Plan Association (1933); the Citizens' Committee on Irrigation, Reclamation, and Drainage; the National Reclamation Association (director); and the California State Planning Board.

Mr. Easley was a member of Antioch Lodge No. 175, F. and A. M., of California; Islam Temple of the Shrine, San Francisco; and Ariel Chapter No. 42, Order of the Eastern Star of Antioch. He was Patron of his Eastern Star Chapter in 1927, and Grand Patron of the Order of the Eastern Star, State of California, during 1937–1938.

In 1911, Mr. Easley was married to Jeanette F. Mowbray in San Francisco. He is survived by his widow and a daughter, Roberta (Mrs. W. D. Trewhitt, Jr.).

Mr. Easley was elected an Associate Member of the American Society of Civil Engineers on October 14, 1930, and a Member on April 22, 1935.

WILLIAM CHESTER EMIGH, M. ASCE[1]

Died September 26, 1946

William Chester Emigh was born on April 28, 1888, in Troy, N. Y. His parents were John H. and Emma F. (Allen) Emigh.

He was educated in private and public schools in North Adams, Mass., and was graduated in 1909 as a civil engineer from Rensselaer Polytechnic Institute in Troy. Following his graduation, he was connected with the Cambria Steel Company at Johnstown, N. Y., and with the New York State Department of Health.

---

[1] Memoir prepared by Francis S. Friel, M. ASCE.

In 1922 Mr. Emigh became associated with the Bethlehem Steel Company in Coatesville, Pa., as a sanitary engineer, and remained with that company until 1931 when he became city engineer of Coatesville. In South Coatesville, he also served as borough engineer and had charge of all city engineering work including, among other things, the operation of the water works and sewage treatment plants.

In addition to being a member of this Society, Mr. Emigh also belonged to the American Water Works Association, the American Public Works Association, and the Pennsylvania Sewage Works Association, and was a past-president of the Pennsylvania Water Works Association.

Mr. Emigh was prominent and active in the religious and civic affairs of Coatesville. He was an outstanding member of the First Baptist Church and for twenty-four years was a Bible class teacher. In his civic activities, he was a past-president of the Coatesville Rotary Club, and a director in the Coatesville Young Men's Christian Association and the chamber of commerce. He also held membership in the honorary technical societies of Sigma Xi and Tau Beta Pi.

Mr. Emigh was elected an Associate Member of the American Society of Civil Engineers on October 8, 1918, and a Member on May 18, 1942.

JAMES DEARING FAUNTLEROY, M. ASCE[1]

DIED JULY 20, 1943

On the three peninsulas of eastern Virginia between the estuaries of the James and Potomac rivers dwells a community which has few counterparts in other sections of the United States. The restful landscape of low rolling hillsides and rich farm lands has left its benign influence on each generation of its people—descendants of the early settlers of the seventeenth and eighteenth centuries, who were already richly endowed with the gracious manners and sincere courtesy of the folk of old England whence they came. It was in this environment and with this fine heritage that James Dearing Fauntleroy was born and spent his earliest years.

The son of Thomas and Mary Anne (Dearing) Fauntleroy, he was born at Oakenham near Saluda in Middlesex County, Virginia, on April 4, 1869. The old Virginia Fauntleroys are descended from Col. Moore Fauntleroy who came to Virginia in 1643, and settled in Nansemond County. In 1650 he moved into that part of the "Northern Neck" Peninsula which was then included in old Rappahannock County. Other ancestral families were the Keenes, Wallers, Griffins, Corbins, Tayloes, and Terrells.

While still a boy, he moved with his parents to Avoca, not far from Altavista in Campbell County (Virginia), the homestead of his great-great-grandfather, Col. Charles Lynch, of Revolutionary War fame. The present "law" that

---

[1] Memoir prepared by William Roy Glidden, M. ASCE.

bears his name is a gross perversion of the fair trial given by Colonel Lynch and his associate justices to the evildoers whom they caught and punished.

His youthful days, spent amid the difficult times of the reconstruction era following the "War Between the States," culminated with his graduation from the Virginia Military Institute at Lexington, on July 4, 1888. Later, this same institute was to confer on him its highest academic award, the degree of Civil Engineer, on June 17, 1926, in recognition of his fine service in the profession.

In Mr. Fauntleroy's professional career there were three distinct periods of activity. From the time of his graduation from the Virginia Military Institute to the outbreak of the Spanish-American War, he was finding his way in the engineering field in various minor capacities. The second or middle period began soon after the oubreak of the Spanish-American War when he was commissioned a First Lieutenant and later a Captain in the United States Army. This connection with the United States Government, thus begun, continued for many years, and took him to Cuba and the Philippine Islands. The third or final period found him back in his native land whose government he served, except for a brief interlude, until his retirement in 1939.

After graduation from the Virginia Military Institute, Mr. Fauntleroy's first engagement was with the Atlantic and Danville Railway Company, where he served as rodman, from December, 1889, to the following March. As an instrumentman he worked for the St. Paul (Va.) and Minneapolis (Va.) Land and Improvement Companies until December, 1890. The following year he became secretary and general manager for the Craig Valley Iron and Mining Company at Goshen, Va. An opportunity for exercising independent engineering judgment came when he was employed as assistant engineer for Langhorne and Allen, Contractors, on railroad location and construction in Buckingham County, Virginia, and Washington County, Pennsylvania. He was employed by them from July, 1892, to August, 1893.

Beginning in August, 1893, he was engaged in the Norfolk (Va.) area by the Norfolk and Western Railway Company, and Thomas L. Rosen, Contractor, in work related to engineering. The outbreak of the war with Spain in 1898 proved a turning point in Mr. Fauntleroy's career which influenced the remainder of his life.

Commissioned a First Lieutenant in July, 1898, and later a Captain in the Third Regiment of Engineers, United States Volunteers, he served as an instructor to enlisted personnel in the construction of such works as entrenchments, blockhouses, and temporary bridges. He saw service in Cuba in the Pinar Del Rio area. After the close of hostilities with the Spanish Government, from July, 1899, to June, 1901, he was, successively, First Lieutenant and Captain with the Twenty-Seventh Regiment of Infantry, United States Volunteers. During this interim Captain Fauntleroy was sent to the Philippine Islands where he was destined to remain until March, 1907.

As a public works officer, Captain Fauntleroy made a conspicuous contribution to the improvement of Philippine civilization. His first task was to compile data for the preparation of military maps for the major part of the provinces of Morong and Manila. Later he had charge of the construction of a

number of public buildings in the City of Manila, and was also engaged on the construction of provincial highways and bridges. In December, 1904, he became sanitary engineer for the Philippine Islands and, acting in conjunction with the medical inspectors and the city engineer of Manila, he set up an organization for sanitary inspection and prepared plans and specifications for standard designs for sewage disposal which included a system of sewage disposal for Bilibid Prison. He did sanitary work at Santa Cruz in Laguna Province, and at the Culion leper colony, where he also made a study of the water-supply system.

While in the Philippines, Captain Fauntleroy made an exhaustive study of the ancient Spanish road laws and prepared legislation for the general improvement of Philippine highways. He also assisted in the preparation of laws relating to sanitation as he was highly accomplished in the use of the Spanish language and the Tagalog dialect, the principal native tongue of the Filipinos.

Returning to the United States in March, 1907, Captain Fauntleroy became associated with the United States Reclamation Service, first as assistant engineer, and then as engineer. He was in charge of the construction of the Laguna Dam in Arizona, the Bumping Lake Dam in Washington, and the Elephant Butte Dam in New Mexico. He was responsible for the field work on the restoration of the Colorado River to its original channel in Mexico, after its historic break into the Salton Sea in Southern California, reporting to Col. J. A. Ockerson,[2] Past-President, ASCE, whose headquarters were in Yuma, Ariz. For about a year, from August, 1912, to September, 1913, Captain Fauntleroy was general manager for the Goldsboro Construction Company in Laramie, Wyo., being in charge of the construction of the Lake Hattie Storage Dam near by and the appurtenant canal system.

Beginning in February, 1914, and until his retirement in April, 1939, except for a period of two years, from February, 1922, to February, 1924, when he was state highway engineer for the State of Texas, Captain Fauntleroy was prominently associated with the United States Bureau of Public Roads.

When he became state highway engineer in Texas, the matter of matching federal aid with state funds was a serious problem, as there was no highway department with centralized control, and very few counties had funds available. Captain Fauntleroy was instrumental in organizing the State Highway Department and deserves much credit for the early advance of this state in highway development.

From November, 1916, to February, 1922, he was district engineer for the U. S. Bureau of Public Roads, in charge of all work in the states of Arkansas, Louisiana, Oklahoma, and Texas. The remainder of his service with this federal bureau was spent in his native state of Virginia, where as senior highway engineer he was responsible for the administration of federal funds expended on the highways of Virginia.

Tall and strongly built, he was a commanding figure in any gathering; yet, mild and persuasive in manner, he seldom needed to crack the whip of authority. In his public relations he was firm but courteous; in his private life

[2] For memoir, see *Transactions*, ASCE, Vol. 88, 1925, p. 1329.

and among his friends his natural proficiency in the social graces was always apparent. He truly exemplified the traditional Virginia gentleman.

In 1942, a year before he died, Captain Fauntleroy was elected president of the Third United States Volunteer Engineers. The yearbook of this organization, published in that year, contains many fine tributes from his former comrades. Typical quotations from them are: "He is God's nobleman"; "A man of high character"; "I am proud to call him my friend"; "All his men adored him"; "He put us boys through some hard drilling and himself, too"; "Known by all as a straight shooter"; "Exacted discipline from intimate friend"; and "He was the best singer in the regiment." This last quotation was in reference to the Captain's repertoire of old southern songs which he sang with a lusty voice on appropriate occasions. His particularly effective rendering of "De Watermillion Smilin' on de Vine" was something to be remembered.

He was a member of the Society of American Military Engineers, the American Association of Engineers, the University Club of Manila, the Columbia Club of Manila, the Veteran Army of the Philippines, the Third United States Volunteer Engineers Veteran Organization, the Society for the Preservation of Virginia Antiquities, and the Sons of the American Revolution (past-president of the Virginia Chapter). During World War II he was appointed by the Hon. Colgate W. Darden, Jr., then Governor of Virginia, to the state technical committee on civilian defense. As is customary among old Virginia families, he was a strong adherent of the Episcopal Church.

Like a sturdy oak felled by a sudden fury of the elements, Captain Fauntleroy was stricken on the night of July 19, 1943, and the end came peacefully the following morning while he slept. His great and genial heart which had endeared him to all who knew him had failed, its labor ended.

Captain Fauntleroy was married to Frances Hamilton Fox of Campbell County at Evington, Va., on February 9, 1903. Mrs. Fauntleroy died in 1941. Surviving are their three daughters, Mary Hamilton (Mrs. George S. Riggs), Frances Dearing (Mrs. A. K. Phillips), and Martha Lorimer; and a son, James Dearing, Jr.

The yearbook of the Third U. S. Volunteer Engineers, previously referred to, was dedicated to him with this fine tribute:

> "Gallant soldier, engineer of the highest standing in training and experience. An officer whose innate ability, sterling character and commanding presence won complete discipline, obedience and cooperation from his men. He was beloved as a lifelong friend by every man in his Company; it was a privilege and inspiration to know him, ideal American citizen in war and in peace—'Chevalier sans peur et sans reproche.'"

Captain Fauntleroy was elected a Member of the American Society of Civil Engineers on June 5, 1907. He became a Life Member in January, 1940.

DONALD EGBERT FUELLHART, M. ASCE[1]

DIED OCTOBER 23, 1945

Donald Egbert Fuellhart was born in Warren, Pa., on December 12, 1899, the son of John H. and Ida Loretta (Howard) Fuellhart. He entered Ohio State University at Columbus in 1916, but World War I forced him to abandon his studies in 1918.

His career as an engineer began when he left the university to serve as surveyor and draftsman with the United States Navy in the construction of a large training station. He was retained by the Navy after his discharge in 1919, and served a year with the Public Works Department in Newport, R. I.

When his work with the Navy had been completed in 1920, Mr. Fuellhart came to Louisiana to practice civil engineering and land surveying. In 1922 he began his outstanding career in the oil and gas industry in the geological department of the Gulf Refining Company. As a result his experience in land surveying and in construction work led to his appointment in 1924 as parish engineer of Natchitoches Parish, Louisiana. While in this office he designed and constructed many highway bridges, culverts, and dams, in and around Natchitoches.

By 1927 he found the opportunity he had been hoping for with the firm of Brokaw, Dixon and McKee, Engineers and Geologists, in New York, N. Y. Mr. Fuellhart's untiring efforts and love for his profession enabled him to accomplish much during the thirteen years he devoted to this work. He became intensely interested in the production of gas and oil, and his research and investigations resulted in the discovery of much useful information. Three technical publications which he wrote are: "Open Flow Capacity High Pressure Gas Wells,"[2] "Natural Gas Flow Tables,"[3] and "Sub-Surface Disposal Oil Field Brines."[4] He also contributed much toward the development of butane gas systems. In 1931 he designed and directed the construction of a $42,000,000 natural gas transmission system for the Panhandle Eastern Pipe Line Company, and was designing and constructing even larger systems at the time of his death.

In the years from 1935 to 1940, Mr. Fuellhart temporarily put aside his work in the gas and oil industry and once again came to the aid of the State of Louisiana in the capacities of engineer with the Highway Commission, assistant agricultural engineer, and engineer with the Department of Conservation. During this period he did much to improve the roads in Natchitoches Parish; he planned and constructed many fish and quail hatcheries; and he designed and built many bridges and dams in the state parks.

[1] Memoir prepared by Edward D. Hogg, Jun. ASCE.
[2] *Oil and Gas Journal*, May 9, 1929.
[3] *Ibid.*, January 20, 1939.
[4] *Ibid.*, January 6, 1938.

The people of Louisiana and neighboring states are grateful to Mr. Fuellhart for the many benefits his achievements have given them. He was an active member of the American Association of Petroleum Geologists, and of the Louisiana Engineering Society.

On September 19, 1921, Mr. Fuellhart was married to Marie Aurelia O'Quinn in Natchitoches. He is survived by his widow and a daughter, Kathryn Marie Fuellhart. His only son died on December 16, 1944, of wounds received in the fighting on Mindoro Island.

Mr. Fuellhart was elected an Associate Member of the American Society of Civil Engineers on January 26, 1931, and a Member on July 10, 1944.

EDWARD GILLETTE, Jr., M. ASCE[1]

DIED JANUARY 3, 1936

Edward Gillette, Jr., the son of Edward and Anna Frances (Selby) Gillette, was born on December 14, 1854, in New Haven, Conn. He was a descendant of Jonathan Gillette, who was born in England; settled at Dorchester, Mass., in 1630; and moved to Windsor, Conn., in 1635. Thus, Edward Gillette had a sound basis for his membership in the Sons of the American Revolution and the Order of Founders and Patriots of America.

After attending the New Haven High School, he entered Sheffield Scientific School of Yale University, also in New Haven. He was graduated in 1876 with the degree of Bachelor of Science.

During 1876 and 1877 Mr. Gillette was employed by the U. S. Coast and Geodetic Survey. In 1878 and 1879 he was topographer on the U. S. Geographical Survey West of the 100th Meridian, working in New Mexico and Arizona before any railroads had been constructed in those territories (later states) and in Colorado near Leadville and the Royal Gorge, toward which the Atchison, Topeka and Santa Fe and the Denver and Rio Grand railroads were racing their surveys and construction. With such experience he became locating engineer for the Rio Grande Construction Company in 1880 in Utah, continuing as chief draftsman through 1881 and 1882.

Then for two years he was engineer in charge of additional construction and maintenance of way for the Denver and Rio Grande Western Railway Company. At one time the company had thirty-six engineering parties in the field, equally divided between location and construction. Numerous lines were run in Utah and Nevada. The route finally selected was by way of Walker pass and down the San Joaquin Valley to San Francisco. In 1885, at the age of thirty, he was appointed United States deputy mineral surveyor for Utah and chief engineer of the San Pete Valley Railway.

In December, 1885, Mr. Gillette was employed as locating engineer by the Burlington and Missouri River Railroad in Nebraska (later the Chicago,

[1] Memoir prepared by Frank T. Darrow, M. ASCE.

Burlington and Quincy Railroad, Lines West) and continued with that road during its rapid expansion until 1892. His work covered hundreds of miles of surveys in Nebraska, Wyoming, South Dakota, and Montana.

In 1892 he opened an office in Sheridan, Wyo., as surveyor and civil engineer; and, from February 18, 1895, to February 18, 1899, he was superintendent of Water Division No. 2 for the State of Wyoming. In 1899 and early 1900 Mr. Gillette located the line of the Chicago, Burlington and Quincy Railroad from Toluca, Mont., in the Crow Indian Reservation, one hundred and twenty-nine miles to Cody, Wyo.—the eastern entrance of Yellowstone Park. This line was built in 1900 and 1901. After this engagement he made a survey for a railroad from Valdez, Alaska, up the Copper River under very difficult conditions. In the fall of 1900 he was made assistant superintendent of the Northern Division of the Chicago, Burlington and Quincy Railroad; and, on December 1, 1902, superintendent of the Sheridan Division at Sheridan, continuing until October 27, 1905.

On January 7, 1907, Mr. Gillette became State Treasurer of Wyoming, serving the full four-year term permitted by law; but he declined repeated importunities to run for other political office. In 1915 and 1916 he was chairman of the Board of Review of the U. S. Reclamation Service for Northern Wyoming and Montana. In 1916 he was appointed a member of the Board of Industrial Preparedness in the United States, representing the Society for the State of Wyoming. He was also Commissioner of Conciliation in the Department of Labor in 1918. In Sheridan, he was an alderman and a member of the board of education.

He died at his home in Sheridan on January 3, 1936, after a period of ill health—although he remained active, and his mind was keen. In regard to his public service, it was stated:

> "Although remaining in the background the Republican party counted him a leader of its ranks. His work throughout his life was of a public character."

He was married on April 10, 1893, in Chicago, Ill., to Hallie O. Coffeen, daughter of the Hon. Henry A. Coffeen, one-time U. S. Congressman from Wyoming. Mrs. Gillette died on January 5, 1937. Mr. Gillette is survived by a daughter, Harriet (Mrs. William L. Kleitz), and a son, Edward Hollister Gillette.

Mr. Gillette was a man of wide and skilled experience in western railway location, considerate of his men, and beloved by them. Genial and affable, he was a good visitor and was held in high esteem by all.

His trip of fifty miles on the ice through the Big Horn River Canyon in Montana and Wyoming during five days in March, 1891, with a prospector as his sole companion is a thrilling story of hardship as described in *Transactions.*[2] His book "Locating the Iron Trail"[3] is an excellent account of his

[2] "The First Trip through Big Horn Cañon," by E. Gillette, *Transactions*, ASCE, Vol. XXV, July–December, 1891, p. 8.

[3] "Locating the Iron Trail," by Edward Gillette, Christopher Pub. House, Boston, Mass., 1925.

experiences in New Mexico, Arizona, and Utah before 1885 and on the Chicago, Burlington and Quincy Railroad western lines from 1886 to 1902. It is indeed fortunate that there is such a clear, accurate, and interesting record of the work of the early United States surveyors and railroad locating engineers in the west.

Mr. Gillette was elected a Member of the American Society of Civil Engineers on July 3, 1889.

STUART CHAPIN GODFREY, M. ASCE[1]

Died October 19, 1945

Stuart Chapin Godfrey, the son of Charles B. and Cora A. (Chapin) Godfrey, was born in Milford, Mass., on January 1, 1886. He was educated at Phillips Exeter Academy, at Exeter, N. H., the Massachusetts Institute of Technology at Boston, and the United States Military Academy at West Point, N. Y. He was graduated from the military academy in 1909, at the head of his class.

Following his graduation, he began his career as an officer in the Corps of Engineers of the United States Army. By 1912 he had experience as a student officer on the Panama Canal, then under construction, and had served a tour of duty with engineer troops, during which time he initiated the survey of the Fort Sill (Oklahoma) reservation. From 1912 to 1917, he was an instructor and an associate professor of mathematics at the United States Military Academy and spent his summer months on river and harbor assignments on the Ohio River.

From 1917 to 1919, he served as Major, Lieutenant Colonel, and Colonel in the Corps of Engineers, U. S. Army. Before going to France with the 318th Combat Engineer Regiment he was stationed at two engineer officers' training camps. In France he constructed the base depot for the American Expeditionary Forces at Gievres, later serving as Engineer Personnel Officer at Tours and as assistant to the Chief Engineer of the First Army in the closing weeks of the Meuse-Argonne offensive. After the Armistice in 1918, Colonel Godfrey became the Executive Officer for the Chief Engineer of the Army of Occupation in Coblenz, Germany, and finished his assignment as Division Engineer of the Second Division, and Commanding Officer of the Second Engineer Regiment. While in Germany, Colonel Godfrey received a commendation from Gen. John J. Pershing for having constructed a pontoon bridge, 1,440 ft long, across the Rhine River in fifty-eight and a half minutes.

Upon the return of Colonel Godfrey to the United States in 1919, he became the principal assistant engineer at Wilson Dam, Muscle Shoals, Ala., which was the largest concrete dam in the world at that time. Later, as chief

[1] Memoir prepared by J. H. Stratton, James B. Newman, Hal H. Hale, and the late J. T. L. McNew, Members, ASCE.

of the Finance Division in the Office of the Chief of Engineers, from 1921 to 1923, he was in charge of contracts, accounting, and field civilian personnel.

From 1923 to 1925, he was District Engineer of the Boston (Mass.) District, Corps of Engineers, on river and harbor improvements and fortifications along the New England coast, including the Portland (Me.) harbor and the Cape Cod (Mass.) Canal. He initiated construction of a forty-foot channel from Boston Harbor and completed construction of a sixteen-inch battery at Fort Duvall, Little Hog Island, Mass., during this assignment.

Colonel Godfrey was graduated with honors from Command and General Staff School at Fort Leavenworth, Kans., in 1926, and was then assigned to the Memphis (Tenn.) Engineer District, in charge of the navigable channel of the Mississippi River from Cairo, Ill., to the sea. He participated actively in the fighting of the great flood in 1927, rebuilding some of the breached levees by dredging, and assisted in preparing new projects for flood control and navigation. During this civil assignment, he had a prominent part in organizing the Mid-South Section of the American Society of Civil Engineers, and served as its first President.

Colonel Godfrey returned to teaching in 1928, when he was assigned as instructor in tactics and military engineering at the Command and General Staff School, where he served until 1932. Following this assignment he spent the summer touring England, Germany, Switzerland, and France. In the fall he attended the Army War College in Washington, D. C., and was graduated with high honors in 1933. As engineer for the First Corps Area at Boston, from 1933 to 1935, Colonel Godfrey was busy on matters of fortification, troop training, and war plans.

In 1935 he became engineer of the Panama Canal Department and commanding officer of the Eleventh Engineer Regiment. In this capacity he installed the antiaircraft guns and searchlights, and built the first asphalt roads for the U. S. Army in the Canal Zone.

Upon his return to the United States in 1937, Colonel Godfrey became Chief of Operations and Training Section, as well as Executive Officer of the Military Division, Office of the Chief of Engineers. In this capacity he supervised, for the Chief of Engineers, all military engineering training, including troops, officers, and student officers at engineer camps. He also prepared plans for new and expanded engineering units, as well as for their equipment and utilization, which included a new air forces component of engineers to be known as aviation engineers. He assisted in the development of several types of transportable steel landing mats which later were to become invaluable in all theaters of operation. As a representative of the United States State Department, he attended the International Navigation Congress at Brussels, Belgium, in 1939, at the time of the opening of the Albert Canal. In his official capacity with the Chief of Engineers, he cooperated with the agencies of the engineering societies in the United States in planning for civilian defense and supervised the preparation of the first official manual on blackouts.

Beginning in 1941 he became Engineer of General Headquarters, United States Army Air Forces, which was later named the Air Forces Combat Com-

mand. On March 9, 1942, he was promoted to Brigadier General. During this period he made exhaustive studies of the problems confronting engineers assigned the mission of supporting an air force in offensive combat. He secured authorization for major changes in organization of engineer aviation units and in their equipment. General Godfrey, more than any other individual, was responsible for the activation and training of additional units which were later to serve with distinction in all theaters of operation. For his accomplishments in this important work he was awarded the Legion of Merit for distinguished service in directing the growth of the aviation engineer component of the U. S. Army Air Forces, his citation reading in part:

> "His vision, devotion to duty and judgment in planning, equipping and training the special engineer units to meet expanding Army Air Forces requirements have been exceptional. His personal contribution to the development of the transportable steel landing mat is an achievement of outstanding note."

As the Air Engineer, U. S. Army Air Forces, on Gen. Henry H. Arnold's staff, he continued the development of aviation engineers and visited every active overseas theater to study airfields and operations of engineer aviation units. General Godfrey was instrumental in setting up aviation engineer replacement training centers and initiated and pushed the formation and development of air-borne engineer aviation units which were unique in the American army. He gave untiring support to the authorization of an Engineer Command, a unit designed to perform all engineer work for an air force in the field. Largely as the results of his efforts, two such commands were activated and operated with signal success in the Mediterranean and European theaters. In addition, the Buildings and Grounds Division, U. S. Army Air Forces, which was the agency responsible for formulating requirements of the three billion dollar program of military air base construction, was placed under the supervision of the air engineer in 1943. Actual construction involved in this program was under the direction of the Chief of Engineers, who proceeded in accordance with the air forces program developed under General Godfrey's supervision.

In December, 1943, General Godfrey became air engineer in the China-Burma-India Theater (CBI) where he supervised for the air forces the planning and construction of United States military airfields. Much of his time was devoted to the program of construction of B-29 bomber bases in China which were built by hand methods in periods as short as three months. From these fields, the second bombing of the Japanese mainland was carried out in June, 1944. As air engineer he planned and supervised the use of air-borne engineers in Burma with Colonel Cochran and General Wingate. At "Broadway," a historic airfield in the Burma campaign, General Godfrey supervised the work of his air-borne engineers and lent encouragement to them in their efforts behind the Japanese lines by his presence during the operation. Later in the capture of the airstrip at Myitkyina, General Godfrey again experienced great satisfaction as his glider-borne engineer aviation units performed miracles in keeping the captured airstrip open, in spite of Japanese efforts and

a monsoon, to the contrary. Without these quickly made airfields to accommodate troops and combat aircraft, the Burma campaigns would have been exceedingly difficult, if not impossible.

After the fall of Myitkyina, General Godfrey planned, staffed, and supplied several engineer aviation battalions to organize the Tenth Air Forces Engineer component which took part in another historic achievement involving the transportation of all its personnel, heavy tractors, eight-yard scrapers, shovels, trucks, and other equipment by air from India—as well as the thousands of tons of supplies necessary for the ground forces. This movement, by air, of some fifteen hundred sorties, carrying heavy construction equipment and personnel of sufficient size to build a large number of all-weather airfields, was accomplished during the monsoon in a land where no road or rail access was available. It demonstrated strikingly and uniquely the efficacy of an air force to supply, by air, a forward operation and to bring up its own engineers for advanced airdrome construction. For his outstanding achievements as aviation engineer in the CBI, General Godfrey was awarded the Air Medal for meritorious achievement in aerial flight, and the Oak Leaf Cluster to the Legion of Merit. His citation for the Air Medal read in part:

> "In the performance of his duties as Air Engineer, Gen. Godfrey accumulated over two hundred hours flying time in supervising the layout, design and construction of airfields in the China-Burma-India Theater. On many occasions his missions were accomplished in the face of hazardous flying weather over territory where enemy fire was probable and expected and where landings were made on difficult terrain behind enemy lines."

Early in 1945 General Godfrey returned to the United States and was assigned to duty as Commanding General of Geiger Field, Wash., which was an Engineer Replacement Training Center he had organized when he was on duty in Washington. It was on this assignment and while returning from conferences at Fourth Air Force Headquarters in San Francisco, Calif., that General Godfrey was killed in the crash of a C-45 Army transport on October 19, 1945.

In addition to his engineering activities General Godfrey was long closely associated with the Boy Scouts of America. He served as a scoutmaster at Fort Leavenworth in 1912 and continued his scouting and cubbing activities at West Point, Boston, Washington, D. C., and the Canal Zone. He was a personal friend of Dr. West, the Chief Scout Executive, and he once visited the International Boy Scout Chalet at Kanderstag, Switzerland. In 1936 he organized a Boy Scout camp in Costa Rica. While he was president of the Boy Scout Council in the Canal Zone, he was awarded the Silver Beaver for distinguished service to boyhood.

Although a busy man with his countless calls of duty, General Godfrey found time to serve other interests for the public welfare. He was a member of the Society of American Military Engineers, and received the Gold Medal award of that society in 1939; the National Council, Boy Scouts of America; the Visiting Committee for the Civil Engineering Department of Massachusetts Institute of Technology; and the Army and Navy Club in Washington,

D. C. As a soldier, as an engineer, as a teacher, and as a gentleman, his influence will endure through the years. His personal friends will long remember him as a wise counselor and one who entered into his every assignment with all his heart and soul.

In 1915, in New York, N. Y., he was married to Dorothy Rich who, with his daughter, Dorothy Hope, and two sons, Charles Stuart and Pearce, survives him.

General Godfrey was elected a Junior of the American Society of Civil Engineers on September 5, 1911; an Associate Member on September 12, 1916; and a Member on January 18, 1921.

GEORGE ESTYN GOODWIN, M. ASCE[1]

DIED SEPTEMBER 15, 1945

George Estyn Goodwin was born on June 4, 1875, in Shelburne, N. H. His parents were Otis F. and Sarah (Hutchinson) Goodwin. He was educated at public and private schools and at Hebron Academy in Hebron, Me., and was graduated from the University of Maine at Orono, in 1901, with the degree of Bachelor of Science in Civil Engineering with honors. In 1910 he received the degree of Civil Engineer from his alma mater.

While performing jobs as timekeeper, assistant foreman, foreman on bridge erection and railway and sewer construction, and assistant locomotive fitter for the Grand Trunk Railway during undergraduate years, he learned first-hand the practical side of construction. This knowledge became the keystone of his career and provided a good background for the future. After graduation he was employed by the Corps of Engineers, United States Army, as inspector of dredging and jetty and breakwater construction in Massachusetts, and was resident engineer for three years in charge of fortifications construction in Boston Harbor.

The spring of 1905 found Mr. Goodwin following other University of Maine graduates out west to work for the United States Reclamation Service, later the Bureau of Reclamation, which was authorized by Congress in 1902. Arriving in Montana, he was placed in immediate charge of design and construction of the Huntley Project. The work involved a main canal and distribution system, pumping plants, and many other structures. Three years later he became project engineer on the Blackfeet Project, where he had supervision of similar work. Those were frontier days in Montana, and many a less hardy and determined individual failed to make the grade.

Mr. Goodwin then became general superintendent in charge of construction of The Dalles-Celilo Canal, a nine-mile navigation canal with five locks which was being built in the Columbia River Gorge by the United States Engineer Department, near The Dalles, Ore. That project was completed in the spring of 1913.

---

[1] Memoir prepared by Ray E. Mackenzie, M. ASCE.

He was then placed in charge of sixty miles of difficult highway construction which the Corps of Engineers was undertaking for the National Park Service in Crater Lake National Park, Oregon. This work lasted four years, and received the special attention of the National Park Service. On its completion Mr. Goodwin became associated with the National Park Service as general civil engineer, with headquarters in Washington, D. C. He had general oversight and technical review of all engineering in the national parks and also served in a consulting capacity.

In 1921 Mr. Goodwin was made chief engineer of the National Park Service, serving until his resignation in 1925. The first suspension bridge across the Colorado River in Grand Canyon Park was designed and built under his supervision; the first paving in Yosemite Park was laid under his specifications and direction. The location of the original Rim Road in Crater Lake Park was made by him personally and the famous Swift Current Trail in Glacier Park was located and built by him.

His love of the soil and the outdoors caused him to return to Oregon and settle on a small fruit orchard in Hood River Valley. There he carried on a consulting and general engineering practice, principally in building construction.

Returning to the Portland (Ore.) District, Corps of Engineers, in 1930, he was associated with revetment and levee work and channel changes on the Willamette and Columbia rivers. In 1933 he was in local charge of deepening and improving Willamette Falls Locks, at Oregon City; and, at the initiation of the Bonneville Dam Navigation and Power Project on the Columbia River, he was made resident engineer. Later, during the early part of 1935, Mr. Goodwin was administrative assistant.

With federal interest in flood control and multiple purpose projects so active, his wide and varied background was indispensable and he was assigned to the investigation of several projects in Idaho, Washington, and Oregon. The following two years he devoted to those investigations; in the spring of 1937 he completed investigations of irrigation, drainage, and ground-water resources, covering twenty-two individual irrigation projects involving 660,000 acres of irrigable land for the Willamette Valley Project in Oregon. His devotion to these investigations doubtless caused the break in health which he suffered near the close of the work in 1937. He retired in July, 1938, after completing studies and estimates for enlarging and rebuilding Willamette Falls Locks.

Returning to his beautiful orchard home in Hood River Valley he carried on a small consulting practice until his death in Santa Cruz, Calif.

Those having more than a casual acquaintance with Mr. Goodwin were generally impressed with his dry, calm, wit. Only occasionally was it caustic. His positive personality was equally impressive. Once, in Montana, a big bruiser, who considered himself injured because he had been fired, towered over him, threatening to tear him apart then and there. Mr. Goodwin calmly sat and slowly reduced the ruffian in stature with cutting and pointed remarks. His ego shattered, the man was glad to leave. A loyal friend, Mr. Goodwin

was ever interested and inquiring about his many associates, both young and old. Being a good conversationalist, he loved to entertain his friends with talk about his travels and experiences.

Mr. Goodwin was a member of Hood River Lodge No. 105 of the A. F. and A. M., a Thirty-Second Degree Scottish Rite Mason, Oregon Consistory No. 1, and a Universalist. In addition, he also belonged to the honorary fraternities of Kappa Sigma and Phi Kappa Phi. He loved the outdoors ardently; his greatest interests were mountain climbing and fishing. With the late Walter W. Crosby, M. ASCE, he was coauthor of the book, "Highway Location and Surveying." [2]

Mr. Goodwin was married in 1901 to Margaret Wallace but was later divorced. To this union were born Esther W. and Susanna B. Goodwin. In 1922 he was married to Ruth G. Oliver, who survives him.

Mr. Goodwin was elected an Associate Member of the American Society of Civil Engineers on January 8, 1908, and a Member on July 1, 1909. He became a Life Member in January, 1943.

NORMAN BASSETT GURLEY, M. ASCE[1]

Died February 27, 1947

Norman Bassett Gurley, the son of William Chamberlain and Catherine (Russell) Gurley, was born in Marietta, Ohio, on May 3, 1890. He was educated in the public and high schools of Marietta, in close association with his father, whose scientific achievements in the fields of astronomy and photography as director of the Marietta College Observatory influenced the son to embark upon an engineering career.

Mr. Gurley was first employed by the Parkersburg and Marietta Interurban Railway Company in Parkersburg, W. Va. He began as a rodman in June, 1908, and by May, 1913, was in complete charge of important construction, remaining until February, 1916, when he entered the service of the Baltimore and Ohio Railroad Company. He continued with the Baltimore and Ohio until September, 1918, as assistant geologist engaged in coal mining property and tunnel structure investigations, with headquarters at Morgantown, W. Va., and, beginning in May, 1917, at Wheeling, W. Va. From September, 1918, to May, 1924, he practiced civil and mining engineering at Williamson, W. Va.

In May, 1924, Mr. Gurley was appointed chief engineer of the Red Jacket Consolidated Coal and Coke Company at Red Jacket, Mingo County, W. Va. During the following fifteen years, he designed many large-scale operations and directed the construction of railroad extensions, coal preparation plants, and

[2] "Highway Location and Surveying," by Walter W. Crosby and George E. Goodwin, Gillette Pub. Co., Chicago, Ill., 1928.

[1] Memoir prepared by J. N. Wallace, Assoc. M. ASCE.

other facilities in a rapidly expanding and modernizing field. Because of ill health, he retired in July, 1939.

Mr. Gurley moved to Huntington, W. Va., in May, 1940, and became track materials sales and service engineer for the West Virginia Steel and Manufacturing Company. During this engagement, he wrote a technical article[2] for *Coal Age*, which is considered an important contribution to modern track layout practice.

In May, 1946, he accepted the position of chief engineer of the Lando Coal Corporation and its affiliates, with offices in Huntington. Possibly the heavy strain under which he worked in this capacity contributed to his untimely death, for he was working on plans for the replacement of a large tipple, which had been recently destroyed by fire, when he collapsed on February 27, 1947.

Mr. Gurley was registered professional engineer No. 54 in West Virginia. A leader among men, "Norm," as he was affectionately known to his friends, was active in the affairs of the West Virginia Section of the Society and in the West Virginia Society of Professional Engineers (former president of the Huntington Chapter and, at the time of his death, member of the State Board of Directors).

On June 29, 1916, he was married to Gladys Smith Hupp, in Parkersburg. From that day until he died, she stood by his side, taking pride in his achievements and sharing with him his love of motoring, photography, and music. Mr. Gurley is survived by his widow; a nephew, William B. Horstman, of Chicago, Ill.; and a niece, Mrs. Carl Berger, of Cincinnati, Ohio.

Funeral services were held at Huntington on March 1, 1947, and interment was in the Oak Grove Cemetery at Marietta on March 2, 1947.

Mr. Gurley was elected a Member of the American Society of Civil Engineers on May 20, 1946.

ISAAC HARBY, M. ASCE[1]

Died October 28, 1946

Isaac Harby, the son of Horace and Emma (Solomons) Harby, was born in Sumter, S. C., on February 25, 1873. His grandparents were early settlers in this community dating back to prerevolutionary days. His preliminary education was obtained in the schools of Sumter, and at the Citadel in Charleston, S. C. Along with a great many young men of the South at the time, he went for his college education to Union College in Schenectady, N. Y., from which he was graduated in 1895 with the degree of Bachelor of Science in Engineering. At Union he was a member of Delta Upsilon fraternity.

[2] "Better Track Through Turnouts as Transition Elements," by Norman B. Gurley. *Coal Age*, January, 1946.

[1] Memoir prepared by Louis W. Abrons, New Rochelle, N. Y.

Upon graduation, from July, 1895, to March, 1896, he was employed as architectural and engineering draftsman by George P. Post and Sons, of New York, N. Y. In March, 1896, he joined the Department of Buildings of the City of New York as special engineer, a position he held until 1900 except for the period of his military service (June, 1898, to February, 1899) as First Sergeant, Company K, First United States Volunteer Engineers, during the Spanish-American War. His work in the Building Department consisted of special examinations of unsafe buildings and in testing strength of various floor systems and various building materials.

In 1900 he was engaged as designer for structural steelwork, first for Brown, Ketchum Iron Works of New York City and later for S. C. Weiskopf,[2] M. ASCE, a consulting engineer of New York City. In the latter part of 1900 he accepted a position with the John A. Roebling's Sons Company of Trenton, N. J., and remained with that company until 1909. Until 1902 he was assistant engineer on the Roebling contract for the installation of the cables and suspenders on the Williamsburg Suspension Bridge spanning the East River in New York City. As a result of his work on the bridge he wrote a paper on "The Footbridge for Building the Cables of the New East River Bridge"[3] for which he was awarded the Collingwood Prize by the Society in 1903. He was also the author of an illustrated article in *Cassiers Magazine*, on "The Cables of the New East River Bridge." From 1902 to 1909 he was engineer in charge of the design and construction of various additions to the Roebling plant at Trenton, and at Roebling, N. J. The work at Roebling consisted of the construction of four hundred and seventeen residences; three hotels; stores; a municipal building; street paving, water, gas, and sewer systems; and sewage disposal works.

From 1909 to 1913 he was engaged on building work first in charge of construction at Forest Hills, N. Y., for the Sage Foundation Homes Company, and then in New York City for the Theresa Hotel and following that for the Lord and Taylor Store on Fifth Avenue. From 1913 to 1914 he was engaged as coordinator of war industries by the United States Labor Department.

In 1915 he joined with two other associates, namely, the late Ludlow L. Melius, Assoc. M. ASCE, who had been a classmate at Union College, and Louis W. Abrons to form the firm of Harby, Abrons and Melius, located in New York City and specializing in building construction. This association lasted until 1929. The company at first acted as general contractors but within a few years decided to limit its construction work to its own investment account. As a general contractor it built the Nurses Home for the Willard Parker Hospital, the Ward Island Power House, and the sewage disposal plant at the foot of Dyckman Street—all in the City of New York. Among the important buildings erected for the company's own investment account were a nine-story apartment building at Forty-four West Tenth Street, a thirteen-story apartment house at Twenty-five Fifth Avenue, office and business buildings at Thirty-three West Sixtieth Street and Two Hundred and Seventy Madison Avenue, and the twenty-five story "Murray

[2] For memoir, see *Transactions*, ASCE, Vol. 103, 1938, p. 1913.
[3] *Ibid.*, Vol. XLIX, December, 1902, p. 165.

Hill" office building at Fortieth Street and Madison Avenue. All these ventures were successful.

In 1929 Mr. Harby retired from active work to spend four years in Europe with his family. Some of this time he devoted to studying housing conditions abroad. Returning to New York in 1934 he mixed periods of retirement with periods of activity until the beginning of World War II. From 1934 to 1937 he was control engineer and adviser on the construction of large developments for the United States Housing Administration—five hundred and eighty-two houses at Greendale, Milwaukee, Wis., and four hundred and forty-eight family units at South Jamaica, Long Island, N. Y. The beginning of World War II brought him back to active service. From December, 1941, to September, 1946, he was supervising engineer for the Defense Plant Division of the Reconstruction Finance Corporation. He approved plans and the purchase of all production equipment for the projects assigned to him as well as supervised construction. Under his direction were four projects for the General Electric Company totaling \$7,500,000 (radio and electronics equipment); a \$2,500,000 project with the Adirondack Steel Company and the American Locomotive Company (guns and heavy steam engine work); a \$6,500,000 project with the National Lead Company (a railroad and development of a titanium mine); and finally a \$1,200,000 project for Lederle Laboratories (penicillin and biological plants).

Isaac Harby was first married in 1900 to May Levin, who died in September, 1920. He is survived by two children by that marriage, Anita and Esther (Mrs. Donald Cook). On November 5, 1921, he was married to Isabel Solomons. Two children by his second marriage, Anne and William, survive him.

Mr. Harby was elected a Junior of the American Society of Civil Engineers on June 6, 1899; an Associate Member on May 6, 1903; and a Member on May 2, 1911.

STEPHEN HARRIS, M. ASCE[1]

DIED JUNE 24, 1946

Stephen Harris was born in Pottsville, Pa., on October 15, 1864. He was the son of Stephen and Catharine (McArthur) Harris. He came from Scotch-Irish stock, his ancestors having settled in the Chester Valley of Pennsylvania about 1747. His father, a civil and mining engineer, was in charge, for the City of Philadelphia, Pa., of valuable coal properties for the Girard Estate. His uncle, Joseph Smith Harris, who had been his father's partner, was president of the Philadelphia and Reading Railway Company from 1893 until 1901. Stephen Harris, Sr., was killed in 1874 in a railroad accident leaving his son, Stephen, then only nine years of age, and three younger children.

[1] Memoir prepared by Laurence B. Manley, M. ASCE.

Under the influence of this environment, coupled with a natural aptitude for mathematics, it was not strange that the boy should be attracted to the engineering profession; and, after the family had moved to Germantown, Pa., he attended the Germantown Academy and, afterward, the University of Pennsylvania at Philadelphia from which he was graduated in 1886 with the degree of Bachelor of Science in Civil Engineering. He kept himself abreast of the rapidly expanding engineering profession, not only by constant study but also, in its practical application, by actual surveying and construction in the field. Few persons who knew him in his later years as a studious office worker realized the extent of his early outside experience and its great value to him in solving design problems, particularly in his specialty, urban transportation.

After graduation, Mr. Harris was assistant superintendent of the Lehigh Coal and Navigation Company. During the next eighteen years he had numerous engagements on surveys and design work, and was in responsible charge of construction—all this experience leading to more than twenty-two years of subway design in Philadelphia and Camden, N. J. Among these early surveys and reports, the most conspicuous was the work, which he directed between 1897 and 1900, of running a line of duplicate precise levels from the Caribbean Sea to the Pacific Ocean for the Nicaraguan Canal Commission. He also made surveys and reports for the United States Army Engineers on a projected 30-mile canal for the Intracoastal Waterway from Cape Fear to Little River, South Carolina, in 1910–1911; surveys for the Reading Railway Company in connection with the elevation of four and one-half miles of tracks in Philadelphia between Green Street and Wayne Avenue; surveys and some plans for two projected single-track tunnels under the Delaware River for three miles of connecting double-track railway at Camden, in 1909–1910; and surveys for other railroad projects in California and Porto Rico, the latter involving surveys and the design of structures for a projected railroad line ten miles long.

From 1895 to 1897 he was employed on preliminary work on the plans and in charge of the construction of a half-mile section of the Pennsylvania Avenue subway for the Survey Bureau, in connection with the City of Philadelphia grade crossing elimination program. He made the principal drawings and superintended the greater part of the construction for the Upper Roxborough filters from 1900 to 1902. From 1905 to 1908, as assistant engineer for the Philadelphia Rapid Transit Company, he was responsible for the determination of the profiles of the elevated lines and supervised the design of the mile of Market Street Subway east of the City Hall.

On July 10, 1913, at the beginning of the program of municipally constructed rapid transit facilities adopted by the City of Philadelphia, Mr. Harris was transferred from the Highway Bureau of the city, where he had been assistant commissioner of highways for about two years, to the newly organized Department of City Transit. He remained for nearly twenty years until the close of 1932 when all active work was brought to an abrupt close by lack of funds. Until 1924, he was assistant engineer on designs, and after

that designing engineer in charge of all plans except those relating to electrical installations.

Among the structures with which he was connected were the Frankford Elevated Railway about 6.2 miles long and about 11.1 miles of subway costing more than one hundred and thirty-seven million dollars, a large part of which were fully equipped for operation in his time. This project consisted, in round numbers, of 6.66 miles of four-track subway and 1.64 miles of two-track subway in Broad Street; 2.32 miles of a branch two-track subway in Ridge Avenue, Eighth Street, and Locust Street; and a short half-mile section of four-track subway in Market Street crossing under the Schuylkill River through the piers of a new bridge constructed as a part of one subway contract. Throughout the work Mr. Harris took a leading part in the determination of the alinement and grades, had full charge of the track layout, and also made many studies and reports on other projected lines.

In 1933 Mr. Harris was made engineer of design on the construction of a two-track branch from the Philadelphia subway system to Camden, about 2.7 miles long—known as the High Speed Rail Transit Line—for which Modjeski, Masters and Case, Incorporated, were the engineers. This line consists of tracks over the Delaware River Bridge, with connecting subways in Philadelphia and Camden (matching, as nearly as possible, those of the Philadelphia system), involving some necessary alterations to the bridge structure.[2] Again, Mr. Harris personally determined the alinement and grades and had complete charge of the preparation of plans and equipment including cars and substation buildings, but not including electrical equipment, the province of the electrical engineer.

The design of a modern rapid transit subway, in city streets bordered by high buildings, completely equipped with tracks, yards, buildings, and cars, constitutes an engineering problem of the first magnitude, calling for the joint efforts of specialists under able direction. The electric power facilities for the Philadelphia and Camden subways did not come under Mr. Harris' jurisdiction while he was designing engineer; but, nevertheless, the successful completion of the design of all other work connected with these subways is an outstanding engineering achievement and marks a fitting climax to his long and honorable career.

Upon the completion of the Camden subway Mr. Harris, then seventy-two years old and in poor health, retired from active engineering work. During the remaining ten years of his life he suffered severely from bronchial asthma and rested quitely, under the ministrations of a devoted wife, at his home in Chestnut Hill, Pa., where he died on June 24, 1946. His life revolved around his work. He enjoyed the outdoors, tramping in the Pocono Mountains (Pennsylvania), and boating on the Muskoka Lakes in Northern Ontario where he spent many vacations seeking relief from the asthma that afflicted him for years; but, in general, his spare time outside home duties and interests was given to study and the perfection of his professional work rather than to the pursuit of hobbies. How well his lifework profited thereby is evi-

[2] "Rapid Transit Begins Across Philadelphia–Camden Bridge," by Laurence B. Manley and Stephen Harris, *Engineering News-Record*, June 4, 1936, p. 811.

denced in the completeness of all his undertakings. A distinguishing trait of his character was his retiring disposition and a failure fully to appreciate and take advantage of his own capabilities, which led him to shun publicity and, unfortunately, not to receive credit for many successes for which he was primarily responsible. In private life, no one but those whom he often helped to tide over hard times will ever know how generously he could share with those in need.

Mr. Harris had many friends. He was respected by all, and loved by those who knew him well enough to pierce his shell of reserve and to appreciate his sterling qualities. He held the ethics of his profession high, and his character was above reproach. He was loyal to his superiors, unobtrusively helpful to any one needing aid or advice, and enthusiastic in his praise of good work—all with the quiet courtesy of good breeding which marked his sympathetic regard for the feelings of others.

Mr. Harris was married in 1899 to Agnes Cointat of Turny, France, who, together with two daughters, Eleonore Dubois (Mrs. Frank T. Gucker) and Katharine McArthur (Mrs. Henry Phillips), and four grandchildren, survives him. Until his retirement he was an associate of the American Railway Engineering Association, and was a registered professional engineer in the states of Pennsylvania and New Jersey. He was an active member of the Mount Airy Presbyterian Church for more than forty years.

Mr. Harris was elected a Member of the American Society of Civil Engineers on June 4, 1902. He became a Life Member in January, 1935.

EDWARD HAUPT, M. ASCE[1]

Died February 6, 1947

Edward Haupt was born at Philadelphia, Pa., on March 24, 1869. He was the son of Jacob Benjamin and Mary Elizabeth (Ziegler) Haupt. His earliest ancestor who came to this country was Sebastian Haupt who emigrated from Germany and arrived in Philadelphia in 1738.

Edward Haupt was a descendant of a noted engineering family and added to its reputation. His grandfather, Herman Haupt of Civil War fame, was responsible for the construction and operation of many lines of the Pennsylvania Railroad Company. He was one of the first men to develop the theories and formulas of scientific bridge design which he issued in pamphlet form in 1846, and a development of which was published by D. Appleton and Company in 1851. In 1862 he was placed in charge of the railway and transportation services of the federal armies and was commissioned a Colonel. Later Herman Haupt was made a Brigadier General and, as chief of construction and transportation of the United States military railroads, he had many inventions to his credit and received many honors. He died in 1905.

[1] Memoir prepared by J. L. McConnell, T. L. Condron, and I. F. Stern, Members, ASCE.

Edward Haupt's father, Jacob Benjamin Haupt, was a mechanical engineer who built the first practical mechanical fire engine used in the United States.

An uncle, Lewis M. Haupt, M. ASCE,[2] was professor of civil engineering at the University of Pennslyvania in Philadelphia, and was the author of a textbook on surveying, which was used as a standard for many years.

His brother, Charles, added an appendix on aerial mapping to this book in 1886. This was among the very first publications on that subject.

Ed Haupt, as he was familiarly known by his associates, attended the Philadelphia public schools and was graduated from the Central High School in 1886. He did not attend college but, on the advice of his uncle, Lewis M. Haupt, gained his vast engineering experience and knowledge in actual practice. From 1886 to 1896 he worked for the Phoenix Iron Company, in the rolling mill and in the drafting room, on the designing and estimating of steel structures.

In 1896 and 1897 he joined the Universal Construction Company, a subsidiary of the Illinois Steel Company, as secretary and later as president in charge of operations. This company designed and fabricated structural steel buildings and bridges, and was among the first promoters of steel car construction. From 1897 to 1904 Mr. Haupt represented various manufacturing companies in Chicago, Ill., among others the Mount Vernon Bridge Company of Mount Vernon, Ohio.

In 1904 and 1905 he was in New Orleans, La., as a partner in the firm of W. W. Bierce, Limited, representing the Cambria Steel Company, handling structural steel. In 1905 he joined Charles L. Strobel,[3] Hon. M. ASCE, as a member of the Strobel Steel Construction Company of Chicago—first as secretary, later as vice-president, and from 1920 to his death as president in executive charge of design and construction of fixed and movable bridges and framed structures all over the United States. His principal responsibility was the design and construction of bascule bridges.

Edward Haupt was a member of the Western Society of Engineers, and of the Chicago Engineers Club (past-president and honorary member). He was director of the Building Construction Employers Association and chairman of the Joint Conference Board to which were referred all disputes among the various building trades. As a member of the arbitration board for the structural steel workers union and their employers, he was instrumental in settling numerous disputes and was highly regarded by both sides. In 1921 he was a member of the citizens' committee sponsoring the "Landis Award."

Although Mr. Haupt was a very busy man, he always found time to serve others in a purely unobtrusive, unselfish manner, and his services were always available. His integrity was unquestioned. He had a wonderful sense of humor and a collection of quaint anecdotes which he related to his intimates but always in a modest way, giving credit for the story to one or other of

[2] For memoir, see *Transactions*, ASCE, Vol. 103, 1938, p. 1801.
[3] For memoir, *ibid.*, Vol. 102, 1937, p. 1491.

his numerous friends, who had probably never heard of it before the telling. His favorite recreation was golf which he played at every opportunity.

In 1894, in Phoenixville, Pa., he was married to Charlotte Maud Wistar who died on September 3, 1943. He is survived by one son, Caspar Wistar Haupt, M. ASCE, who has kept up the family tradition following in his father's footsteps, succeeding him as president of the Strobel Construction Company.

Mr. Haupt was elected an Affiliate of the American Society of Civil Engineers on January 31, 1911, and a Member on October 1, 1928.

JULES JOSEPH HENNEBIQUE, M. ASCE[1]

Died August 14, 1944

Jules Joseph Hennebique, the second son of François Hennebique (1842–1921) was born in Brussels, Belgium, in 1873. He attended the technical school in this city and at the age of twenty two joined the engineering office of his father in Paris, France.

François Hennebique, as a building contractor, desired to protect steel girders from the action of fire; he first embedded them in concrete, but, after making many tests, replaced the steel girders with steel rods placed longitudinally and transversely. This was to become the reinforced concrete beam, patented in 1886. He perfected his invention, making extensive tests on girders, slabs, and posts, and in 1898 he established himself as a consulting engineer on reinforced concrete structures, with offices in the main cities of Europe and America. This last measure contributed to the rapid adoption of the Hennebique system of reinforced concrete in many countries.

Jules Hennebique took an active part in this pioneer work and spent several months of the year 1900 in Bilbao, Spain, where a flour mill and a grain elevator were being built. In 1902 the Hennebique System was introduced in the United States; the Hennebique Construction Company was formed with head offices in New York, N. Y., and agencies in Baltimore, Md., Philadelphia, Pa., St. Louis, Mo., Boston, Mass., and Cleveland, Ohio. This concern, with its construction department, acted as engineer for contractors. The manager was R. Baffrey-Hennebique, a son-in-law of F. Hennebique, and Jules Hennebique was active in the construction department.

From its start, the company met with great success, and after a fire test proved successful in the laboratory at Columbia University in New York, many structures were erected. Reinforced concrete was used extensively in buildings, retaining walls, bridges, piers, quay walls, grain elevators, reservoirs, and similar structures. This development took place in less than five

---

[1] Memoir prepared by Prof. Gustave Magnel, M. ASCE, and Flamant Hennebique, Head of Bureau Hennebique, Paris, France.

years with Mr. Hennebique taking a large part in the improvement of building methods using the new material.

In 1908 he directed the construction of reinforced concrete seashore defenses in British Guiana, and in 1911 he took an active part in the construction of the Brandywine Lighthouse in the Delaware River. This structure is erected on a reinforced concrete caisson built on shore, floated into place, and supported by reinforced concrete piles driven through the bottom.

Among the reinforced concrete structures erected in the United States, the following deserve mention: In 1902—the floors of the McKinley High School in St. Louis, Mo.; the Sheldon House in New York; the reservoir in Fort Greble, R. I., for the War Department; and the Athletic Club Building in Baltimore; and in 1903—the Marine and Engineering Building at the U. S. Naval Academy in Annapolis, Md., and the Salvation Army Citadel in Cleveland.

In later years the many varied structures were to include: The Maverick Cotton Mills in Boston; the Boston Cold Storage building; the Union Cold Storage building in Jersey City, N. J.; a coal breaker for the Delaware, Lackawanna and Western Railroad Company; bridges for the Pennsylvania Railroad Company for the City of Philadelphia and others; piers for the Standard Oil Company in Brooklyn, N. Y., at Atlantic City, N. J., and at Long Branch, N. J.; quay walls for the Navy Department at Key West, Fla., and at Norfolk, Va.; and the National League grandstand in Brooklyn.

In 1914, Mr. Baffrey, the general manager of the Hennebique Construction Company, returned to France to serve in the French Army, leaving Mr. Hennebique to conduct the business. Mr. Baffrey did not return to the United States and Mr. Hennebique continued the management.

In 1904 Mr. Hennebique was married to Aimée Baffrey. He died after a long illness in 1944. A daughter, Yvette, survives.

Mr. Hennebique was elected a Member of the American Society of Civil Engineers on May 12, 1919.

DERWENT GORDON HESLOP, M. ASCE[1]

DIED JANUARY 28, 1944

Derwent Gordon Heslop, eldest son of Thomas H. B. and Gertrude (Goyder) Heslop, was born at South Shields, Durham, England, on October 30, 1877. He attended the Norwich Grammar School, and by the time he had attained school age his father was surveyor for the County of Norfolk. On leaving school he was sent to the works of Messrs. Aveling and Porter at Rochester, Kent, England, for training in mechanical engineering and after two years became a pupil of the Midland and Great Northern Joint Railway. On completion of his training his great desire was to do constructional engineering

[1] Memoir prepared by Mrs. Derwent G. Heslop, Eastcote, Middlesex, England.

work abroad; in the years from 1900 to 1931 he succeeded in seeing much of the world.

His first appointment in 1900 was to Upper Assam Province, India, where he took charge of mechanical construction on the Tiphook Tea Estate. After a year he became assistant engineer on the Bengal Nagpur Railway and remained on construction and maintenance work for six years. In 1907 he was appointed assistant engineer of railway location in the Republic of Colombia, South America, a position which lasted for two years. The next appointment took him to South China where he worked as resident engineer on construction and design of the Canton Hankow Railway. This employment ended in 1911 when the Chinese Revolution forced him to leave the country. Having relatives in Australia, Mr. Heslop spent the next two years there—first, in the west and, later, in Victoria and the northern provinces as assistant engineer and chief of survey party under the Commonwealth Gevernment.

After a leave in England in 1913, Mr. Heslop was appointed assistant engineer on construction of the Ceylon Government Railways; he remained in that country until 1915 when, realizing that World War I was not going to be of short duration, he returned to England and joined the Royal Engineers. He was with the British Army in France, Egypt, Palestine, Syria, and Anatolia, enlisting as a sapper and retiring with the rank of Major. In France and Palestine he engaged in railway construction.

After the cessation of hostilities in the East and while he was still in military service his most important appointment was as chief engineer of the Bagdad Railway and the Hedjaz Railway. He was also officer in charge of the survey company laying out a pipe line across the desert—which work had to be abandoned because of hostile tribes, but which has since been completed.

After the demobilization in May, 1920, Mr. Heslop was acting chief resident engineer on the Gold Coast in 1921, and from 1923 until 1931, when he left the tropics for the final time, he was employed by the Crown Agents for the British Colonies in Tanganyika—first, rebuilding the Lukonde Bridge and, later, extending the railways. Because of his age he could no longer obtain employment abroad; from 1937 to 1940, he held a temporary appointment on the Great Western Railway in England and was responsible for its air raid shelters at many points on the line between London and Oxford.

During World War I Mr. Heslop wrote several articles for the engineer on the Bagdad Railway, and after he left Tanganyika, at the request of his family and friends, he wrote and published the story of his life, entitled "Through Jungle Bush and Forest," which disclosed some very unique experiences.

Soldiering was always one of Mr. Heslop's greatest interests. Wherever he found himself he always joined the local force if one was available. In later years he became an ardent cinematographer and showed his films of Tanganyika to many schools in England under the auspices of the British Empire Society.

Mr. Heslop is survived by his widow; a daughter, Dorothy Goyder Heslop; and a son, Robert Stanley Gordon Heslop.

Mr. Heslop was elected an Associate Member of the American Society of Civil Engineers on May 2, 1911, and a Member on June 2, 1920.

PHILIP BROCKETT HILL, M. ASCE[1]

DIED MARCH 23, 1946

Philip Brockett Hill was born in Brooklyn, N. Y., on April 14, 1877. He was the son of Philip Hamilton and Emma (Tompson) Hill.

He received his early education in the public schools of Nashville, Tenn., his college preparatory training in the Webb School at Bell Buckle, Tenn., and was graduated from Vanderbilt University at Nashville in 1900, with the degree of Bachelor of Engineering. In 1931 his alma mater conferred upon him the professional degree of Civil Engineer at the same exercises during which his daughter, Marion, received the degree of Bachelor of Arts.

Prior to completion of his formal education and for the first two years following graduation, Mr. Hill was employed on the surveys for, and the design of, the Tennessee Central Railroad in and around Nashville and from Nashville to Lebanon, Tenn. In 1902 and 1903 he was with the Walsh and Weidner Boiler Company of Chattanooga, Tenn., as engineer in charge of the drafting room on the design of water tanks and towers and the preparation of all the estimates for structural work and platework and special boilerwork.

In 1903 and 1904 he went to St. Louis as assistant engineer in the Department of Sewers, Water Supply, and Fire Protection for the Louisiana Purchase Exposition. He worked on both design and construction and then, during the exposition, on maintenance of those facilities. Mr. Hill stated, "I had a varied and interesting experience there." Following his work at the exposition he went to Copperhill, Tenn., where he was an engineer with the Tennessee Copper Company, which at that time was doubling the capacity of its plant and adding a sulfuric acid plant to convert the destructive sulfur fumes into a commercial product. Mr. Hill was engineer in charge of the powerhouse extension, and laid out the foundations for the building and machinery and supervised a large part of the construction of the sulfuric acid plant, including a 300-foot chimney, furnaces, and trackwork.

A large part of Mr. Hill's professional work was devoted to practice as a consulting engineer. From 1906 to 1922 he was a partner with Fred M. Lund in the engineering firm of Lund and Hill at Little Rock, Ark. Little Rock was a fast-growing city, and Mr. Hill's firm designed and built many miles of streets and sewers for the City of Little Rock and for neighboring towns. Lund and Hill also designed and supervised the construction of many miles of highways radiating from Little Rock. Other projects handled by Lund and Hill involved the design of special floodway gates for levee work and of pumping plants for low drainage areas in Arkansas and West Tennessee.

From 1923 to 1926 Mr. Hill was engineer for the Continental Rock Asphalt Company in Leitchfield, Ky., a company engaged in mining and

[1] Memoir prepared by Roland A. Kampmeier, M. ASCE.

marketing rock asphalt for use as a paving material. In 1926 Mr. Hill moved to Florence, Ala., and opened a consulting engineering firm of his own. He stated, "Early in 1926 I chose the Muscle Shoals area as a promising field for engineering practice." His principal work there until 1933 was on land development and municipal improvements.

When the Tennessee Valley Authority (TVA) was established in 1933, Mr. Hill was appointed civil engineer at Wilson Dam in Alabama, in charge of transmission line surveys and right of way in the Power Engineering and Construction Department, which position he held until his death in 1946. In 1941 Mr. Hill's office was moved from Wilson Dam to Chattanooga, where he continued in the same capacity. During his thirteen years with the TVA, Mr. Hill's organization surveyed and obtained the right of way for several thousand miles of transmission lines. His work placed him in contact with a large number of landowners throughout the Tennessee Valley and adjacent areas, locating transmission lines across their properties and also making contracts for the clearing of these rights of way. Mr. Hill's work with the TVA was characterized by excellent relationships with these thousands of people; and, because of his fairness and sincere methods of dealing with others, he did much to maintain good will between all parties concerned.

Mr. Hill was an active and faithful member of the Methodist Church wherever he resided and was appointed to the boards of stewards of the churches at Little Rock, Leitchfield, Florence, and Chattanooga. At Florence, he was chairman of the board for several years. He was a member of the Delta Kappa Epsilon college fraternity and of the Masonic Blue Lodge at Little Rock. He was a Thirty-Second Degree Scottish Rite Mason and a member of the Alhambra Shrine Temple at Chattanooga. He was also a member of the American Association of Engineers.

When he resided in Florence and Wilson Dam, he was a member, and at one time president, of the Florence Rotary Club. He was interested and active in alumni work for both Webb School and Vanderbilt University. His work in each of these alumni groups entailed heavy correspondence, but was very gratifying to him, since he always enjoyed hearing from friends and associates of other years.

Mr. Hill was a Christian gentleman in the true sense of both words. His word was his bond. In addition to always being very considerate of the other fellow and having a kind word for and about everyone, he had a wonderful sense of humor and enjoyed a good joke on himself as well as on others. He was indeed young in spirit and was never taken to be his real age. Mr. Hill was very prompt in all his duties and very careful to meet every obligation, both social and business. His thinking was clear, his language was correct and concise, and his work was always done neatly and in an orderly and systematic way. He was very capable with his hands, and created for his home and for his friends many objects reflecting careful and loving workmanship. A talented photographer, he pleased his friends each year with unusual Christmas greeting photographs. He had a valuable collection of old coins and stamps which had interested him a number of years.

In 1908 he was married to Elizabeth Fletcher Fite, daughter of James W. Fite and Marion Fletcher Fite, at Hendersonville, Tenn. He is survived by his widow; his daughter, Marion Dudley Hill of Murfreesboro, Tenn.; and a sister, Edith (Mrs. Marvin S. Enochs), of Jackson, Miss.

On his passing, his local associates in the Society recorded the following expression of their sorrow at his untimely death and of their appreciation of his splendid qualities:

> "With profound sorrow the Chattanooga Sub-Section of the American Society of Civil Engineers records the death of one of its most earnest and loyal members—Philip Brockett Hill. Mr. Hill was for thirty-four years a corporate member of the Society, giving unstintingly of his time and efforts in advancing the affairs of the Society. He was most faithful in attendance at meetings and could be counted on to be present unless prevented by circumstances beyond his control. His friends, neighbors, and the community could count on Philip, too. His counsel and advice were highly valued. His ability as an engineer won the respect of his associates and his warm heart and friendly spirit, the affection of all who knew him."

Mr. Hill was elected an Associate Member of the American Society of Civil Engineers on April 30, 1912, and a Member on September 10, 1918.

THOMAS VICTOR HODGES, M. ASCE[1]

Died June 12, 1946

Thomas Victor Hodges, the son of Thomas Benton Hodges and Katherine Elizabeth (Dissisway) Hodges, was born in New Orleans, La., on September 5, 1881. He was the youngest of four children, having a sister and two brothers, none of whom survive. His father, a contractor, was killed in an accident before Mr. Hodges was born. The Hodges family returned to Maine, the father's home state; the mother died soon after, and Mr. Hodges was reared by relatives.

He attended elementary schools at Bath, Me., high school at Bridgton, Me., and entered the University of Maine at Orono in 1901, remaining for two years. He found it necessary to leave the university to earn money for completing his education.

His first engineering work, from December, 1903, to April, 1904, as a rodman on surveys for the Hampton Terrace Hotel Company of Augusta, Ga., was followed by five months of work as rodman, instrumentman, and draftsman with the International Paper Company on the construction of a new paper mill at Berlin, N. H. He then entered Swarthmore College in Swarthmore, Pa., from which he was graduated in 1906 with the degree of Bachelor of Arts, with a major in civil engineering.

---

[1] Memoir prepared by George S. Beal, M. ASCE.

Mr. Hodges was employed during the summer of 1905, and after graduation from college, until June, 1908, by the American Pipe and Construction Company which was constructing a series of water supply systems for the Pennsylvania Railroad Company along the railroad's lines in Pennsylvania. He was engaged on surveys, design, and construction; among other duties, he was resident engineer on the construction of reservoirs near Latrobe (Pa.) and Mifflintown (Pa.), and engineer and inspector on the laying of fifty miles of cast-iron pipe.

Later in 1908 he was contractor's engineer for the firm of Lewis and Wiley on the Jackson Street regrade, in Seattle, Wash.—an interesting project involving the moving of a large quantity of earth by hydraulic sluicing. For about three years, until 1911, he was draftsman and engineer on surveys and design of highways and highway structures with the Los Angeles County Highway Commission. This was followed by a year with the Department of Public Works of Santo Domingo in the Dominican Republic.

Upon returning to the United States, he spent a year with the American Water Works and Guarantee Company in charge of the installation of mechanical filters at New Castle, Pa., and the construction of an earth dam at Suffolk, Va. Subsequently, he was engaged by the New York Continental Jewell Filtration Company, until October, 1915, building plants at Harrisburg, Ill., and at Albion and Lyons in New York.

Mr. Hodges' next engagement, with the Semet-Solvay Company of Syracuse, N. Y., was a long and interesting one. From 1915 until a reorganization of the company late in 1924, he was safety engineer and insurance manager. In this capacity he was responsible for engineering design and plant operation involving accident prevention, fire prevention, sanitation, ventilation, health, and insurance. In addition, he handled many special investigations and studies for water supplies and sewage disposal as well as studies of labor relations in other industries.

After leaving the Semet-Solvay Company Mr. Hodges had a short engagement as engineer in charge of topographical surveys and property maps for the Laurel Park Estates in Hendersonville, N. C. Then, because of the illness and advancing age of his father-in-law, Joseph M. Cranston, of Philadelphia, Pa., Mr. Hodges assumed management of Mr. Cranston's coal and building material business which was sold in 1927.

Next, in the employ of the Pennsylvania Railroad Company for about two years, he was engineer in charge of: The construction of a water supply system at Conowingo, Md.; the design and construction of a half-mile-long dike on the east side of the Susquehanna River, as an extension of the Conowingo Dam, to protect the railroad; the reconstruction and grouting of the foundation of the Brush Mountain Dam near Altoona, Pa.; and the construction of a mechanical filter plant at Dauphin, Pa.

In 1929 he became resident engineer for the Philadelphia Surburban Water Company on the construction of the Springton Dam on Crum Creek in Delaware County, Pennsylvania. This structure, two thousand feet long and eighty feet high, created a reservoir with a capacity of 3,500,000,000 gallons of water. In addition, he was also responsible for the construction of

a new filter plant with a fifteen million-gallon daily capacity at Media, Pa., for the same company.

From January, 1932, until his death in 1946, Mr. Hodges was employed by the Bureau of Waters and the Water and Power Resources Board in the Department of Forests and Waters of the Commonwealth of Pennsylvania. The first two years he worked on the Pymatuning Reservoir project, which was then being built to regulate the flow of the Shenango and Beaver rivers in western Pennsylvania. He had charge of construction of the dam near Jamestown, Pa., and later of a combined highway and railroad embankment, near Linesville, Pa., which also served as an auxiliary dam across an arm of the reservoir.

Later he supervised the design and construction of forty dams of various types, from seven feet to forty feet high, forming lakes up to 250 acres in extent, in recreation areas on state forest lands. As assistant director of the Bureau of Waters, he was responsible for the proper allocation and use of the water resources of the state and assisted in the state supervision of the design, construction, and maintenance of all dams, except those federally owned, in Pennsylvania. At his death he was district engineer in charge of the Schuylkill River desilting project.

A conscientious, capable, and reliable engineer, he was well loved and respected by his superiors, associates, and subordinates. Mr. Hodges was married twice; his first wife was Mary Bernard Cranston to whom he was married in 1912. She died in November, 1917. One child of this marriage, Elizabeth Cranston (Mrs. James A. Murphy), survives. On June 1, 1920, he was married to Katharine Curtin, of the famous Curtin family of Centre County, Pennsylvania, who survives with one son, Thomas Victor Hodges, Jr., a student at Swarthmore College.

In addition to the Society, he belonged to the Engineers Society of Pennsylvania and the Masonic Fraternity. He was a member of the Beta Theta Pi fraternity at the University of Maine and of Book and Key at Swarthmore College.

Mr. Hodges was elected a Member of the American Society of Civil Engineers on February 13, 1940.

NEIL CUMMINGS HOLDREDGE, M. ASCE[1]

Died October 10, 1946

Neil Cummings Holdredge, the son of William Martin and Ida Paulina (Cummings) Holdredge, was born at West Burlington, N. Y., on January 2, 1883. After attending a little red schoolhouse and two high schools, he was graduated from Union College at Schenectady, N. Y., in 1905, with the degree of Bachelor of Engineering. He was a member of Beta Theta Pi fraternity.

[1] Memoir prepared by Max F. Freund, Assoc. M. ASCE, and Paul H. Bird, Geologist. New York City Board of Water Supply, Ellenville, N. Y.

Immediately following college, he went to work as a structural steel detailer; but soon he realized that his temperament was unsuited to this type of employment. He then secured employment with the Brooklyn Rapid Transit Corporation and rapidly advanced from the position of inspector to assistant engineer on elevated railway construction.

Mr. Holdredge first joined the forces of the Board of Water Supply of New York City, N. Y., in October, 1906, as assistant engineer, and was assigned to the Esopus Division of the Northern Aqueduct Department on the construction of the Rondout pressure tunnel. In 1910 he was promoted to section engineer and the following year was transferred to the City Aqueduct Department, Bronx Division, where he served in the same capacity until November 30, 1915, when he temporarily severed his connection with the Board.

Then, for three years, he was an assistant engineer with the Borough President of Manhattan in charge of sewer construction. From August, 1918, to January, 1919, he was field engineer with the Air Nitrates Corporation on the construction of a nitrate plant at Cincinnati, Ohio.

For the next seventeen years, 1919 to 1936, he was with the North Jersey District Water Supply Commission as assistant chief engineer. In this capacity, he had direct charge of construction for the complete development of a water supply project of one hundred million gallons per day costing $25,000,000. The work included the Wanaque and six other dams together with some twenty miles of pipe line aqueduct, two tunnels, bridges, and the usual amount of highway and railroad relocation. During the last two years of this period he was connected with the operation of the water supply.

From March until September, 1936, he was construction engineer with Greeley and Hansen in charge of a $15,000,000 sewer project in Buffalo, N. Y., but left this position at the call of the New York City Board of Water Supply to serve as division engineer in the Newburgh Division which was then attached to the Watershed Department. After seven months as division engineer, he was made department engineer of the Northern Department, supervising the construction of the Rondout-West Branch tunnel. He retired on June 30, 1944.

The Northern Department and Neil C. Holdredge and the longest continuous tunnel on earth are inseparable in the minds of the men who enjoyed the privilege of calling him "boss" and seeing the "hole" go through. He endeared himself to his associates by his appreciation of sincere effort. He pulled no punches, stated in no uncertain terms what he wanted done, and was eminently fair in his dealings with both his own force and the contracting organizations. His friends will remember a Holdredge institution—the cheer he dispensed at clambakes, at banquets, whenever Board of Water Supply men got together, the best of cheer!

On February 11, 1908, in Guilderland, N. Y., he was married to Emma Veeder Relyea. He is survived by his widow and a daughter, Lois Caroline (Mrs. Halsey Peckworth).

Mr. Holdredge was elected an Associate Member of the American Society of Civil Engineers on October 31, 1911, and a Member on April 17, 1923. He became a Life Member in January, 1946.

PAUL HOLLAND, M. ASCE[1]

DIED APRIL 14, 1946

Paul Holland, the son of Martin and Ann (Drew) Holland, was born on July 14, 1895, in Big Rapids, Mich. He received his grammar school education in Big Rapids and attended high school in Grand Rapids, Mich., being graduated from Central High School in that city in 1913. In the fall of that year, he entered the Engineering College of the University of Michigan at Ann Arbor.

Mr. Holland's university education was interrupted by a period of service in World War I, but he returned to the university upon receiving his discharge after the armistice. He graduated with the class of 1919, receiving the degree of Bachelor of Science in Civil Engineering.

Mr. Holland's employment began on November 15, 1919, with the Board of County Road Commissioners of Wayne County, Mich., and he was employed by that organization until his death. He virtually grew up with it, becoming chief designing engineer in the early 1920's. In that capacity, he was in charge of designing the entire Wayne County road system of 2,400 miles of highways and superhighways.

In 1928, the board undertook the development of the mile square Wayne County Airport. Mr. Holland was placed in charge of preparing the designs, plans, and specifications for this project. More recently, and until his death, he was preparing the plans and designs for the expansion of this airport.

Other activities of the board in which Mr. Holland participated included the out-county sewage disposal and water supply systems, the Wayne County system of parks and parkways, and the John C. Lodge Expressway, now ready for construction in Detroit, Mich. His knowledge of national, state, county, and local road affairs made him invaluable to the county in his professional capacity.

Paul Holland was a member of the Highway Research Board of the National Research Council, the Michigan Engineering Society, the Engineering Society of Detroit, and the Michigan Section of the American Society of Civil Engineers, as well as being a registered professional engineer and land surveyor in the State of Michigan.

He was married to Mary Josephine Whalen on February 1, 1922, at Big Rapids. He is survived by his widow; a son, Robert M. Holland; a daughter, Margery Holland; three brothers, Cornelius, Martin, and Thomas Holland; and two sisters, Ellen (Mrs. E. Commons) and Anne Holland.

Mr. Holland was elected a Member of the American Society of Civil Engineers on November 12, 1940.

[1] Memoir prepared by Joseph W. Gross, Assoc. M. ASCE.

HAROLD RISTINE HOLMES, M. ASCE[1]

DIED JUNE 6, 1946

Harold Ristine Holmes was born in Tabriz, Persia (Iran), on April 6, 1885. His parents were Dr. George W. Holmes, a Presbyterian medical missionary, and Eliza (Wisner) Holmes, both of whom were born in the United States. They lived in Persia until Harold reached the age of twelve, when the family returned to the United States.

He attended high school in Wellesley, Mass., and was graduated from Princeton University at Princeton, N. J., in 1908 with the degree of Civil Engineer. For two years following his graduation Mr. Holmes worked as a rodman for the New York State Engineer's Department, running instruments, drafting, and computing in connection with a barge canal construction at Lockport, N. Y. From 1910 to 1911, he was an assistant engineer for the New York Highway Commission in charge of construction work and responsible for some designing.

Mr. Holmes' next position, for a period of five years, was with the New York State Public Service Commission for the First District, New York, N. Y., on subway and elevated rapid transit construction. From 1913 to 1916, he was in responsible charge of construction on route No. 50, subway and elevated rapid transit route in Long Island City, N. Y. He was then employed by Manion Brothers Company, Incorporated, estimating industrial and school buildings; and, for a time, he was a draftsman for the Shepard Electric Crane and Hoist Company.

From May, 1918, to May, 1919, Mr. Holmes was a member of The American-Persian Relief Commission. Later the work and part of the personnel were taken over by the Near-East Relief, which became the Near-East Foundation. Harry Pratt Judson, then president of the University of Chicago, in Chicago, Ill., was head of the commission. Mr. Holmes was selected for this work not only because of his knowledge of the language and customs of the country, but also because of his engineering knowledge and ability, as the commission expected to set up engineering projects as relief work for war refugees.

Upon arrival at Hamadan, Persia, he took over the duties of secretary-treasurer of a relief committee there. This committee purchased food and clothing for many thousands of people in various near-by camps. It also loaned money to responsible refugees in order that they could return to their homes. In September, 1918, Mr. Holmes stated that the price of bread in Hamadan was twelve krans per mann but six months later it was only five krans per mann, thus reflecting the efforts of the relief committee. Some additions to a hospital building were carried out under his direction, and he also organized a group of refugees and had them making quilts and beds for the hospital.

[1] Memoir prepared by Lloyd D. Knapp, M. ASCE.

In December, 1918, he went to Teheran, Persia, to urge the British Legation to pay the outstanding bills of the Refugee Relief Fund. There he organized relief work and was in charge of it until March, 1919. With the assistance of the native police, the various wards of the city were canvassed, and needy families were given weekly cash relief. While in Teheran, he examined a road construction project which he advised against, as available labor would be needed in the spring for agricultural purposes.

Upon his return to New York, he was employed in several capacities until February, 1921, when he was appointed city engineer and building inspector in Lockport. In 1923 he became office engineer for the Long Island Railroad Company, and following this he was an engineer for Consoer, Older and Quinlan of Chicago.

In 1925 he was employed by the Bureau of Sewers of the City of Milwaukee (Wis.), as a sewer designer, and in a short time he was made chief sewer engineer, which position he held until his death. During this period he was responsible for the design of sewers costing approximately twenty million dollars. Among the more important projects on which he was engaged were the twelve-foot-diameter relief tunnel on North Twenty-Sixth Street, the eight-foot-diameter tunnel on West Becher Street, and the seven-foot by ten-foot double box sewer on North Thirty-First Street.

During the first years of his employment in Milwaukee, Mr. Holmes, in cooperation with others, developed a rainfall intensity curve, considered to be somewhat better than the curve then in use. Later he was instrumental in having the city purchase several rain gages and, with the data thus obtained, continued his studies on rainfall. He did a great deal of original work on the subject, largely on his own time, and finally developed still another rainfall intensity curve which is more accurate than either of the others, particularly in the range of high intensities. It is expected that this curve will be adopted for use by the City of Milwaukee. By the development of this curve he made a distinct contribution to the sum of engineering knowledge.

As a student of world affairs, Mr. Holmes was internationally minded and interested in all efforts to bring about world peace. In Milwaukee he was one of the organizers of the Committee to Defend America by Aiding the Allies; in fact, the first meeting was held in his home. In addition, he was active in urging the United States Government to prohibit the sale of oil, scrap iron, and other war supplies to Japan, anticipating the later known results of such acts.

Mr. Holmes was a registered engineer in Wisconsin and a member of the Wisconsin Society of Professional Engineers. He also belonged to the Princeton Engineering Society and the Engineers' Society of Milwaukee.

On September 26, 1911, he was married to Gertrude Oliver Baker in Lockport. He is survived by his widow and a son, George, a chemical engineer. A daughter, Barbara, died in 1945.

Mr. Holmes was elected an Associate Member of the American Society of Civil Engineers on March 16, 1925, and a Member on July 5, 1933.

ARTHUR GRANT HOLT, M. ASCE[1]

DIED JUNE 28, 1946

Arthur Grant Holt, the son of Edmund Dyer Holt and Caroline (Warner) Holt, was born in Chatfield, Minn., on August 30, 1864. He was a descendant on his father's side of Nicholas Holt, who came to Massachusetts from England in 1635, and on his mother's side of Andrew Warner, who came in 1632.

Mr. Holt had the advantage of an ancestry that was steeped in good old New England ideals. His mother attended Mount Holyoke College in South Hadley, Mass., and his father was a graduate of Amherst College at Amherst, Mass., from which he received the degrees of both Bachelor of Arts and Master of Arts. Later, Edmund Holt was graduated from the Union Theological Seminary in New York, N. Y.

While Mr. Holt was still very young, his father died, leaving his mother to bring up the children alone. In this situation, she proved her fortitude. When the children were ready to attend college, the family moved to Minneapolis so that the children could enter the University of Minnesota there. Mr. Holt was in the class of 1885, specializing in mathematics. He was a member of Phi Delta Theta fraternity.

He first went to work for an uncle in Moline, Ill.; but, since railroads fascinated him, he decided to enter that field. He obtained employment with the Chicago, Milwaukee and Saint Paul Railway Company (later the Chicago, Milwaukee, Saint Paul and Pacific Railroad Company) in August, 1885, as rodman and draftsman in the office of the division engineer at Minneapolis. In 1888 he became instrumentman and resident engineer on location and construction of new lines near Fergus Falls, Minn., for the Minnesota and Manitoba Railroad Company (later the Great Northern Railway Company). The next year he was with the Duluth, Winnipeg, and Pacific Railway Company on work near Cloquet, Minn.

In 1890 Mr. Holt returned to the Minneapolis office of the Chicago, Milwaukee and Saint Paul Railway Company and gradually took charge of location and construction of new lines, especially in South Dakota. He had charge of the lines from Eureka to Linton (N. Dak.), Woonsocket to Wessington Springs, Armour to Stickney, and Madison to Sioux Falls. In 1905 he was sent to Seattle, Wash., to report to the late W. L. Darling, Hon. M. ASCE, then chief engineer of the Puget Sound lines, who placed him in charge of two parties locating a line through Natches Pass of the Cascade Mountains. In this capacity, Mr. Holt supervised four locating parties through the Snoqualmie Pass. Also included in this work was a reconnaissance survey for a line from Cedar Falls to Everett, Wash.

In 1906 he was appointed division engineer in charge of location and construction of the main line from the Columbia River to Plummer, Idaho, and

[1] Memoir prepared by T. H. Strate, M. ASCE.

then of the St. Maries Branch, also in Idaho. After this, Mr. Holt was in Seattle for a short time before going to Spokane, Wash., where he was in charge of location and construction of lines into and through Spokane, including the Coeur d'Alene lines.

When the line to the coast was finished, he was transferred to Chicago, Ill., in February, 1913, as assistant chief engineer. He held this position until 1932 when he was appointed assistant to the chief engineer, continuing until his retirement in 1938.

Mr. Holt enjoyed a wide acquaintanceship in the engineering profession and with railroad contractors, all of whom had a high regard for him and respected his judgment and advice. He was well-liked and admired by all his associates and will always be remembered for his high ideals.

He belonged to the American Railway Engineering Association. He also was a member of the Presbyterian Church, the Blue Lodge, Knights Templar, and the Shrine in the A. F. and A. M.

Mr. Holt was married on October 11, 1893, to Caroline Warner, of Hatfield, Mass., who died in 1917, and, on January 31, 1924, to Alice Brenne, of Sioux City, Iowa. He is survived by his widow; two daughters, Lois Holt (Mrs. L. H. Schmidt) and Elisabeth Holt (Mrs. L. S. Holler); a son, Arthur Grant Holt, Jr.; and two grandchildren, Elisabeth Jane Holler and John Holt Holler.

He was buried in Chatfield.

Mr. Holt was elected a Member of the American Society of Civil Engineers on April 5, 1910.

JOHN CLAYTON HOYT, M. ASCE[1]

DIED JUNE 21, 1946

John Clayton Hoyt was born in La Fayette, N. Y., on June 10, 1874. He was the son of Newton and Mary (Ford) Hoyt.

The broad foundation of his technical education was laid at the College of Civil Engineering, Cornell University, in Ithaca, N. Y., from which he was graduated with the degree of Civil Engineer in 1897. The new hydraulic laboratory in Fall Creek was then under construction, and his first engagement was as an assistant engineer with the Cornell Hydraulic Laboratory Construction Company. He had a few years of experience with the United States Board of Engineers on Deep Waterways, the Bureau of Yards and Docks of the Navy Department, and the United States Coast and Geodetic Survey before entering the service of the United States Geological Survey in the Water Resources Branch where he succeeded Gerard H. Matthes, Hon. M. ASCE, as chief of the computing section on September 3, 1902.

[1] Memoir prepared by Charles H. Pierce, M. ASCE.

Stream-gaging work in Alaska was started by Mr. Hoyt in the spring of 1906 when he was detailed to make an investigation of the water resources available for placer mining in the vicinity of Nome on the southern slope of the Seward Peninsula. Two years later, he made a water-power reconnaissance in southeastern Alaska. The results of these two pioneer investigations are described in Geological Survey *Water-Supply Paper No. 196* and *Water-Supply Paper No. 372.*

After being actively connected with the supervision of stream gaging for several years as assistant to F. H. Newell,[2] M. ASCE, and M. O. Leighton, M. ASCE, in 1911 he was placed in charge of the Division of Surface Water, a position he held until December 18, 1930, when he relinquished his administrative duties to act as consultant to the chief hydraulic engineer and to the director. During his long service in the Water Resources Branch, Mr. Hoyt achieved a nation-wide reputation for his knowledge of hydrology and his improvements in equipment and methods for obtaining hydrologic data. Much of the equipment used in measurements of river discharge was originally designed or improved under his direction while he was chief of the Division of Surface Water.

Mr. Hoyt made numerous contributions to engineering literature on subjects relating to hydrology and water resources. He was responsible for the preparation of many official reports and water-supply papers, including "Droughts of 1930–1934," *Water-Supply Paper No. 680,* and "Drought of 1936," *Water-Supply Paper No. 820*—with discussion of the significance of drought in relation to climate. The authoritative text on "River Discharge,"[3] of which he was author jointly with N. C. Grover, M. ASCE, was first published in 1907 and was followed by a second edition in 1912 and by third and fourth editions at two-year intervals. This was, undoubtedly, the best known and the most widely used publication on the subject at that time.

He was a frequent contributor to the publications of the Society, his paper on "Use and Care of the Current Meter as Practiced by the United States Geological Survey"[4] being an outstanding example. He was always active in the affairs of the Society and was influential in organizing the District of Columbia Section. He gave unsparingly of his time to promote the activities of the Section, serving on many committees and in various offices, including that of President. Notwithstanding his failing health and physical weakness, his unfailing interest in Society affairs brought him to the Annual Meeting in New York, N. Y., on January 16–18, 1946, and to the dinner meeting of the District of Columbia Section on January 29. From 1920 to 1922 he served the Society as a Director and, in 1927–1928, as a Vice-President.

Mr. Hoyt was one of the founders of the Washington Society of Engineers, of which he was secretary (1908–1915) and president (1916). In the formation of the American Engineering Council, he served as secretary of the meeting at which the council was organized and throughout the life of

[2] For memoir, see *Transactions*, ASCE, Vol. 98, 1933, p. 1597.

[3] "River Discharge," by John C. Hoyt and Nathan C. Grover, John Wiley & Sons, Inc., New York, N. Y., 1st Ed., 1907.

[4] "The Use and Care of the Current Meter as Practiced by the United States Geological Survey," by John C. Hoyt, *Transactions*, ASCE, Vol. LXVI, March, 1910, p. 70.

the council he acted either as a representative of the Society or of the District of Columbia Section. He was a member of the Washington Academy of Sciences and vice-president in 1917.

His peculiar talents in organizational work and his wide acquaintance with members of the engineering profession were recognized by his appointment as the representative of the Department of the Interior on the American Committee at the World Power Conference in London, England, in 1923; as the official United States delegate at the Fourteenth International Congress of Navigation at Cairo, Egypt, in 1926; and as a delegate to the World Engineering Congress at Tokyo, Japan, in 1929.

For many years Mr. Hoyt served on the board of directors of the Union Trust Company, in Washington, D. C. He was a member of the Cosmos Club, serving the club as chairman of many important committees and as vice-president in 1920 and president in 1921; the Chevy Chase Club; and the National Press Club. He belonged to the honorary society of Sigma Xi.

Mr. Hoyt's interest in the welfare of engineers, especially those in federal employment, was shown by his work on the Engineering Council Committee on Classification and Compensation of Engineers. An article in *Civil Engineering*[5] gives a brief description of the results that were obtained, largely through the efforts of that committee. The interest that he took in everyday affairs and the wide range of his activities were evidenced by the courtesy card given him by the District of Columbia Department of Vehicles and Traffic as an award for his "Traffic Suggestions" to promote safe and sane driving. The award also included membership in the Traffic Advisory Council.

On October 31, 1900, he was married to Jennie Farnham King of Tully, N. Y. He is survived by his widow; a son, Kendall K. Hoyt; and a brother, William Glenn Hoyt, M. ASCE.

John Hoyt possessed strong determination and great perseverance, and he unswervingly followed the paths that he believed to be right and for the greatest good. A marked characteristic was his loyalty to his friends; his friendship was enduring and his memory will long be cherished by those who were associated with him.

Mr. Hoyt was elected an Associate Member of the American Society of Civil Engineers on May 4, 1904, and a Member on June 1, 1909. He became a Life Member in January, 1939.

FRANK DAVID HUTCHINSON, M. ASCE[f]

DIED DECEMBER 18, 1946

Frank David Hutchinson was born on November 25, 1880, at Pine Lake in the Town of Caroga Lake, Fulton County, New York. His father, Frederick

[5] "Classification and Compensation of Federal Engineering Positions," by John C. Hoyt, *Civil Engineering*, March, 1936, pp. 194–197.

[f] Memoir prepared by Frank D. Hutchinson, Jr., Sales Engr., New York, N. Y.; Theodore C. Tuck, Civ. Engr., New York, N. Y.; and Charles E. Pett and J. H. Lawrence, Assoc. Members, ASCE.

E. Hutchinson, a native of Connecticut, was a lumberman and furniture manufacturer; his paternal grandfather, David Hutchinson, was a western pioneer. His mother, the daughter of John Culver, a farmer, was born in Blandford, Mass. He was named "Frank" after his uncle, Frank, and "David" after his paternal grandfather, but was always known to his friends as "Hutch."

Mr. Hutchinson's early childhood was spent at a logging camp in Pine Lake. When he was nine years old, his father left the lumber business and moved to Keyser, W. Va., to become a partner in a mill for manufacturing furniture. Hutch attended the public schools there and was considered an excellent student—in fact, he was graduated at the age of sixteen. During the years at Keyser, he drove cows for a farmer to earn pin money.

Upon completion of his schooling at Keyser in 1897, he entered West Virginia University in Morgantown, with the idea of becoming a doctor. However, after two years he decided to become a civil engineer and in 1902 was awarded the degree of Bachelor of Science in Civil Engineering. While attending the university, he became a member of the Beta Theta Pi fraternity and was active in its support during his lifetime.

Mr. Hutchinson's first position in the engineering field was with the McClintic Marshall Construction Company in Rankin, Pa., from 1902 to 1903, as draftsman on shop details for mill buildings. On leaving Rankin, he went to Steelton, Pa., where he worked as draftsman and designer in the Erection Department of the Pennsylvania Steel Company, from 1903 to 1904.

In 1904 he began his major lifework with Post and McCord, structural engineers and contractors, on the erection of structural steel in New York, N. Y., and continued with that company for thirty-five years. During this period, Mr. Hutchinson was engineer, in complete charge of preparing shop and erection drawings of the steelwork for many large buildings. These included most of the major electric and steam power plants in New York, as well as many skyscraper office buildings, banks, department stores, pier sheds, schools, and churches. In some cases, his work involved the complete structural design, and, in many others, complicated erection problems. Among the contracts handled by him for Post and McCord were the Empire State Building, 30 Rockefeller Plaza, the Chrysler Building, the Yale Club, the Chase National Bank, and several buildings in the area over the New York Central Railroad tracks about Grand Central Station.

Mr. Hutchinson was twice married, first, to Ellen A. Fowle in 1906, and the second time, to Anne Marie St. Clair in 1922. His son, Frank D. Hutchinson, Jr., survives. His home was in Bronxville, N. Y., where he took particular delight in raising flowers.

In 1940 he was engaged by the Metropolitan Device Corporation of Brooklyn, N. Y., to design the steelwork for industrial plants in the midwest and later was connected with the extensive war work carried on by that company. At the time of his death, he was structural engineer.

Mr. Hutchinson was elected a Member of the American Society of Civil Engineers on November 26, 1918.

THEODORE REED KENDALL, M. ASCE[1]

DIED FEBRUARY 4, 1946

Theodore Reed Kendall was born in Boston, Mass., on April 25, 1890, the son of Joseph Sewall and Bertha (Allen) Kendall. He was educated in Boston elementary schools and in Boston English High School. In 1908 he entered Harvard College, in Cambridge, Mass., and was graduated in 1912 with the degree of Bachelor of Science, and in 1914 received the degree of Master of Civil Engineering from the Harvard Engineering School.

After graduation in 1914, Mr. Kendall studied stanitary engineering projects in France, Germany, and England, and on his return was employed as an assistant to the late Prof. George C. Whipple,[2] M. ASCE, of Harvard University. Under Professor Whipple he was engaged in various sanitary engineering projects, including surveys, mapping and reports, and investigations of stream pollution of the Blackstone River in Massachusetts and Rhode Island, and oyster pollution in Narragansett Bay, R. I. Also, as water works engineer and superintendent, he was in charge of operation and rehabilitation of the Agua Clara Filtration Plant, Gatun, Canal Zone.

In March, 1917, Mr. Kendall entered the publishing field as engineering editor of *The American City,* a career which was destined to continue with distinction for the remainder of his life, except for the interruption of military service in World War I. From January to December, 1918, he served as First Lieutenant with the Sanitary Corps of the United States Army with various assignments in Washington, D. C., and in charge of operation and construction of water works at Petersburg, Va., and Watervliet, N. Y.

In January, 1919, Mr. Kendall returned to his position as engineering editor of *The American City* and also of *The Municipal Index,* and in May, 1920, in addition to his other duties, he became editor of *Contractors' and Engineers' Monthly,* a publication which he helped to found. Later, he withdrew as engineering editor of *The American City,* but continued as its consulting editor until September, 1943.

During the period of more than twenty-five years in which he was associated with the Edgar J. Buttenheim publications, his coverage of engineering projects included field trips and studies of all phases of construction throughout the United States, Canada, and Mexico, writing descriptive articles on water supply, sewage disposal, refuse collection and disposal, street and highway construction and maintenance, bridges, tunnels, foundations, docks, dams, and subways—practically the entire field of the heavy construction industry. His travels and his writings made him a nationally known figure in the engineering and construction world.

In addition to an extremely active life in the professional engineering field, he found time to devote to the activities of technical societies. He served two

[1] Memoir prepared by Dean G. Edwards, M. ASCE.

[2] For memoir, see *Transactions,* ASCE, Vol. 88, 1925, p. 1453.

terms, in 1927–1928 and in 1931–1932, as Director, and one term, in 1928–1930, as Vice-President, of the Metropolitan Section of the Society. He also served for several years on the Metropolitan Section's Committee on Student Guidance and frequently assisted in the work of this committee in the high schools of New York City.

Mr. Kendall was particularly active as a member of the Harvard Engineering Society. He assisted in its organization in 1920, when the society was formed by a consolidation of formerly existing associations of Harvard engineers. He was its first treasurer, serving for two years, then he served as its secretary for seven years, and became its president in 1929–1930.

During his undergraduate days, he had been editor in chief of the *Harvard Engineering Journal*. In 1920, drawing from his rich experience, he started *The Harvard Engineering Society Bulletin* and became its first editor. His keen interest and unselfish devotion to the Harvard Engineering Society will long be remembered by his host of friends.

Mr. Kendall was also a member of the American Road Builders' Association and a director of the association at the time of his death. In addition, he was a member of the American Society of Mechanical Engineers, the Boston Society of Civil Engineers, the Society of American Military Engineers, the American Water Works Association, the New England Water Works Association, and the American Public Works Association.

A resident of South Nyack, N. Y., for many years, he served as village trustee from 1924 to 1926, and was president of the Men's Club of Nyack in 1926–1927. Among his many friends, Mr. Kendall will always be remembered for his delightful personality, his keenness and ability to think and express himself intelligently and forcefully, his unfailing good humor, his ready wit, and his capacity for work.

He was married to Helen Wilbur Brown of Providence, R. I., on January 10, 1917. He is survived by his widow and two daughters, Cynthia Thurston and Bernice Alden Kendall.

Mr. Kendall was elected an Associate Member of the American Society of Civil Engineers on April 25, 1921, and a Member on July 14, 1930.

HENRY KERCHER, M. ASCE[1]

DIED JANUARY 8, 1946

Henry Kercher was born in Germantown, Ohio, on November 12, 1887. He was the son of Alvin C. and Ermina (Fudge) Kercher.

He was educated in the public schools of Germantown and at Ohio State University, in Columbus. From the latter institution he received a degree in civil engineering in 1910.

[1] Memoir prepared by Warren W. Parks, M. ASCE.

Mr. Kercher started work in his chosen profession immediately upon his graduation, and for two years served as draftsman with the Mount Vernon (Ohio) Bridge Company. He continued in this capacity with the King Bridge Company of Cleveland, Ohio, for a few months, when he was advanced to assistant engineer. His connection with this firm continued until January, 1923. For four years he was rated as chief draftsman, and for the last five years as assistant chief engineer.

During his affiliation with the King Bridge Company, Mr. Kercher had a hand in the design and construction of movable railroad bridges, the Detroit-Superior Bridge at Cleveland, various railroad and highway bridges, traveling cranes, movable bridge machinery, turntables, and mill buildings.

In January, 1923, Mr. Kercher joined the engineering staff of the Cleveland Union Terminals Company. His first assignment was as designer on estimates of cost of overhead bridges, railroad viaducts and structures for electrification of railroads, large retaining walls, and building foundations. The next year he was rated as assistant engineer, preparing estimates and checking designs for high retaining walls and railroad viaduct piers, as well as for the foundations for the Terminal Tower Building which rises 735 ft above the footings. His connection with the Cleveland Terminal continued until its completion in 1930.

In 1930 Mr. Kercher moved to Cincinnati, Ohio, to become chief engineer for the Broadway and Newport Bridge Company of Newport, Ky. This company operates a toll bridge over the Ohio River between Cincinnati and Newport. After serving as chief engineer for one year, he was named vice-president and general manager of this company, and he served in this capacity at the time of his death. The operation of this bridge involved many maintenance problems and public relations in connection with its use for street cars, buses, and private vehicular transportation.

During all his years as a structural designer, involved as they were with heavy responsibilities and complicated problems of design, Mr. Kercher found relief and relaxation through two most interesting hobbies. He took great pleasure in collecting rare coins and had assembled a small but superb collection of early Greek and Roman coins, the former from the period prior to the Hellinistic era, and the latter during the period of the Republic. He specialized in early Athenian coins and many of his specimens from Athens are extremely rare—only a few others are known to be in existence. Many ancient cities are represented in his collections.

In connection with the collection of coins, Mr. Kercher spent about ten years on a comprehensive study based on statistical methods of the determining of weight standards of ancient coins. He gathered information from museums and individuals in Europe and the United States. These calculations were completed, but a book which he planned was never finished. Hundreds of pages of calculations and observations, bound in book form, have been forwarded to the American Numismatic Society in New York, N. Y. These were bound into nine large volumes and are to remain on file after a recapitulation has

been completed. A professor at Princeton University at Princeton, N. J., has undertaken to finish the work started by Mr. Kercher.

The other hobby, the pursuit of which gave him much pleasure and material for conversation, was his study of American archeology. He started collecting Indian relics as a boy. "Mill's Archeological Atlas of Ohio" included much material supplied by Mr. Kercher. He had visited and was familiar with practically every site of major importance in southern Ohio. Mr. Kercher personally explored and excavated at the Anderson, Taylor, and Madisonville sites in Ohio, and surveyed and made maps of the Anderson explorations at Fort Ancient. These maps are the property of the Ohio State Archeological and Historical Society.

From this recital of Mr. Kercher's professional activity and his hobbies, it is evident that he never lacked an interesting subject for conversation, and he was always very generous in sharing his experiences and his discoveries.

In addition to all these activities, Mr. Kercher found time to fulfil his duties as a churchman and a useful citizen in the community. He was a member of the Engineering Society of Cincinnati and active in the Cincinnati Section of this Society, having served as President for a term.

Mr. Kercher married Jeannette Good, at Westerville, Ohio, on June 27, 1912. In addition to his widow he is survived by two children, a daughter, Dorothy (Mrs. M. D. Knoop), and a son, Robert A. Kercher.

Mr. Kercher was elected an Associate Member of the American Society of Civil Engineers on April 18, 1916, and a Member on January 16, 1928.

BURR ROBERT KULP, M. ASCE[1]

Died February 27, 1946

Burr Robert Kulp was born in Duncannon, Pa., on December 16, 1883, the son of John David and Alice May (Bowers) Kulp. His ancestors came from Germany and settled in southeastern Pennsylvania early in the eighteenth century. His grandfather's farm was a part of the Gettysburg Battlefield. In 1887 his parents moved to Harrisburg, Pa., and it was in that city that he grew up and went to grammar school and high school. He then attended Rensselaer Polytechnic Institute at Troy, N. Y., where he received the degree of Civil Engineer in 1905, and where he was a member of the Theta Nu Epsilon fraternity.

He was employed by the Chicago and North Western Railway Company in June, 1905, as instrumentman, and spent his entire professional career with that railway. He subsequently held the positions of architectural draftsman, assistant engineer, division engineer, trainmaster, again division engineer, then principal assistant engineer, engineer of maintenance, and chief engineer. He was chief engineer of the Chicago and North Western Railway Company,

[1] Memoir prepared by George W. Hand, M. ASCE.

from May, 1940, and also of the Chicago, St. Paul, Minneapolis and Omaha Railway Company, from April, 1943, until his death.

Mr. Kulp was a member of the American Railway Engineering Association (a director), the Western Society of Engineers, the American Railway Bridge and Building Association, and the Rensselaer Society of Engineers.

The positions he held are indicative of the high quality of engineering skill that he possessed. During his career he planned and constructed may of the railway's important structures and facilities and was responsible for the efficient expenditure of large amounts of money for both construction and maintenance. His professional ability contributed greatly to the success of the railway with which he was associated, and this, together with his winning personality, earned him the respect and warm friendship of his associates.

Mr. Kulp was a trustee of Rensselaer Polytechnic Institute in 1938, 1939, and 1940. He was a communicant of St. Luke's Episcopal Church in Evanston, Ill.

In fraternal matters he was also active, being a member of the F. and A. M., the Knights Templar, and the Shriners. He belonged to the Oriental Consistory at Chicago, Ill. He also belonged to the Union League Club of Chicago and the Evanston Golf Club.

Mr. Kulp was married on February 6, 1906, to Edna Mary Herbst of Chicago, who died in 1927. They had a son, John Herman. On April 1, 1929, he married Gertrude Elizabeth Madden of Sparta, Wis. He is survived by his widow; his son, John Herman; and a brother, George R. Kulp.

He died in his home in Evanston and was buried in Forest Hill Cemetery, Madison, Wis.

Mr. Kulp was elected a Member of the American Society of Civil Engineers on May 18, 1943.

CHARLES SCOTT LANDERS, M. ASCE[1]

DIED JULY 27, 1946

Charles Scott Landers was born in Thurmont, Md., on August 27, 1879. He was the son of John and Harriet (Forman) Landers.

After being graduated in 1900 from the Sheffield Scientific School at Yale University in New Haven, Conn., with the degree of Bachelor of Science, he spent two years as designer and resident engineer on the Guayaquil and Quinto Railway in Ecuador, South America. In 1903 he returned to the Sheffield Scientific School as instructor in engineering and graduate student, receiving the degree of Civil Engineer in 1904, and membership in the Society of Sigma Xi.

When the Hudson River railroad tunnels were projected in 1904, Mr. Landers joined the Pennsylvania Railroad Company as construction engi-

[1] Memoir prepared by Charles R. Krieg, M. ASCE.

neer. On this project he acquired his first experience in compressed-air subsurface operations. This led to his association with The Foundation Company in 1906 as engineer and superintendent on pneumatic caisson foundations for many early skyscrapers, including the Singer Tower and the Trinity buildings, in New York, N. Y. He then joined the engineering staff of the Board of Water Supply of New York City where he remained for a period of two years as engineer and designer.

In 1911 Mr. Landers entered private practice as a consulting engineer in New York, specializing in pneumatic caisson and other difficult foundation methods. As consultant, designer, or as supervisor for owners, architects, and contractors, he participated in the foundation work for such noteworthy buildings in New York as the Woolworth Building at 233 Broadway, the Bankers Trust at 16 Wall Street, the Equitable Building at 120 Broadway, the W. R. Grace and Company Building at 7 Hanover Square, the Continental Bank Building at 30 Broad Street, the Squibb Building at 745 Fifth Avenue, the United States Federal Office Building at Vesey Street, the buildings at 80 Broad Street and 29 Broadway, and many others.

Similar foundation engineering outside the New York area included the Gulf Oil Building at Pittsburgh, Pa.; the Hackensack River bridges for the Pennsylvania Railroad Company; the L. Bamberger Company addition at Newark, N. J.; the powerhouse for the Ohio Power Company's (American Gas and Electric Company) Windsor Plant at Power, W. Va.; and others.

Mr. Landers' participation in underpinning problems included the Trinity Church tower and a number of buildings on the route of the Nassau Street Extension of the Brooklyn-Manhattan Transit System in lower Manhattan. His efforts, however, were not confined to substructure engineering. A great tennis enthusiast, he designed the tennis stadium of the West Side Tennis Club at Forest Hills, Long Island, of which he was a former president. He also acted as expert witness in many cases for the Corporation Counsel of the City of New York, and his extensive knowledge of substrata conditions in and about New York was solicited by many architects and engineers.

As a civic-minded citizen, he was a member of the Federal Grand Jury Association of the Southern District of New York, and gave much time to its work, particularly during his two-year tenure as president. Mr. Landers was also a member of the Yale Club, the Yale Engineering Society, the Society of Sigma Xi, the "Moles," and the West Side Tennis Club.

He was respected by all who knew him, and his benign and gracious personality will be missed by all his associates. Many young engineers benefited by his advice and assistance in placement in engineering positions. He was truly a humanitarian, and broad in all his thoughts and actions.

On November 10, 1909, Mr. Landers was married to Josephine Schramm in New York. He is survived by his widow and a son, Charles Scott Landers, Jr.

Mr. Landers was elected a Member of the American Society of Civil Engineers on October 10, 1927.

LOUIS EMILE LAURENT, M. ASCE[1]

DIED NOVEMBER 5, 1945

Louis Emile Laurent, the son of Eugene J. and Helen A. (Goold) Laurent, was born in Paris, France, on June 30, 1874. He was brought to the United States at an early age by his parents. His family was asociated with some of the leading families of New York, N. Y., such as the Coopers, the Hewitts, and the Havemeyers. He was educated in the public schools of New York, at Cooper Union, also in New York, and at Princeton University, in Princeton, N. J.

From 1897 to 1900 he was employed by the Johnson Foundry and Machine Company in New York and for the next nine years was engaged by the Trenton Iron Company of Trenton, N. J., in the design, and later in the erection, of aerial tramways and mill and mining machinery. In the latter capacity he had charge of the construction of large installations at Bingham Canyon, Utah; Cranbrook and Kimberly, B. C., Canada; Placerville, Calif.; and Velardenia, Durango, Mexico. This work brought him in close touch with the mining industry and developed in him an interest which resulted in his taking part in the organization of the Santa Eduviges Mining Company.

In 1909 Mr. Laurent was made manager and went to Sonora, Mexico, where his company acquired mining property. Under his management the property was developed and the operation was brought to a paying basis when the country was disrupted by the revolution under Francisco Villa. The property was confiscated and the manager was sentenced to be shot. By a ruse he outwitted his captors and escaped. He made his way back to the United States, but with his investments lost.

From 1914 to 1916 he worked for the American Steel and Wire Company at Denver, Colo., as sales engineer on cableways and tramways. In 1917 he entered the employ of the Erie Railroad Company as assistant engineer on the design and installation of heating, refrigeration, and air conditioning facilities.

His ingenuity was put to a test when, in the heat of summer, he was called on by the management to make an immediate installation to cool the six auction rooms at its fruit sale piers in New York. He devised a scheme for pumping ice water through the steam mains and unit heaters. The installation was rushed, and in three weeks he had the temperature in the auction rooms reduced by 8° or 10°, to the satisfaction of all concerned. The idea was original with him, as he had not heard of its use before. It has been used since. In June, 1945, he retired because of ill health.

Mr. Laurent was a member of the New York Engineers Club and of the F. and A. M. He became a citizen of the United States, but the delightful French characteristics of courtesy and chivalry clung to him throughout life.

[1] Memoir prepared by Charles H. Splitstone, M. ASCE.

His fine qualities of honesty, loyalty, and cooperation claimed the affectionate regard of his associates.

On November 16, 1928, he was married to Deal Jean Bushnee Stephens in Jersey City, N. J. His marriage was a happy one. He is survived by his widow.

Mr. Laurent was elected a Member of the American Society of Civil Engineers on September 9, 1940.

WILLIAM IRA LEE, M. ASCE[1]

DIED JULY 5, 1946

William Ira Lee was born in Greensville County, Virginia, on September 18, 1872. His parents were Samuel Wornum and Rebecca Ellice (Wyche) Lee. He was educated at the Emporia (Va.) Academy before enlisting in the United States Army at the age of twenty one.

After serving in the Army for three years, he began work in 1897 as rodman with the Richmond, Petersburg and Carolina Railroad (later part of the Seaboard Air Line Railway). He continued with this company until January, 1900, and was promoted, successively, to levelman, instrumentman, and resident engineer. Then he was employed by various railroads in the south and southwest as locating engineer and resident engineer on railroad construction.

In the fall of 1907, Mr. Lee first entered the highway construction field with the Virginia Highway Department. He returned to the Winston-Salem Southbound Railway in September, 1909, and remained until April, 1911, as resident engineer on construction.

Mr. Lee returned to the Virginia Highway Department in the spring of 1911 and, except for a few months as county engineer of Mercer County, West Virginia, remained with that department until the outbreak of World War I. He served as resident engineer and was promoted to division engineer at Lynchburg, Va.

He went on active duty as a Major in the Engineer Reserve Corps of the Army on October 11, 1917, and sailed for France on October 29. First, he served with the British Ninth Army Corps for observation and training and, later, was assigned as superintendent of roads and quarries for Base Sector No. 1 at St. Nazaire, France. In March, 1919, he returned to the United States being released from active service on June 18, 1919. After the war Mr. Lee remained in the Engineer Reserve Corps until he was retired because of age. During this period he was promoted to Lieutenant Colonel and Colonel. At the time of his retirement he was commanding officer of the 305th Engineers.

Shortly after returning to the Virginia Highway Department in 1919, he was appointed engineer of plans and surveys. However, in February, 1921,

[1] Memoir prepared by Harold J. Spelman, M. ASCE.

he resigned to enter the contracting business for himself. From 1922 to 1925 he was county engineer for Charles City County, Virginia.

He began work for what was then known as the United States Bureau of Public Roads in July, 1928, on the surveys for the Mount Vernon Memorial Highway. In 1930 he was promoted to the grade of associate highway engineer and was placed in charge, under the district engineer, of grading and paving construction on that important project. Upon completion of that work in August, 1932, he was assigned to head the field office then opened at Gatlinburg, Tenn., and was subsequently promoted to highway engineer and senior highway engineer. Although he was retired because of age in September, 1942, he was immediately returned to service and remained at Gatlinburg until October 1, 1945.

During his thirteen years at Gatlinburg he supervised the surveys, design, and construction of the roads built in the Great Smoky Mountains National Park; the Chickamauga-Chattanooga National Military Park; the Guilford Court House (North Carolina) Park; and thirty miles of the Blue Ridge Parkway, immediately adjacent to the Great Smoky Mountains National Park.

Among the projects planned and built by Colonel Lee during this period was the road from Newfound Gap at El. 5050 on the crest of the "Smokies" to Gatlinburg at El. 1800. This road was described by the late W. T. B. MacCormack, a visiting Australian engineer, in 1937, in part, as follows: "The trip down to Gatlinburg was wonderful—stone bridges, massive stone walls, fine tunnels, and one particular work known as 'Lee's Loop,' a triumph for the designer." "Lee's Loop" is a circular alinement requiring a bridge where the road crosses over itself. This unusual design replaced a bad triple switchback in the old pioneer road.

Another difficult, picturesque, and interesting project located, designed, and built by Colonel Lee was the road along the ridge of the Smoky Mountains from Newfound Gap to Clingman's Dome, climbing from 5,050 feet to 6,200 feet above sea level. This splendid mountain highway is the highest road east of the Mississippi River.

In July, 1904, at Atlanta, Ga., William I. Lee was married to a native of that state, Mattie Cunningham, whom he first met while engaged on railroad work near her home. Mary Ellice Lee of Alexandria, Va., is their only child. Mrs. Lee died on April 30, 1924. On April 6, 1941, Colonel Lee was married to Mildred Comyn Crawford of Waynesville, N. C., who survives him.

The passing of Colonel Lee, at the age of seventy four, some nine months after his retirement from active practice, removed from the highway field one of the few remaining engineers whose early training and experience was on railway location and construction. The "Colonel," as he was called affectionately by his many friends for the last twenty years of his life, was known for his hearty laugh which "shook the rafters." Of powerful physique, six feet tall, he was erect and energetic until past seventy years of age. Affable and pleasant in personality, he could be stern and quick to reprove careless errors in his subordinates. Even in his later years he kept abreast of developments in his chosen field by reading. He encouraged his younger associates

to do the same, frequently lending them books from his own not inconsiderable engineering library.

His early experience in railroad location and construction and in highway surveys, plans, and construction contributed to the rounded knowledge as a finished highway engineer that marked his later professional career. He was meticulous in every detail, accurate in his judgment and work. His plans as well as his construction were finished products of quality.

The young men who worked under his direction during the last fifteen years of his professional career obtained a thorough training in engineering fundamentals. Accuracy, careful attention to details, completeness of records of work accomplished, and a high quality of construction were all stressed by Colonel Lee. He was fair and just in his dealings with contractors who performed work under his direction.

He was a member of the American Legion and the Veterans of Foreign Wars, and he belonged to the Episcopal Church.

Colonel Lee was elected a Member of the American Society of Civil Engineers on October 15, 1923.

CONDE BALCOM McCULLOUGH, M. ASCE[1]

DIED MAY 6, 1946

Conde Balcom McCullough, the son of John Black and Lenna (Balcom) McCullough, was born at Redfield, S. Dak., on May 30, 1887. He received his elementary education in the public schools of Fort Dodge, Iowa, and his engineering training at Iowa State College at Ames, from which he received the degree of Bachelor of Science in Civil Engineering in 1910 and the professional degree of Civil Engineer in 1916. Busy as he was with his engineering work, he found the time and energy to complete a course in law at Willamette University in Salem, Ore., receiving the degree of Bachelor of Laws in 1928. He was admitted to the Oregon bar and, although never active in the legal profession, retained his membership until his death. Recognizing his many contributions to engineering literature and his services to the state, the Oregon State College at Corvallis conferred the degree of Doctor of Engineering on him in 1934.

Civil engineering claimed Mr. McCullough's primary interest even in his boyhood. In 1905, prior to entering college, he worked as rodman, chainman, and transitman on railway maintenance and reconstruction for the Illinois Central Railroad Company in Illinois and Indiana. Immediately after graduation, he secured a position as assistant engineer with the March Engineering Company in Des Moines, Iowa. In 1911 he joined the Iowa State Highway Commission at a time when that organization was in its infancy. He served as designing engineer and assistant to Thomas H. MacDonald, Hon. M. ASCE, then state highway engineer of Iowa.

[1] Memoir prepared by G. S. Paxson, M. ASCE.

Oregon State College brought Mr. McCullough to Oregon in 1916 as assistant professor and later as professor of civil engineering. He remained on the college faculty until 1919, being on leave of absence during part of 1918 when he served as Captain of Engineers in the United States Army.

In May, 1919, he became bridge engineer for the Oregon State Highway Commission. The construction of the modern highway system of Oregon was just getting under way following the end of World War I, and the organization which Mr. McCullough built was new and entirely his. During his sixteen years of service as bridge engineer and later as assistant state highway engineer, he planned and supervised the design and construction of literally thousands of bridges and buildings for the state highway commission. The bridges which he built in Oregon are known throughout the world for their beauty. Among the best known are the steel arches over the Willamette River at Oregon City and Yaquina Bay at Newport; the concrete arches over the Rogue River at Gold Beach; the steel cantilever over Coos Bay at North Bend; and the McLoughlin Bridge over the Clackamas River on United States route No. 99, south of Portland. The McLoughlin Bridge, a series of tied steel arches with concrete approaches, was built in 1933 and was rated by the American Institute of Steel Construction as the most beautiful steel bridge in its class built in that year.

In 1936 Mr. McCullough was granted a leave of absence to serve with the United States Public Roads Administration, supervising the design and construction of bridges on the Inter-American Highway in Central America. During the year and a half which he devoted to this work, major bridges in Honduras, Nicarauga, Guatemala, and Panama were built. His headquarters were at San José, Costa Rica; and, because of the large territory covered and the primitive rail and highway system existing at that time, much of his travel was by air.

Upon his return to Oregon in 1937, he was made assistant state highway engineer and immediately undertook an analysis of the economic features of the highway system. The results of this work—three technical bulletins published by the Oregon State Highway Comission on "The Economics of Highway Planning," "The Determination of Highway System Solvencies," and "An Analysis of the Highway Tax Structure in Oregon"—have received nation-wide recognition for their clear and logical presentation of this difficult subject.

Mr. McCullough was the author of several textbooks on structural subjects. They include "Economics of Highway Bridge Types"[2] and "Elastic Arch Bridges."[3] In the latter book he was coauthor with Edward S. Thayer. He also wrote bulletins on "Highway Bridge Surveys"[4] and "Electrical Equipment on Movable Bridges."[5] In recent years he became interested in suspen-

[2] "Economics of Highway Bridge Types," by C. B. McCullough, Gillette Pub. Co., Chicago, Ill., 1929.

[3] "Elastic Arch Bridges," by Conde B. McCullough and Edward S. Thayer, John Wiley & Sons, Inc., New York, N. Y., 1931.

[4] "Highway Bridge Surveys," by Conde B. McCullough, *Technical Bulletin No. 55*, U.S.D.A., Washington, D. C., 1928.

[5] "Electrical Equipment on Movable Bridges," by C. B. McCullough, A. L. Gemeny, and W. R. Wickerham, *Technical Bulletin No. 265*, U.S.D.A., Washington, D. C., 1931.

sion bridges and was coauthor, with other members of the Oregon State Highway Department, of five technical bulletins on this subject. At the time of his death he was chairman of the subcommittee on Interpretation and Analysis of the National Advisory Board on the Investigation of Suspension Bridges. A few months before his death he published, as coauthor with his son, John R. McCullough, a two-volume treatise entitled "The Engineer at Law,"[6] which has had a very favorable reception by the profession because of its clear presentation of the subject.

Mr. McCullough felt keenly his civic obligations to his state and community and was always ready to serve on public projects. He had, for several years, been chairman of the Salem City Planning Commission and had given generously of his time and energy to the development of the city.

He belonged to the American Society of Civil Engineers, the American Concrete Institute, the Northwest Society of Highway Engineers, Tau Beta Pi, Sigma Tau, and Delta Theta Phi, the honorary legal fraternity. He was a communicant of the Episcopal church.

Mr. McCullough was married to Marie Roddan at Perry, Iowa, on June 4, 1913. He is survived by his widow and a son, John R. McCullough.

The following tribute to him as a man and an engineer headed the editorial page of a newspaper in his home town:

> "C. B. McCullough was a gallant soul who lived life to the full. He gave much from his great mind and overflowing heart, and from life he derived rich satisfaction in achievement, in generous participation in affairs and hearty companionship. So there is something appropriate in his being called when life for him stood at flood tide—no slow fading of powers on a tardy ebb. But what a void he leaves in his profession, among his professional associates and among the wide host of his friends!"

Mr. McCullough was elected an Associate Member of the American Society of Civil Engineers on March 14, 1916, and a Member on March 5, 1928.

JAMES HENRY STEWART MELVILLE, M. ASCE[1]

Died April 17, 1946

James Henry Stewart Melville was born on May 2, 1878, in Birnam Wood, Jamaica. His family was closely identified with the British West Indies for several generations.

His father, Charles Melville, a clergyman of the Church of England, was rector of the parish of Saint Elizabeth and canon of the Diocese of Jamaica. His paternal grandfather was a doctor, a graduate of the University of Edinburgh in Scotland; his grandmother was the former Eliza Choppin of St. Vincent, British West Indies.

[6] "The Engineer at Law," by Conde B. McCullough and John R. McCullough, The Collegiate Press, Inc., Ames, Iowa, 1946.

[1] Memoir prepared by George W. Burpee, M. ASCE.

At one time in the early 1860's, his grandfather practiced in New York, N. Y. During that period young Charles, although only fourteen years of age and fired with enthusiasm for the Union cause, attempted to enlist in the Union Army, giving his age as sixteen. As he was large for his age he was about to be accepted when he was discovered by a friend of the family and sent home. He then went to Jamaica to work on an uncle's estate, and was so impressed with the need of the native Jamaicans for help and guidance that he decided to enter the ministry.

James Melville's mother, the daughter of a clergyman, was born in Jamaica. Her father was born in the Barbadoes in the British West Indies, and her mother was the daughter of a clergyman who came to Jamaica from Ireland at the age of two. Since his father, one grandfather, and a great-grandfather were all clergymen, and one grandfather was a physician, it would be natural to expect that James Melville inherited a strong bent toward a life of service to others.

One in a family of ten, having five brothers and four sisters, he was educated at Jamaica College. From 1895 to 1898 he served an apprenticeship as a draftsman with the late W. S. Wortley, engineer and contractor of Kingston, Jamaica. For part of the time, in 1898–1899, he was associated with the Jamaica Government Railway and was assistant to the government inspector of electric tramways during the construction of the tramway system in Kingston. For the next seven years (1899–1906), he was in the office of the Commanding Officer of the Royal Engineers at Up-Park Camp, starting as a draftsman and, finally, becoming chief draftsman.

In 1906 Mr. Melville was attracted by the opportunities which the United States then offered young engineers, and he moved from Jamaica to New York. There he became associated almost immediately with the engineering department of the New York Central Railroad Company, commencing work as a draftsman and, subsequently, becoming assistant engineer under the late Victor Spangberg, engineer on the West Side Improvements in New York.

During the years of his association with that railroad, his work was principally on preliminary plans for the elimination of the freight tracks from the streets in New York, and the incidental layouts for freight terminals and warehouses related thereto. He also participated in valuation studies and in the various investigations which are common to all railroad engineering departments.

In 1913 he was employed as engineer with Westinghouse, Church, Kerr and Company, Engineers and Constructors, of New York, and for the next eight years was engaged on design and construction of many industrial and railroad projects, as well as on numerous engineering investigations. Throughout 1918 and the first half of 1919, he was office engineer on the construction of the United States Nitrate Plant, Number II, at Muscle Shoals, Ala., one of the mammoth undertakings of World War I. In 1921, upon completion of the American Rolling Mill Company's East Works at Middletown, Ohio, on which he was resident engineer, he joined the staff of Messrs. Coverdale and Colpitts, Consulting Engineers of New York. His work with the latter firm

embraced a wide variety of activities. These included valuations of railway and industrial properties, investigations and reports on the economic justification of proposed expenditures and the soundness of plans for financing or refinancing, and studies of the economics of mergers or consolidations and related matters—in which banking or investment houses ordinarily desire an independent outside judgment involving engineering knowledge, financial analysis, and business judgment.

During this period Mr. Melville was much in demand as a highway traffic expert, and his firm numbered among the clients to whom he gave personal services: The Port of New York Authority, the Maryland State Roads Commission, the Kentucky Highway Commission, the California Toll Bridge Authority, the Washington State Highway Commission, and many private firms. His function in these cases was to estimate the probable operations of the toll facilities involved in the respective projects and to advise as to toll rate structures.

Mr. Melville retired in 1939 and returned to his old home in Jamaica. In July, 1942, however, responding to a desire to participate actively in the war effort of the United States, he returned to Coverdale and Colpitts for a few months, engaged on the construction of the Basic Magnesium Plant at Las Vegas, Nev. From November, 1942, to the fall of 1945, he served as a project engineer with the Defense Plant Corporation. In April, 1946, he suffered a stroke from which he never fully recovered.

Mr. Melville was married in 1905 to Lillian Mary Latreille. He is survived by his widow; a daughter, Margaret (Mrs. Hugh Haggard), of England; and two sons, Charles and Alexander, both residing in the United States.

Mr. Melville's avocation was the writing of poetry, and, if poetry had been his principal occupation, there is no doubt that he would have achieved a high place in the literary field. Some of his verses were published from time to time in periodicals and newspapers, but his complete works, which he termed "Mea Impedimenta," were circulated only among his friends. His verses entitled "The Fifth of June" were printed on the editorial page of the *New York Times* for June 5, 1917, the registration day for World War 1. His poem, "We," was one of the one hundred poems chosen in the Doran competition and published in "The Spirit of St Louis," to celebrate Charles A. Lindbergh's New York to Paris flight.

Mr. Melville possessed fine judgment and insight and had the faculty of always stimulating those with whom he was associated to do their best. He was modest to an extreme. By those who knew him well, he will be remembered as one who was the epitome of selflessness. He was held in high esteem and affection by those who were fortunate enough to fall within the orbit of his influence. Wherever he found himself, he assumed the responsibility for developing an esprit de corps and a pride in the job. With all his modesty and unselfishness, he had the qualifications of a leader, the judgment, the courage, and the ability to inspire men.

Mr Melville was elected a Member of the American Society of Civil Engineers on August 28, 1922.

HIRAM MILLER, M. ASCE[1]

Died October 14, 1945

Hiram Miller was born on June 15, 1880, in Middlefield, Conn. His father, Waldo Brainard Miller, a farmer, was named Brainard for David Brainard of Haddam, Conn., an apostle to the Indians, whose sister was married to David Miller, Hiram's great-great-grandfather. Thomas Miller, a paternal ancestor, came to Rowley, Mass., from England, in 1638, and moved to Connecticut, in 1650, where he was one of the founders of Middletown. He built the first grist mill at Miller's brook and had numerous descendants. His son, Benjamin, was the first settler in Middlefield and a great friend of the Indians. Benjamin's son, David, built the ancestral home in Middlefield, in 1741, and the house which is in excellent condition and the farm of one hundred acres has been in the family ever since. Hiram Miller's mother was Betsey Jane Chapman, a school teacher, who came from a family of fine character and strong religious background. Her ancestral home was in Westbrook, Conn. Robert Chapman was her immigrant ancestor who settled in Saybrook, Conn. Mr. Miller's parents, Waldo and Betsey Miller, were married in April, 1870, and had five children.

Hiram Miller acquired his early education at a small district school and later at a private school in Middlefield, before he entered the high school at Middletown at the age of fourteen. During this formative period he was fortunate in having excellent teachers who were an inspiration to him in his studies at all times. He showed his appreciation of their interest and attention by responding wholeheartedly, and, when he graduated, by receiving high honors and standing fourth in his class.

During that summer he decided to take up engineering, and with this purpose in view, he entered the Sheffield Scientific School at Yale University, New Haven, Conn., in September, 1898. He received honors for excellence in French and honorable mention in chemistry in his freshman year and as a senior was given two-year honors and honorable mention in sanitary engineering. He also belonged to the Society of Sigma Xi. He was graduated with the degree, then given to graduates in science, of Bachelor of Philosophy. From August, 1901, to July, 1940, Mr. Miller held the following positions:

August, 1901, to May, 1902—rodman and instrumentman for the Mexican International Railroad, in Mexico, and assistant to the resident engineer on construction of a drainage canal (until October, 1902).

October, 1902, to February, 1903—postgraduate work in civil engineering at Yale University.

February, 1903, to August, 1905—transitman and assistant division engineer with the Mexican International Railroad in charge of field parties on preliminary and location surveys, under the division engineer.

[1] Memoir prepared by F. W. Andros, M. ASCE.

October, 1905, to March, 1906—engineer with A. William Sperry in New Haven, making general surveys, in the city and country.

March, 1906, to November, 1906—rodman and instrumentman for the Pennsylvania Tunnel and Terminal Company in New York, N. Y.

December, 1906, to December, 1907—division engineer with the Mexican International Railroad, in full charge of a locating party on preliminary and location surveys.

January, 1908, to February, 1909—locating engineer with the Bolivia Railway Company in Bolivia; in charge of construction as resident engineer for the La Paz-Oruro line (until December, 1908); then in charge of a locating party on preliminary and location surveys for the Oruro-Cochabamba line.

March, 1909, to June, 1909—traveled in South America and Europe (not engaged in engineering work from July to December).

January, 1910, to March, 1911—city engineer in Middletown and engaged in private practice.

March, 1911, to June, 1912—assistant to the superintendent of the New Haven Water Company, in Connecticut.

June, 1912, to August, 1913—draftsman and designer for the Alabama Power Company in Birmingham, the work involving computations and design of structures such as dams, retaining walls, and reinforced-concrete powerhouse substructure for the hydroelectric development at lock No. 12 on the Coosa River, and also power studies, stream flow, and other hydraulic problems.

October, 1913, to March, 1920—inspector and junior engineer in the U. S. Engineer Department. This included river and harbor surveys, inspection of material, drafting, and report on power developed on the Connecticut River and tributaries in the New London (Conn.) district (until March, 1915); 1915 to 1916—junior engineer in the office of the department engineer in Fort Sam Houston, Texas, in charge of the preparation of special maps of areas in northern Mexico and along the Mexican border; then junior engineer in New London on river and harbor surveys.

1916 to 1920—designer of fortifications and miscellaneous structures.

March, 1920, to March, 1921—resident engineer with Lockwood, Greene and Company; assistant engineer on construction of a new plant for the Hartford Rubber Works in Connecticut (until June, 1920); then in charge of construction of a new mill for the Albany Felt Company in New York, completed in March, 1921.

May, 1921, to May, 1922—draftsman and computer with the U. S. Engineer in New London.

June, 1922, to December, 1922—designer in the hydraulic division on design of hydroelectric developments with the Electric Bond and Share Company in New York.

January, 1923, to February, 1931—assistant hydraulic engineer in charge of design of hydroelectric developments.

April, 1931, to January, 1932—inspector of dredging (Passaic River, N. J.) with the U. S. Engineer Department, Second District, in New York (until

November, 1931); then inspector of borings on a proposed canal across New Jersey, from Raritan Bay to the Delaware River.

November, 1932, to August, 1934—computer with the U. S. Coast and Geodetic Survey in New York.

August, 1934, to August, 1935—designer on hydroelectric developments with the American Gas and Electric Company, in New York.

August, 1935, to January, 1936—junior engineer on flood control surveys in the State of New York; then with the U. S. Engineer Department as chief of party.

March, 1936, to April, 1937—inspector on dredging and flood control studies with U. S. Engineer Office, Second District, in New York; then junior engineer with the first district on flood control studies and design.

April, 1937, to July, 1940—design engineer on design of hydroelectric developments for the Puerto Rico Reconstruction Administration.

Mr. Miller enjoyed many of the usual sports, but was not active in athletics while at Yale. He was of a studious nature and a great reader; naturally, with an active mind and a retentive memory, he absorbed quickly the best there was in the many books, magazines, and papers he read.

He was brought up in the Congregational Church, but later he became a member of the Methodist Church and was regular and faithful in attending the services as well as taking part in the Sunday school, especially if there was a Bible class. His last class was a men's class at Montclair, N. J., led by the minister. He heartily enjoyed the singing on all such occasions.

He was honored and respected by his many friends, for his integrity of character and for his professional loyalty and rigid honesty. Those who were well acquainted with him mourn the loss of a firm friend and a most congenial companion. His death has deprived the profession of a man who represented the finest in engineers. He was a devoted husband and father—a gentleman of the old school, with a most pleasing personality, modest and unassuming at all times. From his Pilgrim ancestors he inherited the traits that are linked to them.

In foreign languages Mr. Miller had a Spanish license. He was a licensed professional engineer of the State of New York and member of the American Association of Engineers.

He was a member of the F. and A. M., Blue Lodge, and of the council in St. John's Lodge, Middletown, and also a life member of the Royal Arch Chapter in New Haven.

On September 20, 1910, he was married in New York City to Minnie Viola Sweet. He is survived by his widow; two sons, Waldo Benedict and Benjamin Thomas; a daughter, Betsey Chapman; two sisters, Sarah Bradley and Grace Eleanor (Mrs. Fred Harris); and a brother, Frederick C.

Mr. Miller was elected an Associate Member of the American Society of Civil Engineers on January 5, 1909, and a Member on January 14, 1929. He became a Life Member in January, 1944.

WILLIAM PRENTISS MORSE, M. ASCE[1]

Died February 21, 1946

William Prentiss Morse, the son of Charles and Lucy (Jennings) Morse, was born in Weston, Mass., on March 29, 1863.

After graduation from high school he studied civil engineering by himself in the evenings. At the age of eighteen he began working as rodman in the city engineer's office in Newton, Mass., and remained in that department until his retirement on July 1, 1935—more than fifty-four years later. During those fifty-four years the population of Newton increased from 17,000 to 66,300, and Mr. Morse took a significant part in the consequent development of the city.

As rodman, instrumentman, and assistant engineer, he worked on such projects as surveys for the establishment of the sewer and surface drainage systems, the grade crossing elimination of the Boston and Albany Railroad lines through the city, the building of Commonwealth Avenue, and, as resident engineer, on the extension of the Newton water supply. He was engaged in the inauguration of an adequate street numbering system for Newton's thirteen hundred streets and of the assessors' block system. He developed comprehensive indexing systems for Newton's record plans and field notes. In 1893 he became principal assistant engineer and on February 4, 1924, was appointed city engineer.

A considerable part of the city engineer's work is in the preparing of board of alderman orders with descriptions of land takings and examination of titles, in figuring and levying street and sewer assessments, and in making all necessary studies and estimates. In addition to this work, Mr. Morse attended practically every meeting of the board of aldermen for more than thirty-five years.

His varied experience gave Mr. Morse an unusually thorough knowledge of his city, a knowledge which prepared him for his later work on the planning board and with the zoning districts of Newton. When he retired as clerk of the planning board, the resolutions adopted stated:

> "Since the Planning Board assumed the functions of a Board of Survey, Mr. Morse has attended all but one of the 122 meetings. The records kept by him as Clerk are models of accuracy and completeness. Owing to his ability as an Engineer and his thorough knowledge of the City of Newton, Mr. Morse has rendered conspicuous service. The effective work performed by the Board since he became a member has been due in no small degree to his ability, fair mindedness, and understanding of the future needs of our City. In dealing with the technical details in connection with the Zoning of the City, the laying out of streets, parks and public improvements and in planning for the future growth and development of Newton, the Board has relied largely upon his knowledge and skill with unfailing satisfaction and gratitude."

[1] Memoir prepared by Albert Morse, Office Engr., Newton, Mass.

Mr. Morse was parish clerk in St. Mary's Episcopal Church for thirty years, later becoming active in the nearer Second Congregational Church and in the West Newton Men's Club. He derived great pleasure from the meetings and excursions of the Society and of the Boston Engineering Society, becoming a life member of both organizations. After his retirement as city engineer he spent his time compiling a very complete genealogical record of his family.

Throughout his life Mr. Morse was invariably honest, courteous, and thoughtful of others. His friends meant much to him, and he always had a smile and a hearty handclasp for them.

His marriage on March 18, 1896, to Laura Elizabeth Snell of Natick, Mass., was followed by forty-seven years of devoted married life. They had no children.

Mr. Morse was elected a Member of the American Society of Civil Engineers on May 4, 1909.

CHARLES SABIN NICHOLS, M. ASCE[1]

DIED APRIL 20, 1946

Charles Sabin Nichols was born in Plainfield, Iowa, on November 28, 1883. His parents were the Rev. Albert Codon and Martha (Simmerman) Nichols.

He was graduated from the Osage (Iowa) High School in June, 1898, and attended a business college in Cedar Rapids, Iowa, until December of the same year. From December, 1898, until September, 1904, he was in the employ of the Burlington Cedar Rapids and Northern Railway Company, a branch of the Rock Island system, at Cedar Rapids; he was a stenographer and clerk, becoming chief clerk on April 1, 1902. By request, he was transferred to the Maintenance of Way Department as rodman, and soon afterward became instrumentman.

Mr. Nichols entered Iowa State College of Agriculture and Mechanic Arts, at Ames, in September, 1904, and was awarded the degrees of Bachelor of Civil Engineering in 1909 and Civil Engineer in 1914. As his entire living and educational expenses for these years were met by his own energy and effort, he naturally had a number of engagements.

From September, 1904, to June, 1905, he acted as stenographer and draftsman in the office of the Iowa State Highway Commission at Ames. The summer months of 1905 were spent as chief of party on the Meander Lake Bed Surveys for the Iowa State Executive Council. During the academic year, 1905–1906, his spare time was spent in designing culverts and short bridge spans, again for the Iowa State Highway Commission. From June, 1906, to October, 1907, which included one year's absence from college, he was instrumentman and assistant resident engineer for the Minneapolis and Saint Louis

[1] Memoir prepared by Lynn Perry, M. ASCE, and Herbert J. Morrison, Assoc. M. ASCE.

Railway Company on fifty-three miles of heavy railroad construction in South Dakota, which included the terminal facilities on the Missouri River.

On re-entering college in October, 1907, his spare time, both during and between academic years, was occupied in the design and construction of reinforced concrete bridges for the Iowa State Highway Commission, a contact that he had maintained for two years after his college days.

On March 1, 1911, he was called to act as assistant to Anson Marston, Past-President and Hon. M. ASCE, then Dean of Iowa State College, and in September of the following year he became assistant director of the Iowa State Experiment Station at Ames, where he carried out extensive research, in addition to editing and publishing technical bulletins, largely on structural, hydraulic, and sanitation subjects. In February, 1916, he became professor of hydraulics and sanitary engineering, and directing engineer at the Experiment Station in these fields. Time brought promotions to Professor Nichols, and, in due course, he was engaged in a number of research projects for the Iowa State Board of Health.

In 1920 he was appointed a member of the Iowa Board of Engineering Examiners by the governor and served until he moved from the state. He became a member of the Iowa Zoning and Planning Commission in 1921, serving, similarly, while he was a resident of the state. He was honored, also, as president of the Iowa Engineering Society.

In June, 1925, Mr. Nichols came to Miami, Fla., commissioned to make a comprehensive plan for the collection, treatment, and disposal of sewage. In February, 1926, he was placed in charge of the Department of Sewers and in September of the same year, upon the creation of the Department of Streets and Sewers, was made director. The office of city engineer in Miami was created in August, 1927; Mr. Nichols became the first city engineer, also remaining as director of the Department of Streets and Sewers.

This placed under his direction all the design, construction, operation, and maintenance of bridges, and water supply, docks, harbors, canals, rivers, and municipal railway, in addition to supervision of the building and plumbing codes and their enforcement, and of the municipal surveys. From 1937 to 1939, he was director of public service, after which he again assumed the office of city engineer which he held until his death on April 20, 1946. The construction work which he directed for the City of Miami amounted to more than ten million dollars.

The Rev. Albert Codon Nichols was a native of Vermont, as alumnus of Colgate University in Hamilton, N. Y., and a Baptist minister. His training and his example instilled in his son those outstanding Christian virtues, so noticeable in men of culture and refinement, and endowed him with all the old fashioned virtues one would expect from a home atmosphere of work, scholarship, and service.

Mr. Nichols had no hobby or avocation; his entire professional life was devoted to his work which was in the public service. After more than twenty years of toil and sacrifice, the crowning project of his career, the construction of a complete sewerage system, including treament and disposal works, for the

City of Miami was authorized by a special election on April 16, 1946—just four days before his death.

On March 30, 1910, he was married to Lucretia Mellor of Ames. He is survived by his widow; two daughters, Norma (Mrs. Glenn Coon) of Mediapolis, Iowa, and Martha (Mrs. Earl Chism) of New London, Iowa; and two sons, Sabin A. Nichols of Ames and Marvin Nichols of Miami.

Mr. Nichols was active in Society affairs, having served as President of the Miami Section. He was an Elk, and a member of the Masonic Lodge at Ames, the Acacia fraternity, and the Central Baptist Church in Miami.

Mr. Nichols was elected an Associate Member of the American Society of Civil Engineers on June 18, 1918, and a Member on June 6, 1921.

WALTER PEARL, M. ASCE[1]

DIED FEBRUARY 10, 1946

Walter Pearl was born in Ableman, Sauk County, Wis., on August 30, 1866. He was the son of Stephen and Sarah (Cook) Pearl.

At the age of twenty Mr. Pearl began what was to become a life of activity in surveying and civil engineering that was to last until within a week of his death. His entrance into this field was as axman for the Montezuma Water Supply Company in Colorado. During the next eight years, he rapidly progressed through the positions of chainman, rodman, leveler, transitman, resident engineer, and assistant engineer. This initial period of his professional life was spent in Colorado and his engagements were in the fields of irrigation and water supply. His self-education was coincident with his field experiences.

At the age of twenty eight he participated in the Oklahoma land race, riding into the "strip" and through what was to be the City of Enid, Okla., on the top of a railroad boxcar—riding "through" because the train refused to stop until they arrived at the "railroad town" some miles farther on. He and his pal hastily hired a team and wagon to take them back to Enid but they arrived too late to stake out any of the good lots. They staked out on the best that was left, however, and immediately organized the firm of Pearl and Codding, Civil Engineers, and started a general engineering practice.

When the activity in Oklahoma subsided, Mr. Pearl returned to Colorado and, for the next seventeen years, was engaged in civil engineering projects, mostly in water supply and irrigation. Part of the time he had his private office, but he also held important employee positions such as assistant engineer, Denver Union Water Company; supervising engineer, United States Government; chief engineer, Fort Lyon Canal Company; chief engineer, Raton Water Works Company; chief engineer, Bar J. H. Cattle and Land Company; chief engineer, Sterling Promotion and Irrigation Company; assistant to

[1] Memoir prepared by Daniel Marsh, Chief Surveyor, Los Angeles County Flood Control Dist., Los Angeles, Calif.

general manager, Denver Reservoir Irrigation Company; and consulting engineer, Pioneer Construction Company.

Most of this work was in Colorado but some extended into Wyoming and New Mexico. Mr. Pearl acquired an intimate knowledge of that region of the Rocky Mountains, and he played an active part in the development of mining, irrigation, and railroads. His reminiscences of that period and that locality were most colorful and interesting.

In 1912 Mr. Pearl went to California and, except for a short time as assistant engineer for the United States Reclamation Service at Yakima, Wash., spent the remainder of his life there. His work during this time followed surveying. He was usually chief of party or assistant engineer and, in those capacities, served the California Highway Commission, Los Angeles County Surveyor, American Beet Sugar Company, Southwest Collon Company, and Southern California Edison Company. During the final eleven years of his busy life, he was an engineering aid of the Los Angeles County Flood Control District.

On August 10, 1910, in Denver, he was married to Loma M. Goodwin. He is survived by his widow; a daughter, Stella (Mrs. John Runge); and three grandchildren.

Walter Pearl's name among engineers is chiefly associated with the early development of Colorado and neighboring states. His was a long life of useful engineering work, spanning the period from the preliminary wood and timber structures to the permanent structures of steel and concrete. He made early studies of the duty of water and was author of a technical publication on that subject.

He was a member of Highlands Lodge No. 86, F. and A. M. (Denver Colo.); the Colorado Society of Engineers; and the Engineers and Architects Association of Southern California.

Mr. Pearl was elected a Member of the American Society of Civil Engineers on June 3, 1908. He became a Life Member in January, 1937.

WILLIAM DAVID PENCE, M. ASCE[1]

DIED JUNE 16, 1946

William David Pence, the son of David and Nancy (Hart) Pence, was born in Columbus, Ind., on November 26, 1865. He was educated at the University of Illinois in Urbana, from which he received the degree of Bachelor of Science in Civil Engineering in 1886, and the degree of Civil Engineer in 1895.

His first engineering experience was obtained as a field party assistant in municipal drainage and highway work in Columbus during summer vacations, from 1882 to 1885. From June, 1886, to September, 1887, he was em-

[1] Memoir prepared by W. S. Lacher, M. ASCE.

ployed as an assistant engineer on surveys and on the design and construction of yards and bridge masonry for the Gulf, Colorado and Santa Fe Railway. For three months, from October to December, 1887, he was roadmaster on the main line from Galveston to Millheim in Texas, and on the Houston branch of the same company, until he became assistant engineer of roadway, bridges, and buildings on 550 miles of this railroad.

In September, 1892, Mr. Pence returned to the University of Illinois as an assistant in theoretical and applied mechanics and thereafter, for the following twenty-one years, devoted his time, interests, and energies to engineering education. He was advanced to assistant professor in 1898, but left the University of Illinois a year later to become professor of civil engineering at Purdue University in Lafayette, Ind. There he remained until 1906 when he joined the faculty of the University of Wisconsin in Madison, as professor of railway engineering. While at Madison, he also served as chief engineer on the Wisconsin Railway Commission and the Wisconsin Tax Commission.

Following the enactment of the federal valuation law in 1913 which led to the organization of the Bureau of Valuation by the Interstate Commerce Commission, he was appointed a member of the engineering board which assumed direct responsibility for the appraisal of the physical property of the railroads. The United States was divided by the bureau into five districts of approximately equal size, and Mr. Pence was placed in charge of the Central District, with headquarters in Chicago, Ill. He continued to serve in this capacity until 1921, when a curtailment of the valuation program led to the disbanding of the district organization. Thereafter he engaged in private engineering practice.

Mr. Pence's interests were by no means confined to railway engineering. His curiosity regarding the rather large number of failures of municipal water supply standpipes led to an intensive study into their causes, and the preparation of a monograph on "Standpipe Accidents and Failures in the United States" that appeared in 1885. In 1901 he was awarded the Octave Chanute Medal of the Western Society of Engineers for a paper on thermal expansion in concrete. In 1900 he collaborated with the late Milo S. Ketchum,[2] Hon. M. ASCE, in the preparation of a surveying manual that appeared in four editions. Also as his interests varied in later years, he became the author of papers on structural analysis, regulation of public utilities, terminal air rights over railway property, and other subjects. He retained a keen awareness of the world about him to the end, especially in the current developments in science and their applications in engineering. He was a member of the Indiana Engineering Society (president from 1903 to 1905), the Western Society of Engineers, the Society for the Promotion of Engineering Education, Alpha Tau Omega, Sigma Xi, and Tau Beta Pi. As a charter member of the American Railway Engineering Association, he assisted in the formulation of its publication policies, later serving as editor.

On December 31, 1888, Mr. Pence was married in Columbus, to Charlotte Gaston, who died in 1938. He is survived by three daughters, Ada (Mrs.

[2] For memoir, see *Transactions*, ASCE, Vol. 102, 1937, p. 1487.

Sumner H. Slichter), Helen Charlotte (Mrs. A. B. J. Wace), and Esther Nancy (Mrs. A. F. Britton).

Mr. Pence was elected a Member of the American Society of Civil Engineers on October 4, 1899.

JAMES EDWARD PIRIE, M. ASCE[1]

Died July 17, 1946

James Edward Pirie, the son of James A. and Scottie Eliza (Roddy) Pirie, was born on January 11, 1881, at Sayers, Tex. He was graduated from Texas Agricultural and Mechanical College at College Station, in 1904, receiving the degree of Bachelor of Science in Civil Engineering.

The professional career of Mr. Pirie extended over a period of forty-two years, and covered a varied type of endeavor. He began his lifework as a special student of operation with the Southern Pacific Railroad Company, in 1903, and worked through the construction, maintenance, and operations divisions as instrumentman, assistant engineer, roadmaster, and chief clerk to trainmaster by 1910.

Then followed a period of service as assistant city engineer of the City of Houston (Tex.), in 1911, after which he was construction superintendent for Street and Born, general contractors, in 1912 and 1913. In 1914 he was locating engineer for the proposed N. V. and R. G. Railroad and, in 1915 and 1916, he followed land surveying and was county engineer of Live Oak County in Texas. Mr. Pirie was employed as instrumentman and resident engineer on railway location and construction for the firm of Howe and Wise at Houston, from January 1, 1917, to May, 1919.

In 1919 Mr. Pirie began his service with the Texas Highway Department as division engineer and thereafter, with the exception of one year (1922–1923), during which time he was city engineer for Ballinger and Winters in Texas, he remained in the employ of this department. From 1923 to 1931, he served as county engineer and resident engineer in Runnels, Concho, Shackelford, and Throckmorton counties in west Texas; and, from 1931 until his death, he served as district engineer of district No. 1 in northeast Texas.

During Mr. Pirie's service with the Texas Highway Department he was actively engaged in the development of the organization and in the formulation of its policies, his wide experience and sound judgment making him a valuable consultant in all matters of public and professional policy. In the spring of 1946, Mr. Pirie received certificates of service and service pins from both the Texas Highway Department and the American Association of State Highway Officials, in recognition of meritorious public service for more than twenty-five years.

[1] Memoir prepared by F. M. Davis, M. ASCE.

The professional and personal ideals of Mr. Pirie were of the highest quality and he enjoyed the respect and friendship of all who came in contact with him. One of his outstanding traits was his keen sense of fairness. He was possessed with a particularly intense sense of responsibility toward the younger professional engineer, and derived much pleasure from observing the younger man develop and progress in the profession. A well-balanced professional training was the reward of engineers fortunate enough to secure employment in his organization, and Mr. Pirie received his greatest satisfaction when professional or public recognition came to them.

On September 3, 1907, he was married to Jessie Erna Still, of Kemp, Tex. He is survived by his widow; one son, James E. Pirie, Jr.; and two daughters, Betsy and Eugenia Lee Pirie.

Mr. Pirie was elected a Member of the American Society of Civil Engineers on April 3, 1922.

PHILIP WALLIS PRICE, M. ASCE[1]

DIED JULY 22, 1946

Philip Wallis Price was born on October 6, 1879, in Pittsburgh, Pa. He was the eldest son of Charles Bohlen and Florence (Macrum) Price. He received his early education in the Park Institute of Allegheny (Pa.), now North Side, Pittsburgh, and in 1899 received the degree of Civil Engineer from Western University of Pennsylvania, in Pittsburgh, later the University of Pittsburgh.

His father was superintendent of the Allegheny Valley Railway Company, and later of the Allegheny Division of the Pennsylvania Railroad Company. From his father he acquired a love for railroading which lasted throughout his life. During vacations he worked as rodman on surveys for the Pennsylvania Railroad Company in western and central Pennsylvania.

In the ten years that followed his graduation he worked, successively, as rodman, transitman, assistant engineer, irrigation engineer (after passing the civil service examination), and draftsman. During this period he was engaged on five railroad surveys and revisions of alinement; three hydraulic projects, one of which was on the Pittsburgh filtration plant; two location and construction jobs on pipe lines and pumping stations; and one draftsman's job with the American Bridge Company. He was employed on this work in the states of Louisiana, Montana, Ohio, Oklahoma, Oregon, Pennsylvania, Texas, and Washington.

In January, 1909, he entered the Allegheny County engineer's office in Pittsburgh as assistant engineer. The work of the office was varied, with chief emphasis on design, construction, and maintenance of numerous highway bridges; Mr. Price's training and past experience admirably fitted him for

[1] Memoir prepared by a Committee of the Pittsburgh Section consisting of Vernon R. Covell, Adelbert A. Henderson, and James C. Jordan, Members, ASCE.

this position. In 1924 when this office became the Bureau of Bridges in the Allegheny County Department of Public Works, he was made principal assistant engineer in the Division of Construction.

During the next seventeen years Allegheny County entered into the largest highway bridge program in its entire history, involving an expenditure of forty million dollars. Its four rivers, rugged topography with many deep ravines, together with numerous minor streams, makes Allegheny County the bridge builders paradise—nearly every type of bridge being found here. In this program, Mr. Price made location surveys and study plans for major as well as minor bridges and had an intimate part in the field construction of the eleven bridges on the Ohio River Boulevard; and the seventeen major bridges over the rivers and deep ravines that include the Sixth, Seventh, Ninth, and Thirty-First street bridges over the Allegheny River; the Point, Liberty, South Tenth Street, and McKeesport-Duquesne bridges over the Monongahela River; the McKees Rocks and West End-North Side bridges over the Ohio River; the Boston Bridge over the Youghiogheny River; and the Duquesne viaduct and the George Westinghouse Bridge on the Lincoln Highway over deep ravines. He had direct charge of the field construction of the Highland Park Bridge over the Allegheny River.

Mr. Price joined the National Guard in 1910, and during the disturbance on the Mexican border in 1916, was called to active service with the First Field Artillery, United States Army. He was mustered out in December, 1916, but in May, 1917, he re-enlisted as an officer candidate in the U. S. Army and was sent to France with the Third Field Artillery in October. In May, 1919, he received his discharge and resumed his work in the county engineer's office. His interest in military affairs never flagged; he was an active member of the 324th Field Enginers, in which he held a reserve captain's commission until his death. One of his bitterest disappointments was to have been disqualified for active service during World War II, because of physical disabilities.

Mr. Price had strong convictions on the ethics involved in his decisions and actions, and he could not be swerved from what he believed was right. After his retirement in 1941, he devoted much of his time to the many civic organizations in which he was keenly interested.

He was a Life Member of the Society, and Vice-President of the Pittsburgh Section. His other memberships included the Society of American Military Engineers, the Engineers Society of Western Pennsylvania, and the Pittsburgh Chapter of Professional Engineers.

Mr. Price was a director of the Church Club (Episcopalian) of the Diocese of Pittsburgh. He took an active interest in the Civic Club of Allegheny County, the Historical Society of Western Pennsylvania, as well as Biard-Atwood Post of the Veterans of Foriegn Wars, and the East Liberty Post No. 5 of the American Legion.

During the early months of 1945, he was employed by the Allegheny County Conference on Community Development to conduct a survey of traffic conditions in Pittsburgh. This was his last formal employment.

In June, 1919, he was married to Edith Arensberg of Oakmont, Pa. He is survived by his widow; their son, Charles Philip Price; a brother Benjamin M. Price; and two sisters, Eleanor (Mrs. Royal Thomas) and Florence (Mrs. Charles H. Barton).

Mr. Price was elected a Junior of the American Society of Civil Engineers on April 2, 1901; an Associate Member on February 5, 1908; and a Member on October 10, 1927.

OTTO JOHN RAIFFEISEN, M. ASCE[1]

DIED OCTOBER 22, 1946

Otto John Raiffeisen was born in Sedalia, Mo., on October 21, 1887. He was the son of Charles H. and Katherine (Bahrenburg) Raiffeisen, whose parents came to the United States in 1849 and settled in what became the family home south of Sedalia. His preparatory education was obtained in the schools of Sedalia. He was graduated from the University of Missouri at Columbia in 1910 with the degree of Bachelor of Science in Civil Engineering.

From 1910 to 1924, Mr. Raiffeisen was engaged in the structural and mechanical design of steel buildings, bridges, and other steel structures for the Kansas City (Mo.) Structural Steel Company and the Fort Pitt Bridge Works in Canonsburg, Pa. In addition, he designed copper smelting and iron ore concentrating plants and equipment for the Arizona Copper Company in Clifton, Ariz., and for S. Shapiro, consulting mining engineer, in New York, N. Y., gaining broad experience in these fields of engineering. In June, 1924, he joined the engineering department of the Gulf Oil Corporation, then located in Port Arthur, Tex., as designer of steel structures, vessels, stills, and other construction associated with a major oil refinery. In 1929, when the Gulf engineering department moved to Pittsburgh, Pa., Mr. Raiffeisen was transferred there as supervisor of design of pressure and vacuum vessels, stills, heat exchange units, steel and concrete structures, wharves, etc.

He was a man of quiet, but strong, personality, who found his greatest enjoyment in his home, and in the company of his many friends. His end came suddenly from a heart attack, while driving home from his office with friends.

The record and ability of Mr. Raiffeisen stand as a tribute to his family, school, and profession, and the benefits of his personality, training, and experience, which were generously shared with his associates, will long be remembered by those who owe much to his friendly guidance. Mr. Raiffeisen was a former member of the American Institute of Mining and Metallurgical Engineers.

On March 18, 1916, in St. Joseph, Mo., he was married to Marguerite A. Jackson. He is survived by his widow; two sons, Charles Jackson and Otto John, Jr.; and one grandson.

Mr. Raiffeisen was elected a Member of the American Society of Civil Engineers on January 11, 1943.

[1] Memoir prepared by J. G. Glasgow, M. ASCE.

MELVILLE EMERSON REED, M. ASCE[1]

DIED OCTOBER 12, 1946

Melville Emerson Reed, the son of William B. Reed and Amanda (Bunnell) Reed, was born in 1865 in Hastings, Minn. After preparation in the public schools of Hastings, he entered the University of Minnesota, at Minneapolis, in 1884, from which he received the degree of Bachelor of Science in Civil Engineering in 1888.

During his first year after college, he was employed as a transitman by the Saint Paul Water Works; and, on leaving that position in 1889, he served as an assistant engineer on the Pacific Extension of the Great Northern Railway. With the exception of one engagement during 1895 as assistant engineer with the United States Engineer Corps on river and harbor construction in Wisconsin, Mr. Reed remained with the Great Northern Railway Company until 1909, serving, successively, as assistant engineer on the construction of the Cavalier Branch in North Dakota and on the west portal of the Cascade Tunnel. From 1899 until 1902 he was employed as engineer in charge of location and construction of this tunnel. For the next seven years he was in charge of location and construction for the Great Northern Railway Company and the Northern Pacific Railway Company in Montana and Washington.

After serving as project engineer for the United States Reclamation Service in charge of the Huntley Project in Montana during 1909, Mr. Reed became chief engineer of the Oregon Electric Railway Company and, on completion of that engagement, maintained a consulting engineering office in Portland, Ore., from 1911 to 1922. During World War I, he was inspector for the Emergency Fleet Corporation on the construction of wooden hulls in the Portland area.

Following World War I until 1931, Mr. Reed was engaged on bridge construction—for the first seven years as principal assistant engineer and resident engineer under Gustav Lindenthal,[2] Hon. M. ASCE, on the location and construction of the Burnside, Sellwood, and Ross Island bridges and on the reconstruction of the Broadway Bridge, all of which are on the Willamette River at Portland. Mr. Reed then served for two years as bridge engineer for Multnomah County, Oregon, which position he left to become engineer examiner and inspector for the Public Works Administration in charge of some fourteen projects, including bridges, buildings, and water works in Oregon and Idaho.

When these projects were completed in 1939, Mr. Reed reopened his consulting engineering office in Portland; but, with the advent of World War II and the rapid development of shipbuilding on the west coast, he was employed by the Henry Kaiser Swan Island Yards as assistant engineer on the

[1] Memoir prepared by Ben S. Morrow, Assoc. M. ASCE.

[2] For memoir, see *Transactions*, ASCE, Vol. 105, 1940, p. 1790.

construction of 16,000-ton tankers, one hundred and forty seven of which were launched from the ways of this plant.

Mr. Reed was an engineer of the highest ethical and professional standards. Throughout his entire career it was his constant effort to advance the standing of the engineering profession and to bring to the general public a proper appreciation of the importance of the part played by the engineer in the development of the social and economic life of the United States. He was an active and interested member of the Portland Section of the Society and served as President in 1921. He was a registered professional engineer in Oregon.

In 1908 Mr. Reed was married to Maud Messner of St. Paul, Minn., who, with their daughter, Josephine (Mrs. Rudolph Eiswick), and a granddaughter, Susan Eiswick, survives him.

Mr. Reed was elected a Member of the American Society of Civil Engineers on March 6, 1901. He became a Life Member in January, 1936.

ROBERT LEMUEL SACKETT, M. ASCE[1]

Died October 6, 1946

Robert Lemuel Sackett, the son of Lemuel Miller and Emily Lucinda (Cole) Sackett, was born at Mount Clemens, Mich., on December 2, 1867. He was reared in a Quaker home, and throughout his life exhibited the gentleness and understanding, combined with unfailing principles of self-discipline and personal rectitude that arose from this environment.

He attended high school in Mount Clemens, and pursued his engineering education at the University of Michigan in Ann Arbor, where he was awarded the degree of Bachelor of Science in Civil Engineering in 1891. Later he was awarded the degrees of Civil Engineer (1896) and Doctor of Engineering (1937) by the same institution.

From 1891 to 1907, Mr. Sackett taught mathematics and astronomy at Earlham College in Richmond, Ind., and for the next nine years he was professor of sanitary and hydraulic engineering at Purdue University in Lafayette, Ind. In 1915 he assumed the deanship of engineering at The Pennsylvania State College at State College, where he remained until his retirement in 1937.

During the period of his academic career, he served also as a practicing consulting engineer in various capacities, in Michigan, Indiana, and Pennsylvania. After his retirement, Dean Sackett moved to New York, N. Y., where he continued his interest in professional and educational matters. He served the American Society of Mechanical Engineers as assistant to the secretary during World War II, and the Engineers' Council for Professional Development as chairman of the Committee on Student Selection

[1] Memoir prepared by H. P. Hammond, M. ASCE.

and Guidance, and also in the capacity of an informal adviser on a great many matters incidental to the activities of this organization.

In 1938 Dean Sackett was awarded the Lamme Medal, the chief honor of the Society for the Promotion of Engineering Education (American Society for Engineering Education). He was a fellow of the American Association for the Advancement of Science, and its vice-president during 1928 and 1940. Dean Sackett was a member of this society as well as of the American Society of Mechanical Engineers, and of the Society for the Promotion of Engineering Education, of which he was president in 1927. Among his fraternities and societies were Sigma Xi, Tau Beta Pi, Phi Kappa Phi, and Phi Gamma Delta.

Throughout his life, Dean Sackett was interested in the development of young people. This interest displayed itself not only in his work as a teacher and dean, but also in his many activities with the Engineers' Council for Professional Development. Although he was a man of strict self-discipline and insisted on the highest ethical standards among his students and colleagues, he was, nevertheless, a man of warm sympathies and understanding of others. To the end he remained active, serving on boards, committees, and commissions, and giving freely of his time and mental vigor to the numerous activities he assumed after his retirement. He was a leader who furnished, both by precept and example, a pattern which could be followed by his students, his colleagues, and his associates. He never outgrew a fresh interest in the problems of young men, and always remained youthful in his thinking.

Dean Sackett was a man of hobbies, not in the trivial sense, but in the development of his own character and interests. He took up painting, as an outgrowth of professional work in his early life, and developed this interest to the point of creditable amateur proficiency in water colors. He was attracted to sailboating at a fairly early age, and pursued that hobby with keen interest. While at Pennsylvania State College he was instrumental in developing instruction in fine arts. In a word, he was a man of broad interests and human understanding, who lived his life with the guiding principle, not only of the highest personal ideals, but of helping others to attain his own standards.

On July 22, 1896, he was married to Mary Lyon Coggeshall in Fountain City, Ind. He is survived by a son, Ralph L. Sackett, professor of economics at the University of Miami in Coral Gables, Fla.

Dean Sackett was elected an Associate Member of the American Society of Civil Engineers on February 6, 1907, and a Member on January 18, 1916. He became a Life Member in January, 1938.

HENRY JENNESS SAUNDERS, M. ASCE[1]

DIED AUGUST 14, 1943

Henry Jenness Saunders, the son of Smith and Emma (Jenness) Saunders, was born in Mount Pleasant, Iowa, on January 14, 1880. He was the elder of two sons. When he was about six years old, the family moved to Council Bluffs, Iowa, where his father was engaged in the grocery business. Henry's business training began early. During his elementary school years he spent his spare time helping his father in the store, performing the chores which only a very energetic boy could accomplish. In addition to his duties around the store, he had a morning paper route, delivering papers to his home community on the family horse. One of his early ambitions was to have a college education, and most of his boyhood earnings went into a fund for that purpose.

When Henry entered high school he lacked weight and size to compete in athletics. However, this did not prevent him from trying. At the first field meet held after his admission to the Council Bluffs High School, he displayed his contempt for odds, and entered the mile run against a field of older and more experienced competitors. He finished last. The humiliation aroused his determination to prove he really could run. Through perseverance and careful training, before he finished high school, he ran the hundred-yard dash in ten and two-fifths seconds, and won the Iowa State Championship. His speed enabled him to play football, and he made an enviable reputation locally, playing halfback.

During his summer vacations he worked for the Union Pacific Railroad Company as chainman, rodman, and instrumentman. He continued working for the railroad for a year after he finished high school. He then enrolled at the University of Wisconsin, in Madison, and received the degree of Bachelor of Science in Civil Engineering in 1903.

The year after his graduation he was assistant engineer for the Union Pacific Railroad in charge of some fifteen miles of construction. From 1905 to 1912, he was employed by various organizations including the United States Reclamation Service, and the consulting engineering firms of Ford, Bacon and Davis of New York, N. Y., and the Arnold Company of Chicago, Ill. In 1910 he received the degree of Civil Engineer from the University of Wisconsin.

In 1912 he opened a consulting engineer's office at Valier, Mont., specializing in municipal work, irrigation problems, and highway bridge design. In July, 1914, he entered the service of the Interstate Commerce Commission, Division of Valuation, Pacific District, with offices in San Francisco, Calif. He was in charge of computing, tabulating, and assembling data inventoried in connection with the valuations of the railroads in that district. In 1921 the San Francisco office was discontinued, and Mr. Saunders was transferred to the Washington, D. C., office, as an assistant to the supervising engineer of the

[1] Memoir prepared by F. W. Amadon, Assoc. M. ASCE, and F. J. Leonard, Associate Engr., Civil, Interstate Commerce Comm., Washington, D. C.

Bureau of Valuation. In that capacity he was in charge of the cost branch, and presented testimony at the valuation hearings supporting the bureau's methods and engineering reports. In all, he appeared in more than one hundred cases and did much pioneer work in preparing exhibits and testimony for the bureau. In 1928 he opened a consulting office in the Transportation Building in Washington, D. C.

The practice established by Henry J. Saunders was of unique character. He was technically a well-trained engineer, and possessed a comprehensive knowledge of accounting. He correlated the two subjects and applied them to the economic problems of transportation facilities and public utilities. Rates were his specialty—transportation rates charged by railroads, steamships, motor buses, trucking concerns, and air lines; also rates charged the consumers by utilities producing gas and electricity. He was often on the consumers' side and represented them before regulatory commissions and in federal and state courts.

Many of the cases in which he appeared included an appraisal or valuation of facilities. In 1938 he made an appraisal of the famous Gandy Bridge in Florida. In some of his important cases he represented Swift and Company, Armour and Company, the Chicago Union Stock Yards and Transit Company, the Koppers Company, the National Coal Association, the Anchor Coal Company, and various other coal operators' associations.

During the fifteen years of his practice in Washington, D. C., among his clients were: The War Department; Tennessee Valley Authority; and state commissions in Virginia, Florida, North Carolina, South Carolina, and the District of Columbia. He represented the Southern Governors' Rate Conference from its beginning to August 1, 1943.

A short time before his death he demonstrated that he had not lost the fighting spirit displayed during his high school days. He had been engaged to testify in an important case that came to hearing when he was at his home fatally ill. Several taxicabs of lawyers drove to his residence and took his testimony there. He weathered the ordeal and was in a jubilant mood at the close of the hearing.

Henry Saunders was a generous, tolerant man, and very considerate of his associates. Friends of his early youth were still intimate friends at the close of his life, despite the fact that he had traveled far from home. Those who knew him best loved him most, and to them his death marks the passing of a Christian gentleman.

He was a member of the Presbyterian Church, the Association of Interstate Commerce Commission Practitioners, and the National Aeronautical Association, and chairman of the Public Utilities and Transportation Committee of the Washington Board of Trade. He belonged to the University Club of Washington, D. C.; In-Com-Co Club of the Interstate Commerce Commission; Delta Tau Delta fraternity; and the Masons. He lectured on valuation subjects before the Washington Society of Engineers and the engineering students of the University of Wisconsin and George Washington University, in Washington, D. C., and was the author of a number of articles on the same subject appearing in technical magazines.

In January, 1904, he was married to Virginia Hayner in Madison. They had two children, Barbara (Mrs. Allen J. Hovermale), and Henry J. Saunders, Jr. He is survived by his widow and children.

Mr. Saunders was elected an Associate Member of the American Society of Civil Engineers on May 3, 1910, and a Member on May 5, 1915.

OLIVER JAY SCHIEBER, M. ASCE[1]

DIED JUNE 23, 1944

Oliver Jay Schieber was born in the City of Bucyrus, Crawford County, Ohio, on August 28, 1888, the son of John A. and Della May (Schell) Schieber.

Oliver Schieber's paternal ancestry stems from Wuerttemberg, Germany. His great-great-grandfather, Christian Schieber, participated in Napoleon's march into Russia, and during the disastrous retreat from Moscow in 1812–1813 he died from exposure at the age of about forty-two years. Johann Gottlieb Schieber (April 23, 1794–August 18, 1869), son of Christian, was born near Stuttgart, and in 1818 was married to Christina Magdalena Brose (April 22, 1799–April 25, 1889). In the spring of 1832 the Schieber and Brose families, with other related families, left their home communities and came by sailing vessel to the port of New York, N. Y., thence by the Hudson River to Albany, N. Y.; by the newly opened Erie Canal to Buffalo, N. Y.; by boat to Sandusky, Ohio; and thence overland to Bucyrus. The country thereabout was then virgin forest, and these early settlers had to clear the land of timber before real farming could begin. Johann Gottlieb brought his wife and several children with the party. His son, Gottlieb (September 11, 1823–June 18, 1865), Oliver's grandfather, was then a boy of nine, and Christina's father, Andreas Brose, was leader of the party.

Gottlieb Schieber was married, in Bucyrus, to Christina Heckenlaible (1827–1895), daughter of Rev. Johann Heckenlaible, a Lutheran minister, and Margaret Loeffler, who had come from Wuerttemberg in 1826.

Oliver's maternal ancestry stemmed from the Rhineland. Early in the eighteenth century Jacob Schell and his wife, with other Palatinates, fled from their homes and the oppression of the armies of Louis of France, to London, England. In 1709 Queen Anne assisted these Palatinates to reach the colonies in America. With them Jacob and his wife reached the port of New York early in 1710 and settled in Schoharie, N. Y. Their son, Peter Schell, with others, accepted in 1719 a grant of land from the governor of Pennsylvania, in the Tulpehocken region, which later became the heart of the Pennsylvania-Dutch area. Peter's son, also called Peter, had a son, Peter, III, born in 1760 in this region. Peter Schell, III, as a youngster pioneered in what was then a remote part of Pennsylvania—Franklin County—where he was married to a

[1] Memoir prepared by Walter E. Jessup, M. ASCE, with the assistance of Homer J. Schieber, Los Angeles, Calif.

Scotch-Irish lass, Eleanore. They settled at Springfield Furnace, then in Huntingdon County. Peter, III, served in the concluding stages of the Revolutionary War, and in 1814 at the age of fifty four enlisted in the War of 1812. He died in Markleysburg, Pa., in 1849.

A son of Peter, III, and Eleanore, James Schell (January 14, 1799–December 6, 1854) and his wife, Ellen Benton, moved from Pennsylvania to Crawford County, in 1846, where they occupied a farm near Bucyrus. Ellen Benton's father, Jonathan Benton, a member of the six-foot, and more, tall King's Guards, came to America in 1781 from England with his bride to escape military prosecution because of his unauthorized marriage, and settled near Reading, Pa. There he enrolled in the Pennsylvania Militia, and so it was that he served in both the English and Colonial armies during the Revolutionary War.

A son of James and Ellen (Benton) Schell, Johnson Schell (February 7, 1826–April 17, 1890), was married to Maria Treusch (September 3, 1841–March 12, 1917), near Bucyrus. Maria's father, Adam Treusch, and her mother, Elizabeth Schmucker, had landed in Baltimore, Md., from Hesse-Darmstadt in 1830 to settle in York, Pa. In 1843 Adam Treusch and his family moved to Bucyrus, where his brother, Louis Ludwig Treusch, great-grandfather of Wendell Wilkie, had settled in 1835. Adam Treusch died in Bucyrus in 1846, and his widow, Elizabeth, was married, in 1847, to a neighbor, Daniel Barlitt (July, 1788–December 11, 1892), who achieved some measure of fame by living to the age of 104 years when he died just six days after the death of his wife. Daniel's grandfather, Jacob Barlitt, was a member of the personal bodyguard of George Washington, and as a boy, Daniel saw George Washington on several occasions. Although Oliver Schieber was but four years old when Daniel Barlitt died, it is recorded that Oliver sat on old Daniel's knee and heard him tell about having seen George Washington.

Oliver's father, John A. Schieber (August 31, 1855–February 7, 1914), son of Gottlieb Schieber and Christina Heckenlaible, was married to Della May Schell (who was born on May 6, 1862), the daughter of Johnson Schell and Maria Treusch, in Bucyrus. She had taught at a country school near Bucyrus. To regain his health John Schieber, with his wife and three children, moved to Los Angeles, Calif., in 1899. There he operated grocery stores in downtown Los Angeles, and Oliver was entered in the Olive Street Grammar School.

Oliver was graduated from the Los Angeles High School in the class of 1906, and then earned his way through college by working during vacations and while in school. Always interested in athletics, he taught physical culture and coached athletic teams in public schools. He was an accomplished gymnast, a good swimmer, and an ardent golfer.

In 1906 he entered the University of Southern California in Los Angeles, specializing in science, mathematics, and surveying. The school year of 1909–1910, he spent in the practical application of his preliminary college work by working in the engineering department of the Southern Pacific Railroad Company in Los Angeles as a rodman.

By now, being sure that civil engineering was to be his chosen field, Mr. Schieber entered the University of Wisconsin at Madison, in 1910, where he became an honor student during his two years of specialization in hydraulics, hydrology, and water-power engineering under the guidance of Daniel W. Mead, Past-President and Hon. M. ASCE. He was elected to Tau Beta Pi, and after completing the requirements for the five-year course leading to the degree of Civil Engineer was graduated in the spring of 1912.

Immediately on graduation, he obtained a position with the Knoxville Power Company, a subsidiary of the Aluminum Company of America, at Alcoa, Tenn., where he was engaged on topographic surveys for the then proposed Calderwood Dam.

Returning to his adopted state in 1913, Mr. Schieber was engaged by the Stone and Webster Corporation of Boston, Mass., as chief of party on the construction of two high-head hydroelectric power plants in the Sierra Nevada at Big Creek, Calif., which were being built for the Pacific Light and Power Corporation of Los Angeles. This was a high-pressure job; construction went on day and night, twenty-four hours a day, seven days a week. There, Oliver Schieber got his introduction and invaluable training for the construction engineering of western water and power projects that was to become his lifework. He was engaged on the field engineering for powerhouse and penstock construction, and the location and construction of access roads to the project. When the initial Big Creek project was completed in December, 1913, he left Stone and Webster and continued with the Pacific Light and Power Corporation until August, 1914.

The next three years, from 1915 to 1917, Mr. Schieber spent on the Salt River project of the United States Reclamation Service with headquarters in Phoenix, Ariz. There he had charge of the location and construction of irrigation canals and structures; he conducted the first silt survey of Roosevelt Reservoir and was resident engineer on the intricate work of concreting the spillways of Roosevelt Dam. He also had charge of the maintenance and operation of the canal system of the Salt River project and, ultimately, was named construction engineer of the project.

When the United States entered World War I, Mr. Schieber volunteered his services to the Corps of Engineers of the United States Army. He was accepted, and in January, 1918, entered active duty as a First Lieutenant of Engineers. After a training period, he was assigned to the 602d Engineers and embarked for France. In France, Lieutenant Schieber was engaged on the construction of roads, bridges, ammunition dumps, and other vital army construction work. He participated in two major engagements, Saint-Mihiel and the Meuse-Argonne. After the armistice on November 11, 1918, his unit was assigned to the Army of Occupation of Germany. While there, Lieutenant Schieber, who commanded Company C, was recommended for promotion to Captain.

In July, 1919, after his release from army duty, the U. S. Reclamation Service again sought his experienced services. This time it was on the King Hill project in Idaho, where, for the next year, he was assistant engineer on

the design of irrigation structures, and then was appointed division engineer of construction of the project.

In 1917 the Big Creek hydroelectric development on which Oliver Schieber had been engaged previously, together with all its other properties, was acquired from the Pacific Light and Power Corporation by the Southern California Edison Company which served Los Angeles and other Southern California communities with electricity for light and power. The company had begun an extensive development of the power available in 5,500 ft of the fall of the waters of the San Joaquin River and its tributary, Big Creek.

In August, 1920, Oliver Schieber accepted a position on this construction in the high Sierra, with headquarters at Big Creek. Here again he demonstrated his willingness to accept responsibility, his dependability, and his capacity for hard work. For the next four and a half years he was engaged, successively, as production engineer, estimating engineer, and assistant resident engineer of the project. The major work after 1917 involved driving twenty-three miles of hard-rock tunnel; the building of two major concrete dams—Shaver Lake at El. 5370, and Florence Lake at El. 7229; the construction of three major hydroelectric power stations with penstocks and turbines for heads of 730, 830, and 2,418 ft, respectively; and the installation of additional power generating equipment in two other previously built power stations. For the recreation of the relatively isolated construction staff of the company at Big Creek, Oliver Schieber initiated, designed, and built a nine-hole golf course on a mountain meadow near Shaver Lake, which is now under the water of the reservoir.

In March, 1925, he was appointed technical assistant to E. R. Davis, manager of construction of the company, and was transferred to the Los Angeles headquarters. There he was engaged on the preparation of estimates and budgets, making layouts for construction plants, and arranging for the purchase of materials and equipment for the construction of the company's developments, which included tunnels, pipe lines, penstocks, powerhouses, transmission lines, and transformer stations.

By 1931, the City of Los Angeles had joined with other communities in Southern California to form the Metropolitan Water District for the purpose of constructing an aqueduct to bring sixteen hundred cubic feet per second of water from the Colorado River to Southern California. The district had selected the late Frank E. Weymouth,[2] Hon. M. ASCE, as its chief engineer. Oliver Schieber's experience was needed on this work, and he accepted an appointment as senior engineer with the district. The 233-mile route of the aqueduct is in mountainous and desert country, and most of it was inaccessible by roads. Since the construction was to be by contract, to avoid duplication of effort by contractors and to remove some of the contingencies due to inaccessibility, and other bidding hazards, the district built district camps, housing facilities, field headquarters, and roads, and drilled water wells along the route for the use of the contractors who were successful bidders on the various sections of the work. Oliver Schieber designed the district camps,

[2] For memoir, see *Transactions*, ASCE, Vol. 107, 1942, p. 1712.

field headquarters, and the water-supply facilities, and then superintended their construction.

After contract construction got under way, and for the succeeding three years, he was resident engineer in charge of construction on division No. 6 of the aqueduct, which included eight and a half miles of fifteen-foot-diameter hard-rock tunnel; six and a half miles of fifteen-foot concrete conduit; and nine miles of twelve-foot-diameter reinforced-concrete siphon pipe. On completion of division No. 6, he was moved to division No. 4, as division engineer in charge of engineering, where for the next eight months he handled the lining of twelve miles of sixteen-foot-diameter tunnel and the construction of ten twelve-foot-diameter reinforced-concrete inverted siphons, having an aggregate length of two miles. He was then made division engineer in charge of construction of division No. 4. This included the lining and pressure grouting of eight miles of tunnel by force account, the contract construction of three and one-fourth miles of sixteen-foot-diameter concrete conduit, and the laying of a half mile of reinforced-concrete inverted siphon pipe. By the end of 1938, when this two hundred million dollar Colorado River aqueduct was nearing completion, Oliver Schieber severed his connection with the Metropolitan Water District.

He became construction superintendent for the Federal Works Projects Administration in Southern California. During 1939 and 1940 he had charge of fifteen hundred men, engaged on the construction of two miles of twelve-foot-diameter storm drain tunnel through the Los Angeles business district, and one and a half miles of the Arroyo Seco storm channel, which has a capacity of twenty-five thousand cubic feet per second. This channel is an integral part of the Arroyo Seco Parkway development, connecting Los Angeles and Pasadena, Calif.

In May, 1940, he returned to the Southern California Edison Company, Limited, where, until his death, he directed and supervised a group of engineers engaged in various investigations and economic analyses. Among the projects on which he was engaged was the accumulation of data for presentation to a federal appraisal board in the determination of damages to be paid by the United States Government to the Edison Securities Company, a subsidiary of the Southern California Edison Company, for the acquisition of water rights appurtenant to the Herminghaus Ranch lands in central California. He made a comprehensive survey and study of the hydrology of the entire Big Creek hydroelectric system, including a determination of the feasibility of additional reservoir capacity at the headwaters of the San Joaquin River, and a determination of the effect of storage by the Southern California Edison Company of the waters of the San Joaquin River upon the operations of Friant Reservoir of the central California project then about to be built by the U. S. Bureau of Reclamation.

Mr. Schieber prepared cost data in connection with Federal Power Commission proceedings concerning the cost of Federal Projects 67 and 120 of the Big Creek—San Joaquin River hydroelectric system. He prepared plans,

specifications, and cost estimates for major maintenance work on several of the company's dams and hydraulic structures. These included repairs to the Ward Tunnel, the thirteen-mile hard-rock tunnel on the construction of which he had been engaged from 1920 to 1925; the upstream backfill of Florence Lake Dam and two of the Huntington Lake dams; and repairs to the top of Shaver Lake Dam. He worked on several projects in connection with the company's Long Beach steam plant, including the general subsidence of the plant occurring after the construction of the graving dock at the Terminal Island Naval Base; and the replacement and valuation for compensation purposes of two steam generator units which were seized by the United States for installation in Russia.

On January 21, 1924, Mr. Schieber was married to Mildred Gray Bulfinch of Los Angeles who had been admitted to the practice of law in the State of California. After their marriage they lived at Big Creek until he was transferred to Los Angeles in 1925. In 1928 they built a home at 1751 Windsor Road in San Marino, Calif., which continued to be their home regardless of where Mr. Schieber's professional work took him. Mr. Schieber died on June 23, 1944, at the Huntington Hospital, Pasadena, after a brief illness. His family and his home were a source of pride and happiness to him. He is survived by his widow; his daughter, Margery G.; and a son, Norman B.—of San Marino; and his mother, Mrs. John A. Schieber; his brother, Homer J.; and his sister, Ella—all of whom live in Los Angeles.

In his youthful days Mr. Schieber took pleasure in mountain climbing, and in his more mature years found recreation in exploring by motor with his family the many remote and inaccessible regions of the West.

Oliver Schieber's interest in his profession never lagged. He was a registered civil engineer in the State of California. In Society affairs, he was very active, serving for many years on the Local Qualification Committee of the Los Angeles Section, and contributing his time and talent to preparing papers for Society and Section meetings.

His solid, substantial, character, based on straight thinking and clean living, was outstanding. Among his associates in the several organizations that claimed his services, Oliver Schieber was loved as few men are loved. His tireless energy and constant striving for the worthwhile things of life were an inspiration to them. He bore no men malice, nor they him. His passing has meant the loss of a sincere friend to all who knew him.

Mr. Schieber was elected an Associate Member of the American Society of Civil Engineers on April 25, 1921, and a Member on July 31, 1933.

SYDNEY ABRAM SHUBIN, M. ASCE[1]

Died September 18, 1946

Sydney Abram Shubin was born on May 14, 1890, in New York, N. Y. He was the son of Jacob and Anna (Sobel) Shubin. After preparation in the public grade and high schools of New York, he entered Cooper Union Institute, also in New York, in 1911, from which he received the degree of Bachelor of Science in Civil Engineering in 1915 and the degree of Civil Engineer in 1926.

For two years after graduation he did drafting, designing, and estimating work for the Buckingham Steel Company in Brooklyn, N. Y., the Lackawanna Steel Company in Buffalo, N. Y., and the Bollinger-Andrews Company in Verona, Pa. This was followed by four years of work (from 1917 to 1921) with the Heyl and Patterson Company in Pittsburgh, Pa., on checking, designing, and estimating work for coal tipples, conveyors, and bunkers. This period also included two six-month engagements with the McClintic-Marshall Company in Pittsburgh, on design and checking of details and connections on long-span highway and railroad bridges, and on buildings. From 1922 to 1924, he was employed by the J. Harold Rapp Company in Pittsburgh, engaged in laying out and checking work in industrial plants, office buildings, and theaters, which included a theater and market house for the City of Memphis, Tenn.

This ten years of training and experience, after graduation, in the design and related work connected with many kinds of steel structures, served as an excellent foundation for the work in which Mr. Shubin spent the remainder of his life. In April, 1924, he was employed by the County of Allegheny, Pennsylvania, in its newly organized Department of Public Works, where he became assistant design engineer in the Division of Design, Bureau of Bridges. From 1924 to 1932, the Allegheny County Department of Public Works carried out a large program, including the design and construction of major and minor bridges, the cost of which was provided by a forty million dollar bond issue for bridges alone, as well as a similarly large expenditure for road construction. Mr. Shubin shared with his associates an intimate and responsible part in this large program, during which were built such structures as the McKees Rocks and the West End-North Side bridges over the Ohio River; the Point, Liberty, South Tenth Street, McKeesport-Duquesne, and Glassport-Clairton bridges over the Monongahela River; the Sixth, Seventh, Ninth, and Thirty-First street bridges over the Allegheny River; numerous ravine bridges on the Ohio River and the Allegheny River boulevards; and the monumental George Westinghouse Bridge on U. S. route No. 30 at East Pittsburgh, Pa., as well as many minor structures.

Mr. Shubin's particular responsibility in connection with this program was the design of the beautiful South Tenth Street (Monongahela River) crossing,

[1] Memoir prepared by a Committee of the Pittsburgh Section consisting of Harry G. Appel, Clarke K. Harvey, and George S. Richardson, Members ASCE, and Ernest Tessitor, Assoc. M. ASCE.

a parallel wire cable suspension bridge, with gravity anchorages and two river piers, having a 725-ft main span and side spans of 275 ft, completed at a cost of nearly two million dollars.

Design and construction having dwindled because of the depression, Mr. Shubin was engaged from 1932 to 1934 in bridge maintenance work, in charge of the county's forty-five major bridges in that period. He again resumed design work for Allegheny County in 1934, becoming bridge design engineer in 1936 in the department, later known as the County Department of Works, and was head of bridge and structural design until his death.

In 1934 Mr. Shubin had charge of the design of extensive improvements in North Park, Allegheny County, consisting of a dam and spillway for a large artificial lake, a boathouse, a swimming pool, and a bathhouse.

Mr. Shubin supervised the design of new structures at the County Airport in 1936, including a hangar which had the largest automatically operated doors theretofore constructed, with a clear opening of forty by one hundred and fifty feet. Later, he was responsible for the design of the Highland Park Bridge over the Allegheny River, the Dookers Hollow Bridge over a deep ravine, the clover leaf at the intersection of state route No. 51 and the Lebanon Church Road, and the elevated roadways and bridges of the Water Street and Duquesne Way improvements along the banks of the Monongahela and Allegheny rivers in downtown Pittsburgh.

Two other structures which he conceived remained to be constructed after his death—the Babcock Boulevard and the Nelson Run Road traffic interchanges on the new McKnight Road, under construction. At his death, plans were practically completed also for the four million dollar Dravosburg Bridge over the Monongahela River, and others were well under way for the Rankin Bridge over the same stream, both included in the county's thirty-four million dollar bridge, road, and airport program.

In addition to his other duties, Mr. Shubin frequently appeared on behalf of the county in public utility commission hearings.

Mr. Shubin was for twenty-three years a member of the Rodef Shalom Congregation. He was a man of high ideals and integrity and enjoyed the respect of his many friends, associates, and acquaintances. His character is clearly shown by the following quotation summarizing his record, from a paper he prepared shortly before his death:

> "I thank God for having lived in this great land of freedom and opportunity. By his Grace he has inscribed me in the book of life as a builder of monuments for a future world, which I hope will be a world of peace and tranquility, and with human dignity."

He was a registered professional engineer in Pennsylvania and a charter member of the Pittsburgh Chapter of the Pennsylvania Society of Professional Engineers.

In 1916 Mr. Shubin was married to Anna Shubin, to whom two children were born, Murray J. and Allan M. Mrs. Shubin and their two sons survive.

Mr. Shubin was elected an Associate Member of the American Society of Civil Engineers on June 7, 1926, and a Member on June 27, 1932.

ALFRED VARLEY SIMS, M. ASCE[1]

DIED JANUARY 21, 1944

Alfred Varley Sims was born in Port Hope, Ont., Canada, on September 21, 1864. His father, Alfred William Sims, an American civil engineer, was on a professional mission, accompanied by his wife Adelaide (Sowden) Sims.

Some years later the family returned to the United States and settled temporarily in Orbisonia, Pa., where young Alfred attended a private school. As is the usual lot of the civil engineer, Mr. Sims was forced by his professional activities to move from place to place, so that the record of his son's early education is somewhat vague.

There is no doubt that his father's vocation influenced Alfred in the profession he was to embrace, and inured him to the almost nomadic existence that he maintained throughout the greater part of his life. However, his father evidently took a hand in his son's technical education; at seventeen the young man began his engineering career in the field, making surveys for the Rock Hill Iron and Coal Company and filling various subordinate positions with the Pennsylvania Railroad Company from 1881 to 1885.

That these five years of actual engineering work were profitable is shown by the fact that in 1886 he entered the University of Pennsylvania in Philadelphia, as a junior, and was graduated two years later with the class of 1888. It is indicative of his character that during his university days he was active in extracurricular pursuits; he played football and baseball in both his junior and senior years, and was a member of various committees concerned with the social affairs of his class. He was popular with his associates, being ready and willing to do his share in any common enterprise. These traits he bore throughout his life and, by them, earned quickly the respect and affection of his fellows in many parts of the world.

For the seven years following graduation his energies were directed to various railroad construction jobs. He was chief engineer for the New England Terminal Company (1888–1889), the Atlantic and Danville Railway Company (1898–1890), the Danville and East Tennessee Railroad Company, and the Atlantic Coast and North Western Railroad Company (1890–1892).

During his association with the Atlantic Coast and North Western Railroad Company he met Ruth Hairston to whom he was married on June 10, 1891. She was of an old Virginia family, and there were murmured protests to her marriage to a "damn Yankee." They were soon quieted when it became apparent that Mr. Sims was in complete sympathy with the problems and viewpoint of the South, and embraced their Democratic faith wholeheartedly.

Mrs. Sims had inherited considerable plantation acreage, in Virginia and North Carolina, which was to afford Mr. Sims an intense and constructive interest in farming that continued through his lifetime.

[1] Memoir prepared by Alden Arthur Knipe, Esq., New York, N.Y.

During the year 1892, Mr. Sims was chief engineer, assigned to a confidential survey of Death Valley, Calif., undertaken by the Utah, Nevada and California Railroad Company. This assignment nearly ended his career. When his desert guide admitted they were lost, it took his skilful combination of keen observation, animal lore, instinct, and practical knowledge of engineering to bring them back to civilization before their water and supplies were exhausted. Because of the secret nature of the expedition Mrs. Sims, who accompanied her husband as far as a desert border hotel, had to acquiesce in the mild fiction that her husband was in the desert for his health, and to receive the heartily expressed sympathy of newly made friends.

During the year 1894 Mr. and Mrs. Sims were in the ancestral home at Berry Hill, Pittsylvania County, Virginia, where Mr. Sims' inquiring mind immediately centered on the farming and social problems of the region. It was tobacco country where the tenants lived a hand-to-mouth existence, and the solution of their problems demanded a radical change in methods. Rehabilitation of the land, diversity of crops, and a more modern system of cultivation were the essential changes Mr. Sims inaugurated. He devised new ways of curing, handling, and storing tobacco, while hampered by the resistance of his tenants who "had always done it that way" and saw no reason to change even though their returns grew less year by year. However, he made headway against their dyed-in-the-wool prejudices, and his sincere desire to promote the welfare of the farmers, in time, dissolved the fogs of misunderstanding that existed between landlord and tenant and that had grown into an antagonistic tradition throughout the region. The "sharecropper" policy Mr. Sims found bad for the land, demoralizing for the individual, and unprofitable for all concerned. Throughout the rest of his life he combated these conditions with tireless energy.

In 1895 Mr. Sims was called to the chair of engineering at the State University of Iowa at Iowa City, where, until 1904, he devoted his attention to teaching. By no means was he the typical professor, a title he disliked, because to his thinking the formalities incident to a pedagogical status placed a barrier between himself and his students. It was his feeling that he and his pupils were as one in the investigation of the engineering problems presented in the curriculum. Of necessity his classes were scheduled, but there was never any limit set for discussion and consultation. Mr. Sims was always available to his scholars, who were quick to embrace these opportunities for informal instruction. In spite of his dislike for the rigidity inherent in the life of a university professor Mr. Sims found a great deal of pleasure in the years spent in Iowa.

During the nine years at the university he did considerable research in cement, concrete, and sand that resulted in the inventions of mechanisms and methods for uniform testing of cement, and the determination of laws of forces and resistances in granular substances. He harnessed them for punching clean holes in metal, building flat arches of sand without cement, and constructing paper and sand columns that exceeded concrete in strength. He was the author of the following pamphlets: "The Engineer and the Death

Rate," "Discussion on Concrete," and "Computation of Structural Stresses."

After nine years of teaching, mitigated by vacation trips to the farms in Virginia, Mr. Sims abandoned the title of professor and returned to active engineering work. In 1904 he was appointed president, chief engineer, and general manager of the Cuba Eastern Railroad Company, the Northwestern Cuba Railroad Company, the Cuba Eastern Terminal Company, and eight other allied enterprises. He was stationed in Guantanamo, Cuba, where for four years he struggled with a hostile Cuban government, a revolutionary junta, and the constant, rather dubious, intrigues of rival railroad competition. After an extremely busy and anxious time, he was on the way to success when the panic of 1907–1908 closed the Knickerbocker Trust Company in New York, N. Y., which was the financial support of the extensive enterprise. It was a discouraging experience because Mr. Sims was already building new railroad lines which would have been profitable and expanding the other affiliated organizations into money-making undertakings. The companies, however, were forced into liquidation, and Mr. Sims returned to the United States, rather worn in health and keenly disappointed in the realization that his hard work had gone for nothing through no fault of his management in Cuba, but because of a lax banking system in New York.

During the rest of his life it was characteristic of him to cherish the remembrance of his years in Cuba. Shortly after returning to the United States he received a handsome watch with the inscription, "To Mr. A .V. Sims from the boys of The Cuba Eastern in recognition of many a square deal, 1908." He retired for a time to Virginia to regain his health and to carry out many plans for the betterment of his tenants and the improvement of his lands.

For a year, 1913–1914, he was in London, England, promoting a hardwood project in Cuba. World War I, however, put an end to these negotiations and he returned to New York. Here he established himself as a consulting engineer and a representative of The James Boyd Company in the sale of four-wheel-drive trucks to the allied armies.

During this period he became aware that the valves obtainable for reciprocating pumps left much to be desired, both functionally and materially. Characteristically, he set to work to invent a better valve; during lulls in his engineering consultations, he produced the "Sims Inclined Port Rotating Pump Valve" which incorporates many features that solve most of the problems inherent in such a mechanism. He was owner and president of the Sims Pump Valve Company of New York. For the remainder of his life, Mr. Sims, in partnership with his son Alfred, devoted much of his time to the development and refinement of this invention. Its wide distribution and general acceptance as power plant equipment in both the marine and stationary fields attest to a correct harnessing of nature's laws into a mechanism for the benefit of man.

The need for air raid shelters during World War II resulted in the request that Mr. Sims make further experiments with granular substances. His early patent of 1905 on sand columns, arches, and floors was supplemented by an-

other that was not issued until after his death. His failing health prevented his following through with his son on their application for the construction of bombproof shelters. However, he had the gratification of seeing the interest of military and civil engineers in the model he constructed in 1941. United States patents were issued to Alfred Varley Sims covering the following: Columns, arches, and floors of sand; ticket holders; processes and apparatus for manufacturing articles from paper pulp; safety sea suit; pump valves (two individual patents); hay drying and the like; bilge pump mechanisms; mixing fluids of different temperatures and densities; and granular supports.

Mr. Sims was a large man, six feet two inches tall, and broad in proportion with a big man's wide, tolerant outlook upon life. He was forever inventing gadgets for the fun of it, or delving into obscure problems to satisfy an insatiable curiosity—to find out what made the physical "wheels go round." His hobby was playing with nature's laws and harnessing them for the use of mankind; his recreation was his family and its interests. He had an innate fondness for horses, dogs, and all nature's children. He lent a ready and sympathetic ear to the everyday troubles of his associates giving advice when it was asked, but tempering its import with a fine sense of humor. His friends, and there were hosts of them, deeply regret his passing; but they are consoled by the fact that he lived a long, useful, and successful life that was inspired by high ethical standards and was rewarded by the gratification that comes with a multitude of tasks well done.

In addition to membership in this Society Mr. Sims belonged to the honor society of Sigma Xi and he was a member of the Episcopalian Church. He is survived by a son, Alfred W., and three daughters, Elsie H. (Mrs. F. Q. Rickards), Ruth H. (Mrs. George Schaeffer), and Adelaide Varley (Mrs. Paul M. Zorn).

Mr. Sims was elected a Member of the American Society of Civil Engineers on March 4, 1896.

WALTER LYNES SMITH, M. ASCE[1]

DIED JANUARY 29, 1947

Walter Lynes Smith was born at Middleburg in Schoharie County, N. Y., on July 15, 1876. He was graduated from the public school in Chicopee, Mass., in June, 1896, and from Union College in Schenectady, N. Y., on June 27, 1900, with the degree of Bachelor of Science in Civil Engineering.

After graduation Mr. Smith entered the employ of the American Bridge Company as draftsman and, after one year, he left to work for the New York, New Haven and Hartford Railroad Company in the same capacity.

In January, 1906, he joined the Toledo-Massillon Bridge Company as assistant chief engineer and in September, 1908, was made contracting engineer of the Pennsylvania Bridge Company.

---

[1] Memoir prepared by Hurleosco Austill, M. ASCE.

His next employment, beginning in September, 1909, was with the Pennsylvania Railroad Company in the office of the engineer of bridges and buildings on the lines west of Pittsburgh, Pa., and, in May, 1919, he was appointed assistant engineer of bridges and buildings. In the latter capacity he was in special charge of design and construction of two lift bridges (about $1,400,000) and of a bridge over the Maumee River at Toledo, Ohio (about $400,000).

While working for the Pennsylvania Railroad Company Mr. Smith was associated with that eminent bridge engineer, J. C. Bland,[2] who was serving as consulting engineer for the Terminal Railroad Association of St. Louis, Mo. There was important work to be done on the terminal's two bridges over the Mississippi River, and on March 1, 1920, Mr. Smith was appointed bridge engineer of the Terminal Railroad Association of St. Louis, which position he retained with distinction until his voluntary retirement on August 30, 1941.

He was particularly fond of music and enjoyed his retirement by devoting his time to the higher things of life and especially to the study of foreign languages. His rather sudden death occurred after a collapse. He was a bachelor and had no near kin.

Mr. Smith was elected an Associate Member of the American Society of Civil Engineers on February 4, 1914, and a Member on May 8, 1922. He became a Life Member in January, 1947.

RUSSELL ELSTNER SNOWDEN, M. ASCE[1]

DIED DECEMBER 5, 1946

Russell Elstner Snowden was born on December 22, 1880, at Snowden, Currituck County, N. C. He was the son of Milton Hume Snowden and Rosa (Halstead) Snowden, of Snowden. He traced his ancestry to Thomas Snowden, whose name appears in colonial records in 1682 as clerk of court of Albemarle County. This county has since been subdivided into Currituck, Camden, Pasquotank, Perquimans, Chowan, and Gates counties, occupying the extreme northeastern corner of the state. Albemarle disappeared as a county, but the name persists in Albemarle Sound, which washed its southern shores.

There are a Snowden crest and a coat of arms, which in all probability were honors borne by more remote ancestors. Some of the Snowdens dwelt in Yorkshire, England, and many families from Yorkshire were early settlers in America.

Russell attended private school in Snowden, until he was fourteen years old; and for the next four years he attended Elizabeth City Academy in Elizabeth City, N. C. In 1898 he entered North Carolina State College (then known as North Carolina Agricultural and Mechanical College) at

[2] For memoir, see *Transactions*, ASCE, Vol. 95, 1931, p. 1453.

[1] Memoir prepared by O. B. Bestor, M. ASCE.

Raleigh. He not only stood well in his classes, but was active and proficient in military affairs, becoming the highest student officer with the rank of major of a battalion. He was graduated on May 28, 1902, with the degree of Bachelor of Engineering.

During the succeeding eight years Mr. Snowden engaged in railroad engineering. From November, 1902, to February, 1903, he was rodman on the construction of the Oxford and Coast Line Railway, a branch of the Seaboard Air Line Railway. From March, 1903, to November, 1905, he was, successively, rodman and transitman on preliminary and location surveys, then assistant resident engineer on heavy railroad construction, for the Coal and Coke Railway on the Clover Fork Residency in Lewis and Braxton counties, West Virginia. The work included a tunnel about 1,000 feet long through unstable rock and shale requiring timber lining. It was driven from both ends, the drifts meeting near the center of the tunnel. Mr. Snowden repeatedly checked the alinement and the stationing, using vertical and slope measurements to check those made horizontally. When the headings met, the closure was practically perfect, both in alinement and measurement. The approach cuts to the portals were made through material that became sliding when wet. Unusual foresight was shown by removing threatening material outside the normal cross sections, and establishing an effective system of ditching to prevent future slides.

Upon completion of the work in West Virginia, Mr. Snowden returned to North Carolina, and from February to July, 1906, engaged in preliminary surveys as field engineer for the Raleigh and Charleston Railroad Company. From July, 1906, to September, 1907, he was assistant engineer with the Southern Railway Company—for nine months in charge of a locating party revising the main line between Washington, D. C., and Atlanta, Ga., and for the succeeding six months on twelve miles of heavy construction, using ten steam shovels, on the revision and double tracking of the main line from Lynchburg to Danville, Va.

During the last quarter of 1907 he was special resident engineer for the Norfolk Southern Railroad Company, on construction from Washington, N. C., to Raleigh. Near the end of the following year he was for about four months field engineer for the North and South Carolina Railroad Company, making preliminary and location surveys. From April, 1909, to April, 1910, he performed similar work as topographer (actually transitman) and as transitman (actually chief of party) for the Seaboard Air Line Railway Company. From April to August, 1910, he was assistant locating engineer for the Coal and Coke Railway, making a survey to extend that railway from Elkins, W. Va., crossing the Morgantown and Kingwood Railroad at Rowlesburg, W. Va., to connect with the New York Central Railroad at Cheat Haven, Pa. From September, 1910, to the end of the year, he was assistant to the chief engineer of the Atlanta and Northeastern Railway Company on a location northward from Atlanta to an ultimate crossing of the Blue Ridge Mountains.

Mr. Snowden then turned from railroad to highway engineering. From February to December, 1911, he was highway engineer, District No. 3,

Covington County, Mississippi.. However, malaria caused him to resign; and he returned to his home state where for the next twelve months he was chief engineer and general manager of the Reynolds Farms, near Winston-Salem, N. C. From February, 1913, to November, 1914, he was highway engineer in Craven County, and part of this time also highway engineer, Goldsboro Improvement, Wayne County. Then he spent two years in general practice, including drainage and per diem work for the North Carolina State Highway Commission.

In May, 1917, Mr. Snowden entered the employ of the reorganized North Carolina State Highway Commission, remaining until his retirement in July, 1931. During the first four years of this period he was division engineer in complete charge of all highway location and construction in the Eastern Division and later in the Fourth Division. In April, 1921, he became district engineer of the Second District, with headquarters at Kinston, embracing ten counties in the middle of the easternmost section of the state.

After his retirement, Mr. Snowden maintained a consulting office at his home in Snowden, specializing in land drainage and topographic, municipal, railway, and industrial surveys, including estimates, designs, specifications, and supervision. He was also the head of the Works Progress Administration work in Currituck County.

Mr. Snowden's most comprehensive and responsible work was during the period when he was district engineer for the State Highway Commission, particularly from 1921 to 1926, when the state carried out its great highway building program, beginning with a $50,000,000 bond issue and augmented by later bond issues. He was required to organize his office, field, and maintenance forces; to determine the location of the new highways, which, under the State Highway Act of 1921, were to be laid to connect all principal towns and county seats; to insure that the construction contracts were executed according to the specifications; and to make monthly estimates of the work done, which were forwarded to Raleigh for payment of the contractors.

The location problems were often serious: All sections wanted roads and the routings determined were of intense interest to everyone; factional disputes arose, merchants insisted that roads should pass their business houses, and landowners objected to having their fields split wide open. Mr. Snowden met these problems with tact and firmness and, of the many appeals carried to the head office in Raleigh, very few came from his district. He had expressly desired that his district should not include his home county, so that he might be entirely unbiased in his decisions.

Much of his district lay in the tidewater region of the state; the flatness of the terrain required careful study of methods of drainage, and drainage became a specialty with him. The high ground in the "pocosins" (swamp lands) which was sought for the road locations might be less than a foot above the general ground level: Mr. Snowden did not resort to accurate leveling to determine this, but found the high ground unerringly through his knowledge of the timber growths in the pocosins, a knowledge probably obtained early in life, and supplemented by thorough study.

"Currituck," as he was called by two or three of his early friends, was soft spoken and reserved, and did not invite familarity; yet he was a genial and entertaining companion, with a keen, dry humor, and a fund of droll stories. He was courageous and determined, and would not change his decisions even in minor matters. He had the reputation of making his word stick with contractors. His rugged honesty, sound judgment, and loyalty to his associates resulted in the establishment of an exceptionally faithful and efficient organization in his district. He inculcated a fine spirit of helpfulness to travelers in trouble, and auto trouble was frequent in those days of "detours" when the state was getting its roads out of the mud.

Mr. Snowden was married on October 24, 1906, at Snowden, to Mary Morris Stevens, who survives him. His one child, Rosa Elizabeth, died in 1916, when nine and one-half years old. There are no living brothers or sisters. One brother, Capt. Basil S. Snowden, was killed in World War I.

Mr. Snowden was a member of Masonic Hall Lodge No. 53, and a Past Master of that lodge. He belonged to the Providence Baptist Church, and taught the Men's Bible Class for several years. He was a charter member of the North Carolina Society of Engineers, which he assisted in founding in 1917, and later became an honorary member of that organization.

Mr. Snowden was elected an Associate Member of the American Society of Civil Engineers on June 18, 1918, and a Member on August 28, 1922.

WILLIAM FRANKLIN STROUSE, M. ASCE[1]

DIED DECEMBER 5, 1945

William Franklin Strouse, eldest son of Joseph and Anna (Krebs) Strouse, was born in State College, Pa., on December 19, 1864.

His is the typical success story of the American boy, born of poor but thrifty parents, who made good in his chosen profession. He was a farm boy and received his early education in the rural district school. A descendant of the early settlers who came to the United States with William Penn, his family had for generations been tillers of the soil. Thus, it came as a surprise, and caused no little anxiety to his parents, when young "Frank" expressed a desire to leave the land to become a civil engineer. He received little encouragement from his mother who was the dominant figure in the home. Indeed, had it not been for the kindly interest displayed by his teachers in the rural school, in addition to his own strong and indomitable courage, he might not have been able to realize his ambition. He was studious, conscientious, and untiring in his efforts to achieve the goal which he had set for himself, and no obstacle, financial or otherwise, could deter him. He worked early and late to earn the money needed to pay his expenses through

[1] Memoir prepared by W. P. Irvin, Assoc. M. ASCE.

"prep" school and college, and many a night he burned the midnight oil over intricate figures and involved engineering problems after a long and tiring day of hard manual labor. All this he accomplished with an added handicap, the use of only one eye; an injury at birth had deprived him of the sight of his right eye.

Mr. Strouse was graduated from Pennsylvania State College at State College, in June, 1887, with the degree of Bachelor of Science. From July, 1887, to September, 1889, he was employed in the office of the Engineer of Construction at Philipsburg, Pa., and as transitman on surveys for the Pennsylvania Railroad Company. In September, 1889, he severed his connection with the Pennsylvania Railroad Company and accepted a position as draftsman with the Maryland Central Railway Company in Baltimore, Md., later working on surveys for the Baltimore Belt Railroad. During this period he continued his studies, and in June, 1890, he returned to Pennsylvania State College to receive the degree of Civil Engineer.

On his return to Baltimore, he was promoted to chief draftsman for the Maryland Construction Company, builders of the Baltimore Belt Railroad, and remained with them until 1893, when he transferred to the office of W. T. Manning, chief engineer of the Baltimore and Ohio Railroad Company, as chief draftsman. From March, 1897, to June, 1903, in addition to his duties as head of the drafting office, he was almost constantly exercising general or detail supervision over odd pieces of construction work or surveys, the most important being the remodeling of the passenger station and the construction of new baggage room and train sheds at Baltimore; construction of new freight and passenger stations at Clarksburg, W. Va., and Connellsville, Pa.; bulk yard and stations at Fairmont, W. Va.; surveys for proposed improvements of the Washington (D. C.) branch; and terminal improvements at Washington, D. C.

In June, 1903, he was appointed assistant engineer of the Washington Terminal Company in direct charge of all work under the jurisdiction of the Engineering Department of the Baltimore and Ohio Railroad Company, which included the construction of the Union Station, train sheds, powerhouses, engine houses, and shops—in short, all the work north of Massachusetts Avenue in Washington, D. C. Mr. Strouse wrote a detailed description of this project,[2] the largest of its kind ever built up to that time. The Union Station was the first building constructed under the McMillan Commission's plan for a more beautiful national capitol. It replaced the maze of unrestricted railroads which cut across the mall and ran down city streets, each to its own shabby terminal. The concourse alone is larger than those of the New York Central Railroad and Pennsylvania Railroad terminals in New York, N. Y., combined. It is a great tribute to Mr. Strouse's innate sense of justice, his patience, and deep understanding of human nature that, in a period of great labor unrest, he was able to complete this project, costing twenty-five million dollars and occupying a space of more than twenty-five acres, without a single strike or lawsuit.

[2] "The Reconstruction of the Passenger Terminals at Washington, D. C.," by W. F. Strouse, *Transactions*, ASCE, Vol. LXXI, March, 1911, p. 11.

When the Union Station was completed in 1909, Mr. Strouse was confronted with the question of whether to remain in the employ of the Baltimore and Ohio Railroad Company, or to accept one of the very excellent offers he had received from other construction companies during this period. Since, in each instance, he would have been required to make drastic changes in his domestic affairs, he finally decided to continue his work with the Baltimore and Ohio Railroad, and thus remain in his beloved Roland Park, Md., where he had established his home.

Subsequent to the Washington Terminal improvements, from December, 1909, to October, 1918, Mr. Strouse was engaged in the construction of the Baltimore and Ohio Railroad bridge in the vicinity of the Gay Street Station in Baltimore. He was also in charge of the Curtis Bay Coal Pier construction in the early stages of that project. As assistant engineer, he had charge of all construction between Philadelphia, Pa., and Cumberland, Md., which included second track work between Sir John's Run and Great Cacapon, and Green Spring and Patterson's Creek, in West Virginia. During World War I, he was in charge of Baltimore and Ohio track improvements on the Washington, Baltimore and Annapolis Railroad between Annapolis Junction and Odenton in Maryland in connection with the costruction of Camp Meade.

In 1918, on the doctor's orders to "take things a little easier," Mr. Strouse resigned from the Baltimore and Ohio Railroad Company, and shortly thereafter accepted the position of Civilian Supervising Engineer with the United States Army, in charge of cantonment construction at Fort Howard, Md. This work came to a close with the end of the war in 1919.

His last professional activity was in the Engineering Department of the Public Service Commission of Maryland, where he served from April, 1919—first, in the capacity of valuation engineer, and later, as chief engineer—until his retirement in October, 1931.

The outstanding work of Mr. Strouse while associated with the Public Service Commission of Maryland was to make valuations of practically all the public utilities of the state, totaling millions of dollars. He also made some valuations of railroad properties, estimates of the cost of several ferry projects, and numerous investigations of service matters throughout the state. These investigations succeeded in clarifying a number of conflicting claims as to service and related matters.

Mr. Strouse was an able engineer, noted for his unimpeachable integrity, for his adherence to his beliefs, and for the very careful and painstaking way in which he did every job on which he was engaged. As an executive he was strict, but just, taking his work seriously and giving unstintingly of his time and effort. He expected those working under him to be equally conscientious, and he was rarely disappointed. His knowledge and experience he shared without reservation. Quiet and unassuming, he was never one to seek publicity, but believed credit should be given where credit was due. A man of rare judgment, tempered with good common sense, he instinctively inspired confidence, and, therefore, made deep and lasting friendships among his associates.

In addition to this Society, of which Mr. Strouse was a Life Member, he was also a life member of the American Railway Bridge and Building Association, and was an active participant in the work thereof, serving on various committees and as chairman of the Committee on the Elimination of Grade Crossings. Several of his articles on safety measures appeared from time to time in its *Proceedings.* In 1921 he served with distinction as president of the association. He was also a charter member and organizer of the Engineers' Club of Baltimore and in 1911, its president.

Mr. Strouse ardently supported his alma mater, and for many years was president of the Baltimore Chapter of the Penn State Alumni Association. During World War I, he kept "open house" for Penn State men in the armed services who were stationed in and around Baltimore. He belonged to the Phi Kappa Sigma fraternity.

His interests were many and diversified. As a young man in Baltimore, he was active in the work of the Second English Lutheran Church and through its Sunday school became interested in a group of teen-age boys. He encouraged them to fit themselves for specialized work and assisted them in finding suitable jobs. This interest was sustained throughout his later life, and through his efforts he made it possible for a number of young men to receive college educations. It was, therefore, a fitting tribute to his memory that so many of "his boys" attended his funeral.

Mr. Strouse was a great student, and over the years acquired a large technical library, which he later presented to the Engineers' Club of Baltimore. He was also intensely interested in the work of civic organizations, and was a loyal supporter of various charities.

After his retirement from the Public Service Commission of Maryland, he devoted a great deal of time to tracing his genealogy, and spent many pleasant hours driving from place to place with his wife, the former Harriet E. Irvin of Clearfield County, Pennsylvania, searching for records and collecting information for a book which he planned to write. However, this pleasant interlude in their lives came to an abrupt end in 1933, when Mrs. Strouse was stricken with paralysis and remained an invalid until her death in October, 1945. It was characteristic of Mr. Strouse to give up his various activities and devote his entire time to caring for her. With him, "first things came first," and once a decision was made he never faltered. It seemed rather significant, therefore, that two months to the day, after her death, his last work accomplished, he too passed away. A devoted husband for a period of fifty-four years, he was also a devoted father. He is survived by two daughters, Miriam (Mrs. M. J. Keller) and Edna (Mrs. E. C. Romaine); and two granddaughters.

Mr. Strouse was elected a Member of the American Society of Civil Engineers on March 1, 1905.

EDWARD GRAY TABER, M. ASCE[1]

DIED FEBRUARY 19, 1946

Edward Gray Taber, the son of Marcus William and Olive Collins (Ashley) Taber was born in Freetown, Mass., on July 14, 1855. He was a descendant of Philip Taber, an Englishman from Essex, England, who landed at Plymouth, Mass., in 1630. The Tabers, in his father's time, were largely a seagoing family, and his father, Marcus Taber, spent the greater part of his active life at sea, mostly as a master on whaling ships.

Shortly after Edward's birth his parents moved to New Bedford, Mass., and it was there he received his early education, being graduated from high school in 1873. He completed a three-year course at the Massachusetts Institute of Technology at Boston, in 1877. Poor health, however, caused him to discontinue his schooling and kept him at home until 1880, when he entered the service of the Northern Pacific Railway Company which was then extending its line of railroad to the Pacific coast.

He enjoyed a long and active life in the almost continuous practice of his profession from 1880, when he began work with the Northern Pacific Railway Company, until June 30, 1941, when he retired. His engagements, principally with western railways, were as follows:

1880—rodman and levelman with the Northern Pacific Railway Company in Montana.

1881–1885—assistant engineer on location and construction with the Northern Pacific Railway Company, mostly in Montana.

1886–1887—assistant engineer on location and construction with the Northern Pacific Railway branch lines in Washington.

1888–1889—resident engineer in charge of location and construction for the Seattle, Lake Shore and Eastern Railway Company, built forty miles west from Spokane, Wash.

1890–1891—with the Union Pacific Railroad Company on the exploration and location of branch lines in western Washington.

1892—resident engineer in charge of construction for the Great Northern Railway Company in eastern Washington. (During this period he made explorations for the final location from Spokane to the Columbia River.)

1893–1898—principal assistant engineer on location and construction with the Nelson and Fort Sheppard Railway Company, the Red Mountain Railway Company, and extensions of the Spokane Falls and Northern Railway Company.

1899—assistant engineer with the Oregon Railroad and Navigation Company, constructing docks at Portland, Ore.; locating and resident engineer with the Snake River Valley Railroad Company; and chief engineer for the Moscow and Eastern Railway Company.

[1] Memoir prepared by Oscar S. Bowen, M. ASCE.

1900—assistant engineer with the Northern Pacific Railway Company, engaged in extending branch lines.

1901–1903—assistant engineer for the Oregon Short Line Railroad Company on location and construction of branch lines.

1905–June 30, 1941—chief engineer with the Spokane International Railway Company, and during this period he also held the following assignments:

1907—chief engineer with the Spokane Valley Land and Water Company;

1908—chief engineer with the E. B. C. Railway Company; and

1910—chief engineer with the Flathead Valley Railroad Company, and the Pasadena Park Water Company.

Mr. Taber had established a splendid home in Spokane, and after his retirement spent most of his time in the care of his home in which he had always taken a great interest. He spent a good part of his life out of doors and was a great lover of nature. During his boyhood and early manhood in New Bedford, his out-of-doors sports were boating and hunting, and during his younger days in the West he hunted buffalo and other big game in Montana and for many years kept a fancy riding horse as a hobby. In his later years his hobby shifted to gardening. He was also an authority on birds and bird life and always saw to it that he had plenty of them about his home. His greatest pleasure and recreation in the latter part of his life, however, were in the care of his flower garden at his Spokane home. This was of such beauty that it was well known in Spokane.

When Mr. Taber retired, he was eighty-six years of age and in fairly good health. He remained quite active until about a year before his death, attending to his flowers and providing for the birds he attracted to his home.

He was a member of the Associated Engineers of Spokane; he was very active in local Society affairs. He also was recognized in a wider sphere of professional interest when he served as Director of the Society for the term 1926–1928, representing District 12. Until his death he was, both in age and time of residence, the oldest engineer in Spokane. He was of quiet disposition—a man of great integrity and exemplary habits. During his long residence in Spokane he acquired a wide acquaintance and many friends, and was held in great respect by engineers and others with whom he came in contact. His passing marked the end of a long and useful life.

Mr. Taber was first married in 1893 to Mrs. Marie Christine Bowen who died in 1923. In 1927 he was married to Mrs. Anna Brown who died in 1936. He is survived by a niece, Mrs. J. M. Duthie of Forsyth, Mont.; and by two cousins, James H. Winslow and B. S. Winslow, M.D., of New Bedford.

Mr. Taber was elected a Member of the American Society of Civil Engineers on September 2, 1914. He became a Life Member in January, 1939.

CARROLL ROSE THOMPSON, M. ASCE[1]

Died February 21, 1946

Carroll Rose Thompson was born on October 6, 1885, in Philadelphia, Pa. His parents were George C. and Adele (Thomas) Thompson. He was a graduate of the old Philadelphia Central Manual Training School. To the best interests of his native city he devoted the major part of his life.

In his early career, from August, 1902, until May, 1908, he was employed as draftsman by the American Bridge Company at its Pencoyd (Pa.) plant, where he was active in plant drafting and checking, under the supervision of the assistant engineer, and where he was in charge of detailing structural steel. From July, 1908, to March, 1909, he was engaged by the Pennsylvania Steel Company at its Steelton (Pa.) plant, again as draftsman and checker.

Mr. Thompson entered the services of the Department of Wharves, Docks and Ferries of Philadelphia, in April, 1909, less than two years after the creation of that municipal agency, and continued in that department until his death, almost thirty-seven years later. He began as a draftsman and, in time, became chief engineer and one of the outstanding anthorities in the United States on waterfront construction and regulation, particularly on matters concerning riparian rights.

In January, 1910, with less than one year of service, Mr. Thompson was promoted to chief draftsman of the new department, which was then busily engaged in an intense program to provide the Port of Philadelphia with a group of modern municipal piers. As chief draftsman, reporting to the harbor engineer, he was in charge of the design and preparation of contract plans for piers, bulkheads, and all other harbor structures. Among the port facilities which he supervised during this period were 3,700 feet of Delaware Avenue bulkhead, costing $225,000; piers Nos. 38 and 40 of the Southwark group, costing (equipped) $1,315,305 each; pier No. 78 south of the Moyamensing group, costing (equipped) $3,400,000; and pier No. 9 north on Cherry Street, costing $1,300,000.

He was also in charge of the comprehensive planning for the development of the Southwark group of four piers and of the Moyamensing group of ten piers, including warehouse sites, freight yards, marginal ways, approaches, and similar construction. In addition, he reviewed the examination and checking of designs of numerous privately-owned harbor structures submitted to the Department of Wharves, Docks and Ferries for approval as to stability and location in accordance with city, state, and federal requirements.

From December, 1916, to December, 1918, a period during World War I, he served as first assistant to the harbor engineer, and was in charge of the engineer's office. In January, 1919, he became principal assistant engineer, and directed the design, planning, and preparation of contract plans and

[1] Memoir prepared by Edwin R. Cox, Director, Dept. of Wharves, Docks and Ferries, Philadelphia, Pa.

specifications for the construction, equipment, and maintenance of all city harbor structures. These improvements included two designs for Penn Treaty Pier No. 57 north, costing $80,000; substructures of piers Nos. 82 and 84 south of the Moyamensing group, costing about $1,500,000 each; pier No. 30 south of the Southwark group, costing $908,400; 1,150 feet of bulkhead along the Schuylkill River, costing $343,400; and substructure of pier No. 80 south, costing $1,300,000.

Mr. Thompson was appointed assistant director of the Department of Wharves, Docks and Ferries on January 16, 1920, and continued in that capacity until August 20, 1923, when he was named chief engineer. He continued in the latter position until his death. As chief engineer, he completed the plans and supervised the construction of the present group of municipal piers which the city authorities of Philadelphia cite as unequaled throughout the world.

For years, Mr. Thompson served as consulting engineer, without pay, for the Navigation Commission for the Delaware River and Its Navigable Tributaries. He was an examiner for the Pennsylvania State Board of Engineers and was a member of numerous engineering organizations, including the Engineers Club of Philadelphia, the American Association of Port Authorities, and the Society of American Military Engineers. He was also a member of the F. and A. M. and the Artisans.

Carroll R. Thompson died on February 21, 1946, at his home, 618 Leverington Avenue, Philadelphia. He had been ill for about a year, and had been confined to his home for six months.

Following his death, the writer, in a public statement declared:

> "The death of Mr. Thompson removes a most loyal and efficient official from the service of the city. His passing is a decided loss to our community and to the engineering profession and, particularly, to the Port of Philadelphia, to the interests of which he gave his most sincere efforts."

In Harrisburg, Pa., in 1908 Mr. Thompson was married to Florence Waldeck. He is survived by his widow; two brothers, Harry H. and Frank; and three sisters, Esther (Mrs. Charles Deychert), Irene (Mrs. Ralph Priest), and Virginia (Mrs. Sevill Schofield).

Mr. Thompson was elected an Associate Member of the American Society of Civil Engineers on March 12, 1918, and a Member on July 6, 1920.

CLARENCE SYDNEY TIMANUS, M. ASCE[1]

Died March 12, 1946

Clarence Sydney Timanus, the son of Elmer and Belle (Culley) Timanus, was born in Kansas City, Mo., on March 20, 1892.

[1] Memoir prepared by Chester A. Smith, M. ASCE.

He attended the public schools of Kansas City, including Central High School and University High School. He enrolled in the Massachusetts Institute of Technology at Cambridge, in September, 1914, and was graduated in 1918. He also received the degree of Bachelor of Science from Harvard University, at Cambridge, in 1918. Prior to graduation, in April, 1918, he enlisted in the United States Navy, and was assigned for training in a Naval Aviation Detachment, stationed at Hingham, Mass.

On December 9, 1918, he entered the employ of Burns and McDonnell Engineering Company, consulting engineers of Kansas City, as a junior engineer. From 1920 to 1924, he served as chief draftsman and office engineer, and later he was classified as associate engineer in charge of the design of major engineering projects for the firm. In 1930 he became a partner in the firm and continued in this capacity until his death.

Because of his technical training, the reading of many technical publications, and association with a large variety of engineering projects, he had a broad knowledge of engineering subjects. His specialties were hydraulic, sanitary, and structural engineering designs.

Among the two hundred and ninety engineering assignments over which Mr. Timanus had personal direction was the twelve-million-gallon water softening and iron removal plant for Springfield, Ill. Later, when the new supply was developed, he had direct charge of the surveys, design, and general supervision of construction of the Lake Springfield dam, water treatment plant, pumping station, and municipal electric power plant—at a total cost of more than $6,000,000. He also had charge of the rehabilitation and enlargement of the $3,200,000 Cincinnati (Ohio) water purification plant.

In 1941 and 1942, he was assistant director of the construction of Camp Crowder, Missouri; and, in 1942 and 1943, he was director of the construction of the Smoky Hill Airfield at Salina, Kans. The runways at the Smoky Hill Airfield were originally designed for 300-ft width and 5,000-ft length, but a change order came through to increase these dimensions to 500 ft by 10,000 ft. This extension of runways was planned for the first B-29 bomber training center.

All his engineering associates, friends, clients, and contractors held Mr. Timanus in the highest regard, not only for his engineering ability but also for his eminent fairness in decisions—never taking advantage of mere technicalities to create an injustice to any person or client.

Mr. Timanus became a member of the Oak Park Christian Church of Kansas City in 1921. He participated very actively in the church organization—as a deacon, an elder, president of the Men's Bible Class, and vice-president of the official board of the church. His outstanding ability in organizing engineering projects was useful in his church work. The minister stated he knew everything would be ready for starting services when Mr. Timanus was in the city, as he was always there early and saw that all details were arranged. He was a lover of good music, and was a regular subscriber to the Kansas City Philharmonic Orchestra. At home he spent hours at the piano, solely for his own amusement and relaxation. He was a member of the

American Water Works Association, American Concrete Institute, and Engineers' Club of Kansas City.

On June 10, 1920, Mr. Timanus was married to Lella Glayd Saunders at Kansas City. He is survived by his widow and a daughter, Marjorie.

Mr. Timanus was elected an Associate Member of the American Society of Civil Engineers on August 31, 1925, and a Member on May 12, 1930.

LEE TREADWELL, M. ASCE[1]

DIED MAY 15, 1946

Lee Treadwell was born in Hill County, Texas, on May 18, 1864, the son of Steven Clement Treadwell, of Tennessee, and Missouri (Hodges)Treadwell, of Georgia. In 1865 the family moved to Arkansas where he was graduated from Arkansas Industrial University at Fayetteville, in 1888, with the degree of Civil Engineer. Mr. Treadwell was president of his senior class and became instructor of field practice in surveying at the university during his senior year and held the position for two months thereafter.

From November, 1888, to October, 1896, he was with J. A. L. Waddell, consulting engineer of Kansas City, Mo., for whom he became principal assistant engineer. In almost all his work, from 1891 to 1896, he was "in responsible charge." His work covered designs and foundations of six large bridges, one of which was the longest swing drawspan in the world, and surveys and foundations borings of five bridges. He worked on the elevated railroad in Chicago, Ill.; the train shed at Sioux City, Iowa; and other structures.

In 1895, he was with Sooysmith and Company; in 1896, with the Phoenix Bridge Company in Philadelphia, Pa., engaged on the Wissahickon Bridge; and, in 1898, again with Sooysmith and Company, in New York, N. Y. He was also employed on cofferdam and foundation work in Ottawa, Ont., Canada, and in 1899, he constructed a dam at Tariffville, Conn.

From November, 1899, to January, 1905, he was superintendent and engineer in general charge of construction for John Peirce and Company, contractor for the stone dry dock at the United States Navy Yard at Portsmouth, N. H.

It is not often that Navy Department records are made of acts of personal bravery of civilians who have not been members of the United States armed forces, or directly employed by the government. From the official navy yard record of the dry dock construction work is quoted the following:

> "At one time during the course of the construction he distinguished himself in a heroic manner. The cofferdam built across the entrance to the dock developed a serious leak which threatened its destruction. Mr. Tread-

---

[1] Memoir prepared by L. F. Bellinger, M. ASCE.

well ordered all workmen off the cofferdam and personally went on the dam and with a large quantity of oakum succeeded in checking the leak so the cofferdam was saved."

He obtained patent No. 693465 dated February 18, 1902, for "Machines for Delivering Comminuted Solids," at constant rate and in measured quantities, as for concrete.

In 1904, he was consulting engineer for the Phoenix Bridge Company on the foundations of the Quebec Bridge, the superstructure of which suffered two wrecks. In January, 1904, he was consulted by the Imperial Drydock Company at St. John, N. B., Canada, and prepared an estimate of cost for the John Peirce Company.

From 1905 to 1907, he was superintendent for the Foundation Company, contractors for the caisson and slips at Chalmette, La. The caisson was named "Lee Treadwell."

In the period, from June, 1907, to July, 1913, he was one of the four founders of the Union Bridge and Construction Company of Kansas City, and held the positions of vice-president and chief engineer. Among the numerous items of work of this company that were handled personally by Mr. Treadwell were the Atchafalaya River Bridge in Louisiana, in 1907–1908; the Broadway Bridge in Portland, Ore., in 1911; and the Iowa Central Railroad Bridge at Keithsburg, Ill.

After 1913, he undertook only one job—that of inspection engineer for Fuller and Maitland of New York, on the water works of Kansas City.

In September, 1933, he moved to Atlanta, Ga., with his eldest daughter, Althea (Mrs. Dale Allen).

It is seldom that letters of reference to the candidates for transfer of membership in the Society are such warm, personal letters of esteem, as are preserved among Mr. Treadwell's papers. These references were written by seven of the most prominent engineers of that time (1893)—namely, the late William H. Burr,[2] M. ASCE, of Columbia University, in New York City; John Sterling Deans,[3] M. ASCE, chief engineer of the Phoenix Bridge Company; W. Kiersted, M. ASCE; C. C. Schneider,[4] Past-President, ASCE, chief engineer of the American Bridge Company; Charles Sooysmith, M. ASCE, contractor and soft foundation engineer; J. A. L. Waddell, Hon. M., ASCE, consulting bridge engineer; and Paul Wolfel,[5] M. ASCE.

He was married on December 22, 1896, at Kalamazoo, Mich., to Althea Laura Fletcher. He is survived by his two daughters, Althea Virginia (Mrs. Dale Allen) and Laura (Mrs. Robert Galbraith); three grandsons; one granddaughter; and one great-granddaughter.

Mr. Treadwell was elected a Junior of the American Society of Civil Engineers on November 5, 1890; an Associate Member on October 4, 1893; and a Member on December 2, 1896. He became a Life Member in January, 1928.

[5] For memoir, *ibid.*, Vol. LXXXIV, p. 940.

WOLFGANG GUSTAV TRIEST, M. ASCE[1]

DIED SEPTEMBER 21, 1946

Wolfgang Gustav Triest was born in Oppeln, Germany, in 1863, the son of Felix and Clara Triest. He was graduated from the Royal Technical College in Berlin in 1888 and in the same year moved to the United States.

Mr. Triest started his business career in March, 1888, when he joined the engineering department of the Passaic Steel Company in Paterson, N. J. From 1890 until 1895, he was the principal assistant of the late A. P. Boller,[2] M. ASCE, assisting in preparing plans and supervising construction for the Fifteenth Street viaduct in New York, N. Y., and also for a number of railroad bridges. This was followed by his partnership in the firm of James R. F. Kelley and Company, Contracting Engineers in New York, that lasted until May, 1897. The work that Mr. Triest helped to supervise for this company included the high service pumping station at 181st Street, in New York City.

For two years, from 1897 until 1899, he was engaged in private practice as a contracting engineer, with headquarters in New York City. The work executed during that period consisted of a number of private and government contracts for structural steel buildings which included the preparation of plans and the supervision of construction. He built several fireproof buildings in the Brooklyn Navy Yard.

On January 1, 1900, Mr. Triest and the late Frederick Snare, Affiliate, ASCE, formed a company then known as Snare and Triest, Incorporated, with Mr. Triest as vice-president. The firm later became known as the Snare and Triest Company. He continued with the corporation until 1919, at which time he left to form his own company, known as the Triest Contracting Corporation.

While Mr. Triest was vice-president of the Snare and Triest Company, he supervised the activities of the company within the United States. Some of the notable work done under his supervision was the building of a large coaling plant for the United States Navy at East Lemoine, Frenchmen's Bay, Maine, from designs prepared by his company; five of the Chelsea piers for the Cunard Line and other steamship companies; a section of the Lexington Avenue Subway, in which his company was associated with Arthur McMullen; the rebuilding of many miles of the New York elevated railroad for the Interborough Rapid Transit Company; the superstructure for the piers for the Hell Gate Bridge; the Cherry Street pier in Philadelphia, Pa., and the superstructure of piers thirty eight and forty in Philadelphia, both of which were built for the Department of Wharves and Docks of that city; the reservoir for the City of Perth Amboy, N. J.; and the Manhattan approach to the Blackwell's Island Bridge for the City of New York.

[1] Memoir prepared by A. W. Buttenheim, Pres., Frederick Snare Corp., New York, N. Y.
[2] For memoir, see *Transactions*, ASCE, Vol. LXXXV, 1922, p. 1653.

During World War I he did a great deal of work for the United States Navy, including the construction of a fitting-out pier at League Island, in Philadelphia, and of many buildings at Lake Denmark and Iona Island, N. Y. He supervised the building of ten shipways at Hog Island, on the Delaware River near Philadelphia, and also the construction of the quartermaster terminal in Philadelphia and the Raritan ordnance depot at Perth Amboy, both for the United States Army.

After forming the Triest Contracting Corporation, he successfully completed several sections of the Independent Subway System for the City of New York and a section of subway in Camden, N. J., for the Delaware River Joint Commission. He also completed the Bay Way (N. J.) approaches to the Goethals Bridge, and an aqueduct for the Borough of Brooklyn. Additional work done by Mr. Triest's own company included the enormous doors of the Lakehurst (N. J.) Hangar, which he built for the United States Navy, and which are considered to be some of the largest doors ever constructed. He also erected a hangar for the United States Navy at Cape May, N. J.

In recent years Mr. Triest was not active in the field of construction. However, he was a regular visitor at the Engineers Club, of which he was a life member, and in this manner kept in close contact with his many friends in the construction industry.

In 1894 he was married to Lucy Wood, who died in 1899. In November, 1901, he was married to Lillie Macdonald, who, with their two sons, Willard G. and Carl G., survives him.

Mr. Triest's activities in engineering and construction work were carried on during a very interesting period. He started at a time when a capable engineer with small capital could carry on successfully and without undue competition. From the time he signed his first contract until he retired, he and his associates completed over 1,100 different contracts. That he was able to carry on so many and such diversified types of construction, and that he successfully completed every contract awarded to his company, is a record of which his family and associates can be very proud.

It is interesting that his death on September 21, 1946, occurred within a few hours of, and at the same age as, his old friend and former associate, Frederick Snare.

Mr. Triest was elected a Junior of the American Society of Civil Engineers on September 3, 1890; an Affiliate on March 6, 1900; and a Member on January 31, 1905. He became a Life Member in January, 1934.

HERMAN van der VEEN, M. ASCE[1]

DIED OCTOBER 27, 1946

Herman van der Veen was born in Vollenhove, Holland, on July 1, 1878, and was awarded the degree of Civil Engineer at the University of Delft, Holland, in June, 1903.

He was a civil engineer of wide experience on hydraulic matters, his speciality being river improvements.

Having started his career as an engineer with the Triangulation Bureau of the Dutch government, Mr. van der Veen was an assistant to the professor in geodesy at the University of Delft, before leaving his native country in 1904 to fill the appointment of engineer with the Chung-ting fu in China. There he became engineer in charge of the Whangpoo Conservancy Board at Shanghi, China, in 1906.

In 1911 he left for the Netherlands East Indies where he held the position of acting engineer in chief of the Surabay Harbor and, afterward, chief of the Padang Harbor Works.

Mr. van der Veen returned to China in 1914 as adviser to the Conservancy Bureau of China, and later to the ministries of the interior and communications. In November, 1929, he was repatriated and returned to Holland. His task, however, was not yet finished and he continued his activities as government engineer in chief on the improvement of the river, the Meuse, and afterward was in charge of the Rotterdam waterway, from which position he resigned on August 1, 1943.

From this summary it can be seen that the greater part of his career was spent in China and, indeed, it was in this country that he developed his full energies. . It was certainly not an easy task to be an adviser to the government in this gigantic country where powerful rivers required drastic improvements to prevent fatal inundations, causing devastation and famine in wide areas. Being a prominent member and a technical adviser of many committees on this subject, he had a sound knowledge of the problem. Two of the committees with which he was associated were the Famine Relief Bureau of the Technical Committee of the Yangtze River and of the Yung-ting ho Commission.

Many reports containing valuable data and advices were prepared by him. Among his technical publications, "The Improvement of the Chihli River System" (1928) and "The Improvement of the Yellow River" (1924) are his important work.

Obviously most of the projects which he recommended required huge capital investments and could not be completed. Notwithstanding, all his efforts were directed toward the river improvement problem in China which will require many years of work and the utmost exertion to solve. Mr. van der

[1] Memoir prepared by O. C. A. Van Lidth de Jeude, The Hague, Netherlands.

Veen, however, was a pioneer who has laid the foundations upon which others can continue the task.

His long experience in China made him what is called "an old China-hand," and after his repatriation he kept in contact with this fascinating country, where his lifework lies. The Chinese government recognized his services by conferring the order of "Golden Rice Blade" upon him.

This pioneering work suited his vital personality and his energetic character. He was popular with his friends because of his straightforwardness and cordiality and was a welcome guest in the Shanghai Club and in the Peking Club.

While in Tientsin, where he made his home for several years, he was married to Adriana Alida ten Nave on June 23, 1920. Mrs. van der Veen survives him.

Mr. van der Veen was elected a Member of the American Society of Civil Engineers on November 9, 1920.

LOUIS JOSEPH VOORHIES, M. ASCE[1]

DIED AUGUST 25, 1946

Louis Joseph Voorhies, the son of Martin J. and Amelie (Bienvenu) Voorhies was born in Saint Martinville, La., on August 29, 1886. He was a distinguished member of a family which contributed much to the social, educational, and economic development of Louisiana. He received his early education in private schools in his home community and, in June, 1906, received the degree of Bachelor of Science in Civil Engineering from Louisiana State University at Baton Rouge. In college, Mr. Voorhies was not only an outstanding student, receiving the faculty medal for attaining the highest scholastic record in his graduating class, but also an athlete, being the regular catcher on the university baseball team for two years. He was a member of Tau Beta Pi, Kappa Sigma, and Phi Kappa Phi fraternities. In 1928, in recognition of his professional accomplishments, Louisiana State University conferred upon him the degree of Civil Engineer.

Following graduation, Mr. Voorhies was employed by the Southern Pacific Railroad Company from August, 1906, to December, 1911, for the first two years as rodman and instrumentman and for the remaining three years as resident engineer in charge of construction. From December, 1911, to June, 1912, he was employed by the Galveston, Houston and Henderson Railroad Company, appraising right-of-way and terminal grounds between Galveston and Houston, Tex. Between June, 1912, and September, 1913, he practiced engineering in Crowley, La., designing, locating, and constructing drainage and irrigation canals in southwest Louisiana.

[1] Memoir prepared by a Committee of the Louisiana Section consisting of S. Steve Carnegie, Jun. ASCE, Chairman, Frederick Fischer Pillet, M. ASCE, and John Henry Bateman.

He was city engineer of Lafayette, La., from September, 1913, to May, 1915, during which period he designed street pavements, storm sewers, and other street facilities for the city. For a year beginning in May, 1915, he held the position of senior civil engineer with the Interstate Commerce Commission on the federal valuation of railways. Since he was unable to spend much time with his family, he decided to enter the commercial field and moved back to Lafayette, where he engaged in private practice. In February, 1917, he became district engineer in Louisiana for the J. B. McCrary Engineering Corporation of Atlanta, Ga., which had been specializing in municipal engineering for many years.

When the United States entered World War I, James C. Nagle,[2] M. ASCE, dean of engineering at the Agricultural and Mechanical College of Texas at College Station, urged Mr. Voorhies to join the faculty as associate professor of railway and highway engineering. Mr. Voorhies took a leave of absence from the J. B. McCrary Engineering Corporation and taught engineering from September, 1917, to June, 1918, during which time three thousand young men were undergoing intensive engineering and military training at this college.

He returned to the J. B. McCrary Engineering Corporation in June, 1918, as district manager for Louisiana and adjoining states with headquarters in Lafayette. During the following eight years, he developed an extensive engineering practice—designing and supervising the construction of municipal public work projects involving the expenditure of many million dollars.

In December, 1926, Mr. Voorhies decided to go into business for himself and opened an office in Baton Rouge. From 1926 to 1946 he served as consulting engineer for a large number of municipalities designing and supervising the construction of water distribution systems, water treatment plants, sanitary and storm sewer systems, sewage treatment plants, power plants, gas distribution systems, municipal buildings, swimming pools, pavements, parks, and other municipal improvements.

Mr. Voorhies possessed great natural ability and an unusual capacity for work. He continued his extensive and thorough studies of engineering developments throughout his professional career. His ability to deal with people in all walks of life was outstanding and, with his extensive knowledge and experience, enabled him to rise to the top of his chosen career in public works engineering.

His principal interests were his family, his work, and his friends. His great personal charm, his ready wit, his keen understanding of the economic development of the United States, his state, and his community, together with his unusual aptitude for expressing his thoughts in clear, concise language made visits in his home a delightful privilege. He will long be remembered by his friends and associates for his great ability, his outstanding achievements, his high standards of professional and personal conduct, and his wish to be of service to others.

The willingness of several of his employees to remain with him for a number of years reflects his personal character. One employee, Frederick

[2] For memoir, see *Transactions*, ASCE, Vol. 93, 1929, p. 1878.

E. Smith, was associated with him for more than eighteen years, during which time Mr. Voorhies trained and guided Mr. Smith, with the intention of having someone to continue with the high professional standards that he himself had followed during his career. In October, 1945, they formed a partnership which continued until Mr. Voorhies' death.

In 1913, Mr. Voorhies was married to Hilda Labbe of Saint Martinville. Besides his widow, he is survived by one son, Louis Joseph, Jr.; three daughters, Corinne (Mrs. Wayne Amos), Hilda (Mrs. Roy Nystrom), and Mary Nell (Mrs. D. T. Waller); and nine grandchildren.

Mr. Voorhies was elected a Member of the American Society of Civil Engineers on August 14, 1939.

CHARLES EDWARD WADDELL, M. ASCE[1]

Died April 20, 1945

Charles Edward Waddell, the son of Francis Nash and Anne Ivey (Miller) Waddell, was born on May 1, 1877, on Mooresfield Plantation, near Hillsboro in Orange County, North Carolina. He received his early education at the Bingham Military Academy, in Asheville, N. C., from which he was graduated in 1894, and in the shops of the General Electric Company.

In 1883 Mr. Waddell's family moved to Asheville, where he received his first professional appointment in 1891, when, on October 30, he became the superintendent of the Asheville fire alarm system. He entered the shops of the General Electric Company in Boston, Mass., in 1894 as a student. This was followed by a period of field work for this company in Bangor, Me., and in Asheville. In 1897 he became superintendent of the Asheville and Biltmore Street Railway Company, supervising installation of lines, powerhouse, and equipment; in 1900, as engineer in charge of tracks for the General Electric Company, he rebuilt a greater part of the system in Asheville.

Mr. Waddell became chief engineer to the late George W. Vanderbilt in 1901, and designed and built all the engineering works on the Biltmore estate, including three substations, the largest electrical heating plant yet attempted, a complete refrigeration plant, and other works. He lived on the estate, which became his home for the rest of his life.

In 1903 Mr. Waddell entered, actively, the field of consulting engineering practice, and became one of the leading engineers in the southeast for hydroelectric and steam generated plants, hydraulic power resources, and water supply. An impressive list of works constructed under Mr. Waddell's supervision include, in addition to the development of the Vanderbilt estate, the North Carolina Electric Power Company's system with Weaver and Marshall

[1] Memoir prepared by G. H. Maurice and D. M. Williams, Members, ASCE.

hydroelectric plants and the Elk Mountain Steam Plant (now Western Division of the Carolina Power and Light Company); the Sunburst Arch Dam and the forty-million-gallon filter plant for the Champion Fibre Company in Canton, N. C.; the Bee Tree Dam and water supply system in the City of Asheville; and the water supply system for the American Enka Corporation in Enka, N. C.; besides a number of notable wooden, earthen, gravity concrete, arch or multiple arch, dams.

As consulting engineer, in 1913, Mr. Waddell served the United Electric Securities Company in Boston; in 1915 he made waterway studies for the Southern Railway Company on the main line south of Washington, D. C.; and in 1917 he made similar studies on the Queen and Crescent Railroad between Cincinnati, Ohio, and Harriman, Tenn.

During World War I he was a consulting engineer for the Power Section Council of National Defense for power resources in the southern states' war emergency and also Director of Conservation for the United States Fuel Administration in the State of North Carolina. He was engineer to the Quartermaster Department of the United States Army for construction on general hospitals Nos. 12 and 19.

In recognition of his work in developing hydroelectric power in North Carolina, the degree of Doctor of Science was conferred upon him by North Carolina State College of Agriculture and Engineering at Raleigh in 1925.

Dr. Waddell was a member and chairman of the North Carolina State Board of Engineering Examiners, from 1921 to 1926, of which he was one of the originators; a member of North Carolina Ship and Water Transportation Commission, from 1923 to 1924; commissioner of Biltmore Forest, from 1923 to 1927; consulting engineer with the North Carolina Corporation Commission in readjustment of utility rates, from 1932 to 1934; consulting engineer with the Tennessee Valley Authority, from 1936 to 1938; and consulting engineer for the City of Asheville for two terms, from 1925 to 1927 and from 1940 to 1941.

In 1927 Dr. Waddell's activities took him to South America. He was a consulting engineer for the Departmente de Antioquia in Colombia, and for the City of Medillin in Colombia, where he worked on the hydroelectric plants.

Dr. Waddell was a born leader and teacher who gave himself unsparingly to all civic and educational undertakings. To young engineers in his employ and to others who sought his advice, he was never too busy to impart to them the benefit of his vast store of knowledge and experience.

One of North Carolina's outstanding financiers recently stated: "Do you know what made Waddell great? It was his love for things beautiful." He would never compromise with quality, nor would he follow through with a project unless he was convinced that it was sound.

In his early years, while employed by the Biltmore Railway Company in Asheville, he received a blow on the head from a trolley. This injury was forgotten for years until, in 1913, after constant pain, it was discovered that the skull had been fractured and that a piece was now pressing on the brain.

Three major operations followed during the next fifteen years. After the last one, he suffered a partial paralysis of the legs, from which he never fully recovered. Although in almost constant pain, he maintained his characteristically cheerful outlook on life. His civic activities were many: He was president of the Pen and Plate Club in Asheville in 1916; president of the Biltmore Hospital, from 1920 to 1925; president of the Civitan Club in Asheville in 1923; governor of the Biltmore Forest Country Club from 1923 to 1933; and a member of the Cosmos Club in Washington, D. C.

Dr. Waddell was one of the men who organized the North Carolina Section of the Society on October 24, 1923, at Durham, N. C., and was elected, and served as President from 1923 to 1925. He retained membership in the Section after the western counties of the state were transferred to the Tennessee Valley Section, and was made an Honorary Life Member of the North Carolina Section on January 30, 1943.

Besides membership in this Society, he was a Fellow of the American Institute of Electrical Engineers; a member of the American Society of Mechanical Engineers; and a member of the North Carolina Society of Engineers, of which he was president in 1928, and an honorary member in 1941. He was the author of numerous technical publications and papers.[2, 3, 4, 5]

On April 19, 1904, he married Eleanor Sheppard Belknap of Louisville, Ky., who survives him. A son, Charles E. Waddell, Jr., and a daughter, Eleanor Belknap (Mrs. George M. Stephens), also survive. Funeral services were held April 22, 1945, at All Souls Episcopal Church in Biltmore, of which Dr. Waddell had been a member of many years. Interment was in Riverside Cemetery.

An editorial in the *Asheville Citizen* closed with the following eulogy:

> "Charles Waddell lived and breathed his profession. He loved difficult problems in hydraulics and delighted to dwell in the realm of mathematics. He was a good and useful citizen, generous, socially-conscious and always a striver for the best causes in the community he loved and served. To a full life he gave more than is asked of most men, courageously and ruggedly, untiringly and to the very last."

Dr. Waddell was elected a Member of the American Society of Civil Engineers on March 1, 1910.

RAYMOND FOWLER WALTER, M. ASCE[1]

DIED JUNE 30, 1940

Raymond Fowler Walter's parents, John Huffman and Susan (Garlock) Walter, established their home in Iowa but moved to Chicago, Ill., where their son, Raymond, was born on October 31, 1873. He was named Arthur Raymond Walter; but, as a youth, he dropped the name Arthur and added the middle name of Fowler, and he was thereafter known as Raymond Fowler Walter. His father was a printer and publisher, who, attracted by the stories of gold mining in Colorado, loaded his belongings and with his wife and son drove to Cripple Creek (Colo.), the center of the gold mining activity, where the family lived for a short time and then, like many miners, found their reward in agriculture.

Probably influenced by the establishment of the Greeley Colony in Weld County, of which the Town of Greeley (Colo.) became the county seat in 1886, the family finally settled at near-by Fort Collins, where young Raymond attended grade and high schools and continued at Colorado State College of Agriculture and Mechanical Arts. At first, he was an agricultural student, but, later, he studied engineering and was awarded the degree of Bachelor of Science in Civil Engineering in 1893.

He was thus ready to take advantage of the unprecedented interest and demand for irrigation development throughout the West, particularly in Colorado, where financing was easy and irrigation bonds were in demand. This condition unfortunately encouraged many wildcat projects, resulting in financial failures and much human suffering.

Mr. Walter's services as a young engineer were in demand for surveying and designing several undertakings in northeastern Colorado, but his knowledge and canny analysis prevented the mistakes too common in those times. He enlarged and completed Terry Lake and designed and constructed the Independence Canal for the Big Horn Mining and Irrigation Company, as well as the Big Creek Reservoir in Wyoming. In 1895 he became the junior partner in the firm of Baker and Walter in Greeley. This firm designed and built reservoir No. 6 for the North Poudre Irrigation Company. He also was elected county surveyor of Weld County, and was mostly engaged on the construction of roads and bridges for three years. From 1899 to 1901 he served as city engineer of Greeley, being responsible for the design and construction of water and sewer extensions.

Thereafter, Mr. Walter designed and built the Seven Lakes Reservoir at Loveland, Colo., and the Fossil Creek Reservoir at Fort Collins for irrigation. Meanwhile he designed and installed a sewer system for Eaton, Colo., and designed and supervised the construction of many irrigation works, including the Union Reservoir at Longmont, Colo.; McClellan and Law Reservoir at Windsor, Colo.; and the Clark Lakes Reservoir and canals at Wellington,

[1] Memoir prepared by John C. Page, M. ASCE.

Colo.—among others. He served also as deputy state engineer in charge of river and canal flow records and at the same time designed Jackson Lake and Riverside reservoirs near Greeley.

Finally, in 1903, ten years after graduation, he was appointed assistant engineer in the United States Reclamation Service, and was assigned to making surveys and plans for the Belle Fourche Reclamation Project in South Dakota. At this time he was married to Lillian Leon Phillips of Fort Collins. In 1904 he was designated project manager and supervised the construction of Orman Dam and the canals and drains on the Belle Fourche project.

After completion of this project, Mr. Walter progressed to the position of supervising engineer at Denver, in charge of all projects of the Bureau of Reclamation in Colorado, Wyoming, Nebraska, and Utah. He held this assignment from 1909 to 1915, when, as senior engineer at El Paso, Tex., he supervised the Rio Grande Project, in New Mexico and Texas. After a year in Texas he returned to Denver as assistant chief of construction and assistant chief engineer. During this time he concentrated on administrative duties as well as on strictly engineering matters; and it was due to his careful scrutiny of all operations that he earned the title, within the organization, of the "watchdog of the treasury" because of his insistence on economy and efficiency. He guarded federal funds more zealously than his own.

Finally, on May 1, 1925, he was appointed chief engineer, with supervision of all construction activities of the Bureau of Reclamation. To increase efficiency and to promote the highest type of design and construction, he helped organize and man the design and construction organization which is recognized all over the world for outstanding ability and for the creation of new methods and improvements on great irrigation enterprises. During his period of service, Mr. Walter was instrumental in building, successively, "the highest dam in the world" on five separate occasions. These dams included, of course, Boulder, Shasta, and Grand Coulee, for which he was privileged to sign the construction contracts on behalf of the government. Can an engineer ask for finer memorials?

In addition to the industry and conscientious attention he brought to his constructive activities, he recognized his duty as a family man and a member of society. This was demonstrated by his care and education of his two children, Dorothy L. (Mrs. F. B. Cook) and Donald S., the latter following in his father's footsteps as a responsible engineer for the Bureau of Reclamation. Mr. Walter's widow and two children survive.

He joined the Presbyterian Church and the F. and A. M., becoming a member of the Shrine at Deadwood, S. Dak. Although lack of time curtailed his activity, both these organizations knew of his loyalty, sincere interest, and support.

He was by nature a friendly and courteous individual, even to the point of hurting himself to perform properly his administrative duties; and as a protection he shielded his feelings by a shell of gruffness which fooled no one who knew him well. It did protect him from imposition by individuals having only a superficial acquaintance.

Death by heart disease ended the career of this lifelong and outstanding public servant who left a memorable record of engineering and constructive accomplishment through a busy life. The value of his service is well described in the statement by the Hon. Harold L. Ickes, then Secretary of the Interior, who was particularly well qualified to evaluate the services rendered by Mr. Walter during his thirty-seven-year employment in this department:

> "The death of Chief Engineer Walter after a lifetime of service to the Bureau of Reclamation and the Department of the Interior is a severe blow. For 15 years Mr. Walter had been in active charge of what is generally recognized as the greatest engineering office in the world—the Denver engineering headquarters of the Bureau of Reclamation. His services were outstanding. His unfailing loyalty to his organization, to his Bureau and his department, and to the United States Government has provided an example for the thousands of young men working under him. His unexpected death is a shock to the whole Department."

Mr. Walter was elected a Member of the American Society of Civil Engineers on October 5, 1909.

WILLIAM MACINTIRE WHITE, M. ASCE[1]

DIED APRIL 25, 1946

William MacIntire White was born in Philadelphia, Pa., on January 28, 1873, the son of Thomas Earle White and Emmaline (Dunot) White. He was graduated from the University of Pennsylvania at Philadelphia with the degree of Bachelor of Science in Engineering in 1892, and received the degree of Civil Engineer in 1893.

In the fall of 1893 he began his engineering work as second assistant in the district surveyor's office in the City of Philadelphia. In March, 1894, he became a draftsman at the Pencoyd Iron Works, and after two years was made an assistant in the engineering department. He remained with the Pencoyd Iron Works until 1899, when his company recommended him to the Union Pacific Railroad Company. He was employed in the Omaha (Nebr.) office of the Union Pacific as assistant engineer in the bridge department for a year and a half, and also worked for the Baltimore and Ohio Railroad Company for several months as assistant engineer in the bridge department.

Mr. White returned to the American Bridge Company in December, 1900, where he remained as assistant engineer, estimating and designing at Pencoyd, in Pittsburgh, Pa., and in New York, N. Y., until 1906. During this period he had charge of the work on the reconstruction of the Poughkeepsie Bridge in 1905, inspecting the bridge and designing changes to strengthen it.

In 1906 he was granted a leave of absence to go to Peru. The Peruvian railroads were expecting to install heavier rolling equipment and had asked

---

[1] Memoir prepared by William G. Grove, M. ASCE.

the American Bridge Company to recommend an engineer to inspect the bridges to see if they could stand the increased loads. He inspected the sixty-five bridges of the Ferrocarril Central del Peru and the Ferrocarril del Sur Peru, and submitted a report recommending the necessary repairs and renewals. When this tour of duty was completed, he returned to the American Bridge Company for six months before being sent to China in June, 1907. In China, where he remained a year and a half, he was resident engineer for the United States Steel Products Export Company with headquarters in Shanghai; he designed the Canton River Bridge and other bridges; and he also sold various U. S. Steel products.

When he was in China, Mr. White traveled quite extensively, sometimes for business reasons and sometimes to see the country. He made a trip to the great wall where he visited the chief engineer of the railroad who had been a Chinese student at the University of Pennsylvania. Chinese art interested him and he brought home some lovely pictures and embroideries. He got along well with the Chinese businessmen and admired the Chinese people very much.

While in Peru, Mr. White had an unusual experience. One day when he was inspecting a bridge over a deep canyon, his Mexican helper, stationed at the mouth of a tunnel to warn him if a train should be coming, fell asleep while he was out on the bridge. Mr. White looked up just in time to see the train coming out of the tunnel and on to the bridge, and was forced to drop down and hang on to the ties as the train thundered over his head.

Returning to the United States in 1909, he was located in the Chicago (Ill.) office of the American Bridge Company and later in the New York office of the chief engineer as engineer, estimating, designing, and handling special contracts. In 1913 he was transferred to the contracting department and was a contract manager in the New York office until his retirement in 1938, after forty-three years of continuous service.

Mr. White lived in Fanwood, N. J., from 1909 until his death in 1946, and had been active in the civic affairs of that town. He served on the board of health for several years and was the chairman of the building committee of the board of education when the township high school was built. He was the president of the civic association and active on the defense council during World War II.

In 1913 he was married to Katherine Brown of Plainfield, N. J. They had two children. Mr. White is survived by his widow; a son, William M., Jr.; a daughter, Katherine (Mrs. E. R. Beecher); and two grandchildren, William M. White, III, and Katherine M. Beecher.

Throughout his long business career he had the happy faculty of making lasting friendships and his many friends will remember him for his high ideals of living.

Mr. White was elected an Associate Member of the American Society of Civil Engineers on January 2, 1901, and a Member on March 2, 1909. He became a Life Member in January, 1936.

RALPH WHITMAN, M. ASCE[1]

DIED FEBRUARY 3, 1946

From the date of his commission as Ensign until he reached the age limit for active service, when he was retired as Rear Admiral, Ralph Whitman was on active duty as an officer of the Civil Engineer Corps of the United States Navy. This covered a period of nearly thirty-seven years and was the principal part of his professional life. It is one of the longest tours of active duty by any member of the Civil Engineer Corps since its inception in the 1860's.

Ralph Whitman was born in Boston, Mass., on April 7, 1880, a son of Kilborn and Ella M. (Wightman) Whitman, and a direct descendant of Edward Winslow, the first governor of the Massachusetts Bay Colony. He was a member of the John Alden family and also of the Briggs family, prominent shipbuilders of sailing vessels from early Colonial days.

Mr. Whitman was educated in the public schools of Boston, and in 1901 he was graduated from the Massachusetts Institute of Technology in Boston with the degree of Bachelor of Science in Civil Engineering. His education was further continued later in life when, as Commander Whitman, he was assigned to the senior class at the United States Naval War College, in Newport, R. I., composed of commanders, captains, and rear admirals. Here he became familiar with the broader problems in naval operations, logistics, and policy which were to be of value to him and to the Navy in later years. In 1923 he was granted a certificate of graduation on completing the course.

On being graduated from the Massachusetts Institute of Technology in 1901, Mr. Whitman was engaged in field and drafting room service for the bridge department of the City of Boston and continued with this department until 1905. From 1905 to 1907, he was employed by the Isthmian Canal Commission on preliminary estimates and studies for the Panama Canal.

As a result of his success in a competitive examination, he was commissioned an Ensign in the Civil Engineer Corps of the U. S. Navy on August 12, 1907. His ability, together with his satisfactory performance of duties, led to the successive promotions to Lieutenant (junior and senior grades), Lieutenant Commander, Commander, and Captain. Finally, on March 22, 1939, he was commissioned Rear Admiral, Civil Engineer Corps, U. S. Navy, having been selected by a board of senior officers as the best qualified on a list of eligibles. He was the senior officer on the active list under the chief of civil engineers for a period of more than five years, and he continued with this rank after retirement from active duty.

His naval career began, when, as Ensign, he was assigned to the public works department of the navy yard in Philadelphia, Pa., from 1907 to 1910, and until 1911, to the Bureau of Yards and Docks of the Navy Department.

[1] Memoir prepared by R. E. Bakenhus, M. ASCE.

As Lieutenant, j.g., he was the public works officer of the United States Naval Station, Guantanamo, Cuba, in independent charge of the construction work from 1911 to 1913. In 1913 he became public works officer of the United States Naval Academy at Annapolis, Md., and had charge of new construction, and of the maintenance of buildings and grounds until 1917. While at Annapolis he was promoted to Lieutenant, senior grade.

In April, 1917, as Lieutenant, he was detailed to duty as aide on the staff of the United States Military Governor of Santo Domingo, Dominican Republic, and, from 1919 to 1920, he was a member of the Dominican Claims Commission. During this tour of duty in Santo Domingo he was promoted to the rank of Lieutenant Commander.

From May, 1920, to May, 1922, Lieutenant-Commander Whitman was public works officer of the United States Naval Ordnance Plant at South Charleston, W. Va., when he had charge of the construction of the naval armor plant, largely by day labor. While stationed at South Charleston he was promoted to Commander. His course at the U. S. Naval War College covered the year 1922–1923. After its completion he was assigned, appropriately, for two years to administrative duty in the Bureau of Yards and Docks. This tour of duty involved the public works of the Navy as a whole, and their relations to other branches of the naval service.

Subsequently, Commander Whitman was public works officer in responsible charge of new construction and maintenance at one of the largest navy yards, namely—Norfolk, Va., where he remained for nearly four years. In 1929 Commander Whitman was ordered to important duty as public works officer of the navy yard at Mare Island, Calif., and also of the 12th Naval District, comprising northern California, Utah, Colorado, and Nevada. While on this duty, he was promoted to Captain. In 1934 Captain Whitman was again assigned to administrative duty in the Bureau of Yards and Docks. This particular assignment continued until January, 1939. He was then ordered to duty as public works officer of the naval operating base and 5th Naval District at Hampton Roads, Va., and, while on this duty, was promoted to Rear Admiral.

He became a member of the Hepburn Board, created in 1938 by an act of Congress as a naval board for the purpose of investigating and reporting on the need for further naval bases, including those for naval aircraft, submarines, destroyers, and mines. This board was, in reality, created so that the United States might be in a more secure position in the event of a second world war. The recommendations of this board were largely the basis for the important naval shore station development that was finally carried out. Admiral Whitman was the engineer member of the board, his training at the Naval War College being of particular benefit.

Upon detachment from this duty in June, 1939, Admiral Whitman was assigned as public works officer of the 3d Naval District, with headquarters in New York, N. Y., and covering northern New Jersey and New York State. He served for some months in Washington, D. C., as a member of the War Production Board. Admiral Whitman was retired on reaching the statutory

age limit of sixty-four years and was detached from all duty on April 30, 1944.

The engineering projects which Admiral Whitman dealt with in his naval career covered an unusual variety, including such items as dredging, waterfront improvements, dry docks, industrial plants at navy yards and the naval armor plant, shipbuilding ways, piers, wharves, housing of all kinds, power plant construction and operation, and railroads and highways in industrial plants, as well as the operation of railway and truck transportation systems and many other incidental types.

Outstanding characteristics of Admiral Whitman were his painstaking ability as an engineer, his unusual devotion to duty, and his unshakable loyalty to his high principles and to the naval service, as well as to his family and friends. His integrity was exemplified in all his undertakings—he was the "Captain of his Soul."

Admiral Whitman served in World War I and was awarded a special letter of commendation with Silver Star, a Victory Medal with West Indies Clasp, and the United States Marine Corps Commemorative Expeditionary ribbon for services in Santo Domingo. For his service in World War II he was awarded a number of commendatory ribbons; posthumously, he was awarded the American Defense Service Medal and the Victory Medal for World War II.

The order retiring him from active duty contained the following statement:

> "The Secretary of the Navy regrets your retirement from the active list of the Navy and takes this occasion to extend to you his heartiest congratulations and appreciation for your long and distinguished service to our Nation. During the time which you have so faithfully and efficiently served, you have witnessed many advancements in the morale, strength and efficiency of the Navy; and you have the satisfaction of knowing that you have contributed to the accomplishment of these results. May I wish for you continued success and many years of health and happiness."

He was married to Frances Guyon Seabrook of Westminster, Md., on December 12, 1916. His wife and daughter, Frances Guyon Whitman, survive him. A sister, (Mrs. William Hanna, and a brother, Kilborn Whitman, Jr., also survive him.

He was a member of the Metropolitan Section of the Society; of the Boston Society of Civil Engineers; the American Association for the Advancement of Science; the Society of American Military Engineers; the American Society of Naval Engineers; the United States Naval Institute; and the Newcomen Society of London, England (American Section).

Admiral Whitman was elected an Associate Member of the American Society of Civil Engineers on November 6, 1907, and a Member on June 24, 1914.

WALTER FRANK WHITTEMORE, M. ASCE[1]

Died October 27, 1944

Walter Frank Whittemore, the son of Walter D. and Philomena Antoinette (O'Gier) Whittemore, was born in Camden, Me., on June 12, 1858. His father was a sea captain, and that may have accounted for young Walter's attraction to the life at sea, which resulted in his signing up as a seaman on a sailing vessel out of New York, N. Y., bound for foreign ports. He was, successively, promoted to second mate and mate, and by the time he reached the age of twenty one, he was master of his own ship and licensed by the United States Government as a sailing master authorized to command a steamship "on any ocean."

As a career, he evidently did not find a sailor's life to his liking, and decided on engineering as the profession of his choice. He was matriculated in New York University, in New York City, and was graduated in 1883 with the degrees of Bachelor of Science and Civil Engineer. On being graduated he was appointed instructor at New York University, and at the same time attended postgraduate courses which led to the degree of Master of Science, awarded him in 1886. In the meantime, in 1884, he had been appointed assistant professor, a position which he held until 1887.

While teaching at New York University, he spent his spare time in the employ of the late Charles B. Brush,[2] M. ASCE, with offices in Hoboken, N. J. He held the position of assistant engineer until 1889, when he was promoted to principal assistant engineer. In 1896 he became a member of the firm, known as Charles B. Brush and Company, and in 1915, upon the death of Mr. Brush, he continued as successor in the capacity of consulting engineer, maintaining offices for that purpose until his death.

While specializing in harbor improvements, Mr. Whittemore was also retained on a great variety of engineering projects, including water works, sewage disposal, and railroad and highway bridges. He designed the piers and buildings of the Hoboken Ferry Company at Barclay Street, in New York City, which were built in 1887 and 1897, and those of the various steamship companies, including the Fletcher Iron Works, for almost the full length of Hoboken, north of the Lackawanna Railroad Terminal on the Hudson River front. Outstanding among these are the piers and buildings of the Holland-American and North German Lloyd Steamship Lines, including a sea wall nine hundred feet long, and three piers one thousand feet long, surmounted by two-story steel pier sheds.

He was appointed a member of the State Highway Commission by the governor of New Jersey in 1920, and served for three years in that capacity.

He joined the New Jersey National Guard in 1897 and was duly commissioned a Captain, then Major, and finally a Lieutenant Colonel, the latter in

[1] Memoir prepared by John L. Vogel, M. ASCE.

[2] For memoir, see *Transactions*, ASCE, Vol. LXXXIV, 1921, p. 818.

the Engineering Corps. Rifle shooting was practically his only hobby. In 1900 he won the Individual National Rifle Championship at Sea Girt, N. J. In later years he liked to say that he made good use of that skill, keeping a twenty-two caliber rifle beside his breakfast table with which he accounted for many a rabbit and woodchuck attempting to raid the garden near his house.

His life at sea evidently endowed him with a rugged constitution; he deplored the softness of the students who could not come to class in the famous blizzard of 1888, whereas, he seemed to find no difficulty in getting to Washington Square in New York City from Brooklyn, only to find an empty classroom. In similar vein, he often told of his father's instructions prior to his going to sea: "Never get in a fight. If you have to hit a man, be sure you are in the right, and then hit him once, so hard that it will end the argument instantly." Mr. Whittemore exemplified this type of person; he was not pugnacious, but he certainly was virile.

Although courteous and kind to all he met, he did not make friends readily; but those whom he did honor with his friendship remained faithful through life. In an era when an "educated" engineer was frowned upon, he maintained that the engineer should be a gentleman of culture, in addition to possessing an extensive technical training.

After his retirement, he enjoyed the active management of his farm, and rode his saddle horse almost daily, from early spring to late fall. The day after Election Day, however, always found Colonel and Mrs. Whittemore installed in a midtown hotel in New York City, which was a more convenient base for attending the theater, concerts, the opera, libraries, museums, and lectures, and for visiting his close friends.

In 1885 he was married to Alice Jayne in Hoboken. He was devoted to his wife, and was deeply affected by her death in 1939. He left no children of his own. A brother, Joseph O. Whittemore, M. ASCE, survives.

His was a long life replete with accomplishment in many fields of endeavor, including public service. Colonel Whitemore was a member of the Marine Society of the City of New York and served as its president, and was a trustee of Sailors' Snug Harbor, a home for seamen. He was also a member of the New York State Chamber of Commerce.

Colonel Whittemore was elected a Junior of the American Society of Civil Engineers on March 6, 1889; an Associate Member on April 6, 1892; and a Member on October 31, 1905.

WILLIAM HOOK WOODBURY, M. ASCE[1]

DIED JULY 5, 1946

William Hook Woodbury was born on August 22, 1876, in Saint Clair, Mo. He received his Bachelor of Arts degree from the University of Kansas at

[1] Memoir prepared by Wayne A. Clark, M. ASCE.

Lawrence, in 1903, and completed the three-year course required for the degree of Bachelor of Science in Engineering.

Immediately following graduation he began what proved to be an exceptionally busy, varied, and continuous career in his profession. He worked in the west and in the south of the United States, and in parts of Canada—always in connection with railroad activities.

His civil engineering career covered a broad field in which he served as rodman, draftsman, assistant engineer on maintenance of way, resident engineer on construction, inspector, bridge erector, and reconnaissance and location engineer. After 1916, he also engaged in railroad valuation work. He held various railroad engineering positions with the Kansas City Southern Railway Company; the Atchison, Topeka and Santa Fe Railway Company; the Northern Pacific Railway Company; the Great Northern Railway Company; the Soo Line; and the Canadian Pacific Railroad Company.

In 1916 Mr. Woodbury joined the Duluth and Iron Range Railroad Company as valuation engineer and continued with its successor, the Duluth, Missabe and Iron Range Railway Company. In this position he handled the railroad's many problems and controversies with the government that arose in an effort to determine its so-called "excess earnings." He continued in that capacity until December, 1933, at which time he became engineer of maintenance of the same railroad company, holding the latter position until he retired on October 1, 1942, because of physical disability. At this time he moved to Kansas City, Mo., his former home.

Mr. Woodbury became a member of the Society in 1913 and was a regular attendant at the meetings of the Duluth Section during his residence in that city. In 1918 he was active in organizing the Duluth Engineers Club and in 1920 was its president. He also represented that organization on the American Engineering Council and was active in its work. In addition M. Woodbury was a member of the American Railway Engineering Association, serving on its committees from time to time.

Being particularly interested in the development of public improvements along sound engineering lines, he was an active member of the Duluth Chamber of Commerce, and a member and director of the Duluth Automobile Club. He was unassuming, friendly, and exceptionally energetic.

His religious and social affiliations included the Pilgrim Congregational Church and the F. and A. M.

On July 8, 1908, in Kansas City, Kans., he was married to Della Mae Hamilton, who survives him. Two sisters, Amy and Blanche Woodbury, and a brother, Richard, also survive.

Mr. Woodbury was elected a Member of the American Society of Civil Engineers on December 31, 1913.

LOUIS YAGER, M. ASCE[1]

DIED NOVEMBER 22, 1946

Louis Yager, son of Frederick R. and Mary (Eberlein) Yager, was born in Germantown, Wis., on July 12, 1877. He was graduated from the University of Minnesota in Minneapolis, with a degree in civil engineering in 1900. While at the university he was a member of the honorary society of Sigma Xi.

When he was graduated from the university, Louis Yager entered the service of the Northern Pacific Railway Company; and, from that time until his death, was continuously in the employ of that company, with the exception of the years 1919 and 1920, when he was Chief Maintenance of Way Engineer of the United States Railroad Administration in Washington, D. C.

He served the Northern Pacific Railway Company in the following capacities: Rodman and inspector from 1900 to 1901; assistant engineer on construction from 1901 to 1902; supervisor of bridges and buildings in Minneapolis from 1902 to 1907; assistant engineer on construction from 1907 to 1910; division engineer in St. Paul, Minn., from 1910 to 1917; engineer on maintanence of way on the lines east of Paradise, Mont., from 1917 to 1919; engineer on maintenance of way in St. Paul from 1920 to 1922; and assistant chief engineer of the system, from 1922.

Among the important work on which he was in charge as construction engineer was the rebuilding of the St. Louis Bay bridges, drawspans for Minnesota and Wisconsin channels, between Duluth, Minn., and Superior, Wis., in order to handle modern rolling stock safely, and provide sufficient openings for lake traffic; and the construction of line from Glendive to Sidney in Montana, a distance of fifty-five miles.

In 1934–1935 he was chairman of the directing committee of the Twin City Terminal Study for coordination of terminal facilities of the various railroads entering St. Paul and Minneapolis, as well as a similar study of the Head of the Lakes Terminals, at Duluth and Superior.

During his service with the United States Railroad Administration in Washington, D. C., he was chairman of a special maintenance committee appointed to study the effects of time and use on the various elements that make up track structure and that are involved in the cost of maintenance of way and structures. The formula developed for each element of track structure, such as ties, rail, ballast, etc., has become known as the "Yager Formula," and is in general use among railroads today.

Mr. Yager's great interest in the affairs of the American Railway Engineering Association is evidenced by his assignments and by the offices he held: Committee III—Ties, member from 1913 to 1920, inclusive; Committee IV—Rail, member from 1922 until his death, serving as vice-chairman in 1937 and 1938; Committee XXI—Economics of Railway Operation, member from 1921

[1] Memoir prepared by Bernard Blum, M. ASCE.

to 1922, inclusive; Committee on Stresses in Railroad Track, member from 1937 to 1940, inclusive, serving as vice-chairman in 1940; Committee on Research Administration, vice-chairman from 1941 to 1943, inclusive; and director from 1923 to 1926, inclusive. He was elected second vice-president in 1927 and served as first vice-president in 1928, and as president in 1929. While he was president he represented the association as delegate to the World Engineering Congress in Japan. In addition to his interest in the American Railway Engineering Association, he was a member of this Society and also of the American Association for the Advancement of Science.

Mr. Yager attended the House of Hope Presbyterian Church and was a member of its Board of Deacons. He belonged to the Palestine Lodge of the A. F. and A. M. at Duluth, and the Scottish Rite and Shrine bodies at St. Paul.

On August 14, 1902, he was married to Hester Elizabeth Whiteley. He is survived by his widow and a sister, Mrs. Mary Y. Riphenburg of Wilton, Wis.

Mr. Yager was elected a Member of the American Society of Civil Engineers on September 9, 1919.

LAWRENCE RICHARD YOUNG, M. ASCE[1]

DIED AUGUST 24, 1946

Lawrence Richard Young was born in South Colton, N. Y., on December 26, 1897, the son of Oscar and Flossa (Powers) Young. He was graduated from Clarkson College in Potsdam, N. Y., in 1922 with the degree of Bachelor of Science in Civil Engineering.

Soon after graduation he became associated with the New York Power Corporation, where he worked on a number of smaller hydroelectric power plants under William P. Creager, M. ASCE. This early experience seems to have set him on his course, for the remainder of his professional life, with but few interruptions, was in the field of water resources development and control.

A short period as designer on the Beauharnois project with the late W. S. Lee, M. ASCE, at Charlotte, N. C., was followed by more than ten years of work with the United States Engineer Department. For this government department Mr. Young was engaged on the Passamaquoddy project, the Muskingum (Ohio) Flood Control, the Los Angeles (Calif.) Flood Control, and in related work in the offices at Washington, D. C.; Seattle, Wash.; Kansas City, Mo.; and Little Rock, Ark. Much of his time at the Little Rock office was devoted to the planning of Norfolk Dam.

Mr. Young left the Little Rock office of the U. S. Engineer Department in 1941 to join the Aluminum Company of America in Pittsburgh, Pa., where he made preliminary layouts of a dam for the Fontana site. He went west again as an engineer for the Morrison-Knudsen Company in Boise, Idaho, for whom he estimated and designed the construction plant for the Norfolk Dam,

[1] Memoir prepared by W. G. Huber, Dist. Mgr., International Eng. Co., Inc., Denver, Colo.

Dale Hollow Dam, and numerous other jobs. A brief trip to South America in the spring of 1945 completed his wartime assignments.

The International Engineering Company, Incorporated, in Denver, Colo., with Mr. Young as vice-president and general manager brought him back to water power development work. This time he collaborated with John L. Savage, Hon. M. ASCE, consultant, on the general design of Bhakra Dam for Punjab Province, India. On this project he had an opportunity to exercise his talent for organizing an engineering force and guiding the arrangement of a large development.

He was less patient with details but indefatigable in his striving for the most effective and economical combination of the major features of a job. Great as was his love of the out of doors, particularly of fishing, his work always was given first claim on his time. This devotion to duty, his sense of justice, and his generosity will long be remembered by his many friends and acquaintances in the engineering and construction fields throughout the United States.

In 1927, Mr. Young was married to Florence J. Quady of Rome, N. Y., who survives him.

Mr. Young was elected an Associate Member of the American Society of Civil Engineers on June 6, 1927, and a Member on September 9, 1935.

GEORGE WILLIAM BORDEN, Assoc. M. ASCE[1]

DIED JUNE 11, 1946

George William Borden was born on August 21, 1881, in Kansas City, Mo. He was one of two brothers, the son of James Thomas and Sarah R. (Felan) Borden. While he was still a child, the family moved to Terre Haute, Ind., where he received his elementary school education. Later his parents established their residence in Paris, Ill., and it was there that he was graduated from high school.

At this period, Mr. Borden evidenced a trait of character which was to remain with him for the rest of his life. His main interest was in people; he delighted in passing on to others, particularly younger people, any knowledge or information which he had gathered. It was not surprising, therefore, that for two years succeeding the completion of his high school course he remained at the school to teach mathematics. However, his personal ambition lay in the field of civil engineering, and he determined that he would make it his chosen profession.

Accordingly, in the fall of 1903, he entered the University of Illinois at Urbana, in the School of Civil Engineering. As has been the case with so many young men, he was forced by circumstances to make his own way, and

[1] Memoir prepared by a Committee of the Sacramento Section consisting of Henderson E. McGee and Roy J. Sykes, Assoc. Members, ASCE.

he temporarily abandoned his college career in October, 1905. He worked for a year as chainman and rodman for the Chicago and Northwestern Railway Company, after which he returned to the university for a short period.

Recognizing the tremendous possibilities for young engineers in the Pacific Northwest, Mr. Borden left the university in April, 1907, and went to the State of Washington where he accepted a job as instrumentman and draftsman with the Oregon-Washington Railroad and Navigation Company. Another opportunity to teach could not be resisted; in October, 1907, he became a member of the faculty of the Lyle (Wash.) High School where he remained for more than a year.

About this time the State of Washington was experiencing a rapid development in its road and highway systems. Beginning with his election as county engineer of Klickitat County, Washington, in January, 1909, and carrying through until 1919, Mr. Borden was intimately connected with the development of roads and highways in that state. He served two two-year terms as county engineer of Klickitat County, and the remainder of the time, with the exception of a short six-month period in private practice. For the State of Washington he was engaged in planning, design, construction, and maintenance of road systems.

In 1919 he was appointed assistant state highway engineer of the State of Nevada, and, from 1921 to 1927, he was state highway engineer for that state. During these periods a great many of the important highway systems in Nevada were planned, and construction work was initiated on several.

In 1927 Mr. Borden became sales engineer for the Santa Cruz Cement Company in San Francisco, Calif., and, from 1929 through 1932, he was assistant manager of sales in the asphalt department of the Shell Oil Company. In 1931, while on this latter assignment, he worked with the Argentine Government, spending six months in that country furnishing expert advice on the use of asphalts in road building. From 1933 to 1941, he was, successively, park engineer and associate engineer with the National Park Service, engaged on the development of roads in the national parks of the West.

In 1941, just before the commencement of World War II, during the period when the national defense program was being undertaken, Mr. Borden felt that he should make his engineering experience available to this program. Accordingly, he became a member of the staff of the United States Engineer Office in Sacramento, Calif., where he served until his death. During this latter engagement all the years of experience in road building were channeled into the development of military airfields and other military installations; his contribution to the war effort, through this service, was of considerable consequence and importance.

Mr. Borden was a member of the F. and A.M., and while at the University of Illinois was affiliated with the Triangle fraternity. He also belonged to the Society of American Military Engineers.

In his work, he was steady and meticulous, and he delighted in having placed under his direct supervision young men whom he could father and nurture in the highest ethical principles of the profession. As a result, there

are many men in the states of Washington, Nevada, and California who owe their earliest practical professional training to the guidance given them by Mr. Borden.

Mr. Borden was justly proud of his family. In October, 1909, he was married to Catherine Knox of Lucas, Wash. During the years of their married life Mrs. Borden was a constant inspiration both to him and to his many friends and associates. His widow and two sons, Thomas Knox and Donald Spencer, survive him.

Mr. Borden was elected an Associate Member of the American Society of Civil Engineers on November 26, 1918.

LYNN MOORE BURROWS, Assoc. M. ASCE[1]

DIED FEBRUARY 10, 1944

Lynn Moore Burrows was born in Saginaw, Mich., on June 17, 1884. He was the son of Lorenzo and Julia Louise (Moore) Burrows. His family had recently moved to Saginaw, but they returned to Albion, Orleans County, N. Y., shortly thereafter, where they lived the remainder of their lives.

The Burrows family, of pioneer stock, migrated from Connecticut to western New York in 1824. Their activities in the political, financial, commercial, and civic life had much to do with the development of western New York. This section became a prosperous region having varied interests that contributed to progress and expanding growth. Mr. Burrows' life and affairs were greatly influenced by these activities and by the progress of the region.

Mr. Burrows received his early education in private schools, and later attended Rensselaer Polytechnic Institute, Troy, N. Y., from which he was graduated in 1907 with the degree of Civil Engineer. Immediately thereafter he took charge of sewer construction for the Village of Medina, N. Y. At that time, the State of New York had just begun to enlarge the Erie Canal into what became known as the New York State Barge Canal. This project was to employ many new methods of construction which brought out the ingenuity and talents of the engineering profession. Mr. Burrows started work during the year following his graduation as assistant engineer in charge of construction of one of the large sections of the Barge Canal. This had a broadening influence on his engineering life, which was later very valuable to him. Since he was small of stature, this interesting out-of-door work strengthened him physically as well as mentally and he often referred to the unusually beneficial effects of such work. During this period, he was in close contact with many men and many problems connected with this large project, as it was then considered. By nature he was a little reticent, and not blustering. He knew how to make friends and to get along with his compeers, as well as those in lesser positions, and this brought him very successful results.

[1] Memoir prepared by Schuyler Hazard, M. ASCE.

Likewise, after the years on the Barge Canal project that so broadened Mr. Burrows' outlook in engineering matters, he applied his unusually potent talents to the solution of problems of development and opening of large areas of rich virgin lands for intensive agricultural treatment and use. Although he was not interested directly in this engineering problem, he took note of its progress. These large areas amounted, in the aggregate, to a little less than fifteen square miles. They were the remains of prehistoric swamps, and were rather flat and level tracts of large and continuous sections. They were generally referred to as muck lands. To prepare these areas for cultivation required the application of well-balanced engineering talent, since drainage of the land produced many problems.

Mr. Burrows was particularly tactful in straightening out ownership of the land in this general area. The region concerned reached from the north state line of Pennsylvania to the shore of Lake Ontario and from the Niagara frontier on the Niagara River eastward to the Genesee Valley near Rochester, N. Y. In early days, it was referred to as "The Genesee Country." In general, the region had been surveyed in the latter part of the eighteenth century, following out "The Hundred-Thousand Acre Tract," "The Connecticut Tract," and similar grants. The original notes of these different portions had not been properly preserved in many cases, and some had been kept with meticulous care. Many of them, when placed together and studied, made it possible to map the entire territory. By deep analysis and the diligent application of the true spirit and resourcefulness of the engineer, it was possible to bring this land into proper juxtaposition, but strict application and painstaking tramping over the areas were necessary. Although Mr. Burrows did not have direct responsibility, he was very much intrigued, and gave his ideas and counsel which aided materially in finding the right answer.

Mr. Burrows spent considerable time and effort in land surveying, and engineering and drainage, from April, 1909, to December, 1924. He was greatly interested in the design and construction of, and the surveying for, water distribution, sewer systems, and drainage—to which he gave his close attention for fifteen years. During this period he worked in partnership with others, but the various projects with which he was concerned were completed largely by his own efforts.

Mr. Burrows' forefathers, from pioneer stock, early foresaw the possible future value of the region in which they, and later he, lived, and had given an impetus to its development. One result of this background was his interest in the spanning, by means of bridges, of the Niagara River Gorge at the frontier along the International Boundary Line between the United States and Canada. Such bridges were primarily for railroad traffic, but were designed for combination uses to include vehicular and pedestrian traffic as well. As greater demands were made, these facilities had to be increased and revised, and Mr. Burrows was given charge of designing the improvement of the approaches to the Niagara Railway Arch Bridge at Niagara Falls, N. Y. He was consulting engineer and in charge of construction for such improvement, including the consequent changes in affected water and sewer systems—

water and sewer systems being his specialities. About this time he became a director of the Niagara Falls International Bridge Company at Niagara Falls, but still resided at Albion. Also, during this period, greater demands were made on Mr. Burrows, but he had considerable versatility and aptitude; and, when called upon, he undertook the work of designing and supervising the construction of the sewer extension and disposal of factory wastes for the Village of Albion. Concurrently, he made surveys for subdivisions of property for city planning in the general region referred to as western New York.

In addition to his duties connected with the office of director, he was chosen as president of the Niagara Falls International Bridge Company and filled that position with honor and success, although part of that time illness interfered somewhat with his activities.

Mr. Burrows was a likable man, and had many friends in and out of the engineering profession. He was quiet and unassuming. An ardent yachtsman, his love for yachting was a great help in maintaining his health and spirits, and he took delight in annual cruises in his yachts. In earlier days he enjoyed sailing craft, and later motor cruisers. He always took pleasure in having his friends accompany him on cruises (including a trip along the Canadian shore, with suitable stops en route, and many shorter trips across Lake Ontario and along the shore of the lake east and west of his home port of "Oak Orchard-on-the-Lake," where he had his summer quarters for rest and recreation).

Mr. Burrows was a member of the Rensselaer Society of Engineers; the Officers Reserve Corps (Captain of Engineers); the University Club of Rochester; the Oak Orchard Yacht Club ("Commodore"); the Rochester Yacht Club; the Town Club of Albion; Renovation Lodge of Benevolent and Protective Order of Elks at Albion; American Red Cross (treasurer of the local chapter); the Board of Commissioners of Mt. Albion Cemetery (treasurer); Albion Chapter of International Rotary; and the Board of Directors of Arnold Gregory Memorial Hospital at Albion. He was a Republican and belonged to the Christ Episcopal Church at Albion.

On July 24, 1907, Mr. Burrows was married to Beatrice Signor of Albion. He is survived by his widow.

Mr. Burrows was elected an Associate Member of the American Society of Civil Engineers on December 15, 1924.

WILLIAM ROBERTS CONARD, Assoc. M. ASCE[1]

Died April 30, 1946

William Roberts Conard, the son of William and Julia Ann (Powell) Conard, was born in Burlington, N. J., on May 19, 1872. His father was the great-

[1] Memoir prepared by Howard T. Critchlow, M. ASCE, and Wilfred G. Conard, Asst. Canal Supervisor, New Jersey Dept. of Conservation, Trenton, N. J.

great-great-grandson of Thomas Kunders (who later became known as Dennis Conard) and his wife, Elin, who settled in Pennsylvania in July, 1683. A member of the Society of Friends, Thomes Kunders came from Crefeld, on the lower Rhine in Germany, near the Netherlands border. Before sailing for America, Thomes Kunders, or Conard, obtained from Lenart Arets a warrant for five hundred acres of lands that were formerly purchased from William Penn. These lands lie in the northern part of the City of Philadelphia (Pa.), later known as Germantown. The seven children of Thomes and Elin and their offspring have spread the family of Conards, Cunards, Connards, Conrads, and Conreds throughout Chester, Montgomery, and Philadelphia counties in Pennsylvania and the bordering states of Delaware and New Jersey.

William Roberts Conard was the youngest son of William, who was employed by A. H. McNeal and Company in the manufacture of cast-iron pipes in Burlington. He was educated in the public schools and at Trenton Business College in Trenton, N. J., and worked in various clerical capacities while still a young man. During his employment with the Underwood Ink Company in Brooklyn, N. Y., he was married to Carabelle Topping, a descendant of Robert Humphrey Nichols, a sailing master in the American Navy during the War of 1812.

After his marriage, he moved to Burlington, where he built up a business in inspection and testing engineering. Throughout the United States Mr. Conard was also widely known in the water works field and, as a consultant, was engaged by many communities in the eastern part of the United States, as well as by some communities in Mexico and South America. During World War I, he was with Hazen, Whipple and Fuller, constructing the pumping station and supply main to Camp Dix, New Jersey, and also at Mays Landing, N. J., where he developed the water and sewage systems for the Bethlehem Loading Company.

At the end of the World War I, he entered into partnership with John Stewart Buzby, who had previously been his principal assistant. Conard and Buzby expanded their business; it finally covered the inspection of cast-iron pipes and fittings imported into the United States from Europe with inspectors on both continents. They also branched out into the construction field, dealing principally with the installation of hydraulic equipment, with work involving mass concrete, and with bridge building.

Of an inventive turn of mind, Mr. Conard designed and developed many items used in the water works field. He was interested in the General Pipe Cleaning Company of Philadelphia, which engaged in a business of hydraulic pipe line cleaning. Always progressive, and always one to avail himself of the latest developments and modern trends, it is remembered that he was the owner of the first shaft and gear driven bicycle in town, a Pierce Arrow. When the automobile appeared, again he was owner of one of the first in town.

Mr. Conard was very fond of gunning and, when time permitted, spent many hours in the field. In later years this was supplanted by golf at the Burlington County Club where he was a life member. During World War II, he found time to take his turn at an aeroplane observation post. He de-

voted much time and energy to civic betterment; he advocated city zoning; he was a member of the Young America Fire Company of Burlington; and he actively worked for improved fire protection. All his life he was a Republican in politics and a member of the Union League of Philadelphia. He was a member and trustee of Broad Street Methodist Episcopal Church of Burlington as well as a member of, and officer in, numerous fraternal organizations. In Burlington, he had been postmaster, a member and president of the board of education, and secretary of the Burlington Postwar Planning Board. In the State of New Jersey, he served on the Water Policy and Supply Council of the Department of Conservation, and was a licensed professional engineer.

Mr. Conard was a man of sterling character, reticent and dignified, and in conversation he impressed his interlocutor with complete and instinctive confidence in his ability and integrity.

Despite his many interests, Mr. Conard was very active in the American Water Works Association and was one of the founders of its New Jersey section of which he served as chairman in 1937. He was a member of the New England Water Works Association, the American Society for Testing Materials, and the Engineers Club of Philadelphia.

He is survived by his widow; two sons, Wilfred George and Robert Powell Conard; and two daughters, Mrs. Carabelle Mitchell and Esther Laurie Conard.

Mr. Conard was elected an Affiliate of the American Society of Civil Engineers on January 3, 1906, and an Associate Member on July 7, 1915. He became a Life Member in January, 1941.

CLARENCE DEXTER CONWAY, Assoc. M. ASCE[1]

DIED JUNE 19, 1946

Clarence Dexter Conway was born on March 31, 1889, in Millersburg, Ky. His mother, Lida B. Johnson, and his father, William B. Conway, came from prominent Kentucky families. He received his early education in Paris, Ky. In 1905, he was graduated from Millersburg Military Institute, and in the same year entered the University of Kentucky at Lexington, to study civil engineering. In 1906 he came to California and entered civil engineering work, completing his engineering studies by correspondence courses and practical experience.

Mr. Conway's professional career began with construction work for the Western Pacific Railroad Company in the Feather River Canyon, extending from Oroville eastward to the California state line, from 1906 to 1910. On this project he was instrumentman and tunnel inspector part of the time. Following this position he was with the Southern Pacific Railroad Company

[1] Memoir prepared by a Committee of the Sacramento Section consisting of Martin C. Polk, M. ASCE, and Fred T. Robson, Assoc. M. ASCE.

in the division engineer's office on the construction of the Natron Cutoff in Oregon.

In 1911 and 1912 he was in charge of subdividing and laying out an irrigation system for a large tract of land consisting of about twelve thousand acres in the Sacramento (Calif.) Valley, known as the Los Molinos Land Colony. The next year he was in charge of maintenance and operation of the irrigation system for the same project; until March, 1916, he was occupied in intensive land development and irrigation engineering on various projects in the State of California. He then returned and became manager for the Los Molinos Land Company and chief engineer of the Coneland Water Company which irrigated the colony lands. Thus, Mr. Conway had complete charge of mainnance and operations of the irrigation system and management of the land company. He remained in this work until his death. During the time of his management of the land company he also specialized in, and had a large practice in, land development and irrigation engineering.

The Sacramento River and its problems of flood control, navigation, and irrigation especially interested Mr. Conway. He knew every foot of its length through Tehama County, California, and the damage that was being done by floods. Continually striving to have this menace curbed, he was untiring in his efforts to get help from federal and state sources and used moving pictures of the large floods on the Sacramento River to further the interest of flood control work. He was consulted in an advisory capacity by the state engineer's office and by the United States Army Engineers in charge of flood work on the Sacramento River, and was a member of the flood control committee of the chamber of commerce of the State of California.

During his thirty-five years as a resident of Tehama County, Mr. Conway was always a leader of any movement that might better the citizens of the county, either mentally or materially. For fifteen years he was a member of the board of the Corning (Calif.) Union High School District, as well as being a very active member of the Los Molinos Mosquito Abatement District, the Tehama County Planning Commission, and the Tehama County Probation Board. His efforts, in fact, were untiring in every way for the benefit of the fellow citizens of his community.

In 1917 he was married to Della E. Rowe of Oroville. He is survived by his widow, and two sons, Richard D. and William E. Conway.

Mr. Conway was elected a Junior of the American Society of Civil Engineers on November 28, 1916, and an Associate Member on January 19, 1920.

GWYNNE WALLACE ELLIS, Assoc. M. ASCE[1]

Died October 9, 1945

Gwynne Wallace Ellis, the son of Augustus Wallace Ellis and Katherine (Axline) Ellis, was born in Colfax, Wash., on October 23, 1882.

[1] Memoir prepared by Chester A. Smith, M. ASCE.

In 1883 his parents moved to Pratt, Kans., where Mr. Ellis spent his boyhood days and attended the grade and high schools.

He received the degree of Bachelor of Science in Civil Engineering from the University of Kansas at Lawrence, in 1908.

During his senior year at the university, Mr. Ellis, in conjunction with another senior engineering student, prepared the plans and specifications for the sanitary sewer system for his home town. Upon his graduation from the university, he was appointed city engineer of Pratt and supervised the construction of the sewer system.

In November, 1909, he entered the employ of the Burns and McDonnell Engineering Company in Kansas City, Mo. He served as resident engineer in the supervision of construction of the sanitary sewers for Washington, Minneapolis, Osage City, and Harper in Kansas and the water works system for Sapulpa, Okla. He resigned from Burns and McDonnell Engineering Company in September, 1913, to engage in private consulting practice. In 1914 Mr. Ellis was appointed city manager of Osage City.

During World War I, in 1917, Mr. Ellis was commissioned as Captain in the United States Army Engineering Corps and, after finishing officers' training camp, was assigned to the 110th Engineering Regiment. Upon his discharge from the army, he again engaged in private engineering in Pratt, where for about four years he did considerable work on the design and construction of sewers, water systems, and paving, and also on power plant construction for several cities in the southern and western sections of Kansas.

In 1921, he moved to California and purchased a home in Glendale. There he entered the contracting business as G. W. Ellis, Contractor. Street and highway paving were the principal types of work required in his contracts. With the entry of the United States in World War II, Mr. Ellis placed his equipment for use on war projects, and maintained a repair yard for equipment from near-by localities as well as from the war zones.

Mr. Ellis was highly respected among engineers, contractors, material salesmen, and others with whom he was in contact for his honesty, integrity, and straightforward decisions. In his early engineering experience as supervisor of construction, he demanded careful work and adherence to the plans and specifications, and carried the same principles into his contracting work.

Although he led a very busy life with his engineering regardless of the type on which he was engaged, he spent his leisure hours reading good books and technical magazines. Also, although not active in outdoor sports, he enjoyed attending baseball, football, and other manly sports events.

On June 19, 1912, he was married to Reba Bauman of Osage City. He is survived by his widow, and his son, Ralph.

Mr. Ellis was elected an Associate Member of the American Society of Civil Engineers on September 3, 1913.

DAVID FERGUSON, Assoc. M. ASCE[1]

Died December 9, 1945

David Ferguson was born in Inverness, Scotland, on July 18, 1892. He was the son of John and Mary (Groat) Ferguson. When he was four years of age, his family settled in the vicinity of Boston, Mass., where he received his education. He attended grade school and high school at Cliftondale and Methuen in Massachusetts. He received his engineering education at Tufts College in Medford, Mass., and was graduated in 1916 with the degree of Bachelor of Science in Civil Engineering.

Following his graduation from college, from August, 1916, to August, 1917, he was employed by the War Department on survey work for the Mississippi River Commission at Memphis, Tenn.

During World War I, from October, 1917, to May, 1919, Mr. Ferguson served in the armed forces of the United States. In 1918, he saw service in France with Battery E, 319th Field Artillery of the Eighty-Second Division. His unit took part in the Saint-Mihiel and Meuse-Argonne offensives.

After the war he was with the United States Engineer Office at Memphis, as chief of survey party, from 1919 to 1923. In this capacity he surveyed the shore lines of the Mississippi River from Cairo, Ill., to the mouth of the White River in Arkansas.

From May, 1923, to November, 1927, Mr. Ferguson was employed by several steel fabricators: The Ingalls Iron Works; the Tennessee Coal, Iron and Railroad Company; the Virginia Bridge and Iron Company (Birmingham, Ala.); and the Richmond Structural Steel Company (Richmond, Va.). In November, 1927, he entered the service of the Chesapeake and Ohio Railway as a structural designer and remained with that company until June, 1930.

Mr. Ferguson was a structural engineer with the Treasury Department (Supervising Architect's Office and Procurement Division), and the Federal Works Agency in Washington, D. C., from 1930 to 1941. He was responsible for the preparation of structural drawings for various types of federal buildings throughout the United States. The court house and federal building at Salt Lake City, Utah, and the gold depository at Fort Knox, Ky., are examples of important structures which he helped to design.

In February, 1941, Mr. Ferguson returned to the War Department, as chief of the structural unit, Airport Section, Office of the Chief of Engineers. In addition to the usual airport construction, he was responsible for the review of plans and studies for airplane hangar construction submitted to the Office of the Chief of Engineers. In May, 1942, Mr. Ferguson was appointed assistant chief of the Fortifications and Protective Design Section, Engineering and Development Division, Office of the Chief of Engineers, and worked in this position until his death in December, 1945. The work included

[1] Memoir prepared by Christian Beck, M. ASCE, and Walter G. Hiner, Structural Engr., Office, Chf. of Engrs., War Dept., Washington, D. C.

planning, tests, and designs of all kinds of protective structures, such as land and seacoast fortifications, submarine mine installations, and fixed antiaircraft defenses. The sound manner in which he attacked all engineering problems won him the respect of fellow engineers.

Mr. Ferguson had been active in the work of the Baptist Church at Clarenden and Manassas, in Virginia. He was a member of the F. and A. M., Lewis Ginter Lodge No. 317 of Richmond. David Ferguson was a man of sterling character and high principles. Although of slight stature, he was energetic and fearless, and a man firm in his convictions. A characteristic sense of humor and friendly interest in others will long be remembered by his friends and associates.

Mr. Ferguson was married on May 14, 1918, in Long Island City, N. Y., to Hazel (Todd) Merrill. He is survived by his widow; one daughter, Evelyn; his father, John Ferguson; three sisters, Anna (Mrs. R. R. Gibson), Emma (Mrs. J. A. Henderson), and Margaret (Mrs. C. E. Wilkinson); and a brother, Daniel Ferguson. Funeral services were held at the Fort Meyer Chapel and burial was in the National Memorial Cemetery, Arlington, Va., on December 12, 1945.

Mr. Ferguson was elected an Associate Member of the American Society of Civil Engineers on March 12, 1923.

CHARLES NEEDHAM FORREST, Assoc. M. ASCE[1]

Died December 2, 1946

Charles Needham Forrest was born on September 30, 1873, in Baltimore, Md. He was the son of Andrew Jackson and Emily (Dorsey) Forrest.

In Baltimore, he attended the public schools and the Maryland Institute, and began his professional career when he entered the employ of the Baltimore and Ohio Railroad Company, in the Test Department. In this department he became, successively, assistant in the chemical and physical laboratory and principal assistant chemist.

In 1896 he was employed by the Southern Railway Company as chemist in the Test Department in Washington, D. C. During this year he took advantage of the evening courses that were being held at Columbian University (later George Washington University) in Washington, D. C., where he specialized in chemistry under the very eminent Charles Monroe.

In 1897 he became chemist and inspector for the Long Island Railroad Company in Long Island City, N. Y., remaining there until 1904. During this period he was active on the important projects of the Port Washington extension of the railroad and on laboratory and mill inspections. Later he supervised the chemical and physical laboratory work for the Atlantic Avenue

[1] Memoir prepared by J. Strother Miller, Asphalt Technologist, Rahway, N. J.

Improvement project in Brooklyn, N. Y., and, for the last three years, served virtually as engineer of tests and assistant purchasing agent.

In 1904 Mr. Forrest was associated with Clifford Richardson as chief chemist in the New York Testing Laboratory at Long Island City. When the New York Testing Laboratory was moved to Maurer, N. J., in 1907, he was in full charge of the design and control of street and highway paving, and materials entering this field, particularly asphalt. In addition, he supervised the operations of the largest firm of asphalt paving contractors at that time, the Barber Asphalt Paving Company. When the laboratory was taken over by the Barber Asphalt Company, he continued with that corporation until his retirement, under its pension plan, in 1941. For these many years he served as manager of the Technical Bureau, entirely supervising paving operations, and plant operation, in both asphalt and oil refining. In 1927 he made a world tour in the interest of paving operations in various countries.

During the early years of improved highway paving, Mr. Forrest lectured on this subject. At that time he also took an active part in the meetings of the Society, even before the Highway Division was formed. Throughout the period of great specialization in asphalt and its many applications, Mr. Forrest served as an expert in many court cases including some very interesting patent suits.

In addition to the Society, he was a member of the American Society for Testing Materials (A.S.T.M.), the American Chemical Society, the Society for Chemical Industry, Franklin Institute (Philadelphia, Pa.), the Association of Asphalt Paving Technologists, the Society of Municipal Engineers, and the American Association for the Advancement of Science (a fellow).

He was most active in the A.S.T.M., serving on Committee E-1, Methods of Testing; Committee E-8, Nomenclature and Definitions; Committee D-1, Paint, Varnish, Lacquer and Related Products; Committee D-4, Road and Paving Materials (past-chairman); Committee D-2, Petroleum Products and Lubricants; and Committee D-8, Bituminous Waterproofing and Roofing Materials (past vice-chairman). He also served a term on the executive committee (later the board of directors) of A.S.T.M.

These activities are indicative of the leading part he had in standardization and research work for road and paving materials, waterproofing compounds, roofing, and petroleum products. He wrote many technical reports and papers presented before meetings of the A.S.T.M. and other societies. Mr. Forrest also served as chairman of the Advisory Research Committee of the Asphalt Roofing Industry Bureau in New York, N. Y., and continued in this capacity for several years after retirement from active corporate work.

His placid and pleasant personality, his wit, and his humor won for him many friends—in and out of his profession—at home and abroad. Many times when an impasse developed at a committee meeting, the situation was saved by his wit and humor, along with his ability to explain the technical necessities of the situation. Only his breadth of experience in his chosen fields could have solved many such situations.

He is survived by his widow, the former Cora Linthicum, and their two sons, Arthur Linthicum and Charles Dorsey.

Mr. Forrest was elected an Associate Member of the American Society of Civil Engineers on April 6, 1909.

JOHN HARRISON FOSS, Assoc. M. ASCE[1]

DIED JANUARY 5, 1946

The life and career of John Harrison Foss well exemplify the widely varied influences and types of engineering, the rapid development, and yet the secure economic and technical controls of that most intriguing outpost of America—Hawaii.

Born in Loleta, Humboldt County, Calif., on January 7, 1879, the young and vigorous life of the West was a part of his heritage. The Foss family is of Norwegian extraction, their original American members being shipowners and traders. They became permanent residents of Maine in about 1700, although they may have engaged in American trade earlier. James C. Foss, the father of John Harrison Foss, came to California from Saco, Me., during the gold rush of the early 1850's. Lavina Dickson was born near Digby on the Bay of Fundy in Nova Scotia, Canada. Her family were of British and French Huguenot extraction and had been Tory refugees from New York during the Revolutionary War. She came to California to visit a brother, and there she met and married James C. Foss. This pioneering ancestry, and the frontier life in this early and remote California settlement contributed to the dependability and rugged independence of mind and character notable in their son John.

His career in engineering began with his matriculation at Leland Stanford Junior University, Stanford University, Calif., as a member of the class of 1903. In those early days of Stanford, the influence of that remarkable group of young men, the late C. D. Marx,[2] Hon. M. and Past-President ASCE, and the late C. B. Wing and J. C. L. Fish, Members, ASCE, who were the civil engineering faculty, was far more direct and potent a force in the formation of professional and personal ideals and character than can be the case with huge schools and mass education. The training fell on fertile ground. Since Mr. Foss was gifted with an acute and penetrating mind, an amazing patience, and a capacity for hard and thorough work, no economic or engineering problem ever appeared insoluble to him. It was merely a call for long hours of extra work, frequently late at night. The sound grasp and the amazingly detailed mastery of highly complex problems that he so frequently displayed were the results of his added efforts.

[1] Memoir prepared by Joel B. Cox, Assoc. M. ASCE.

[2] For memoir, see *Transactions*, ASCE, Vol. 105, 1940, p. 1785.

Immediately following his graduation from Stanford in 1903, at the age of twenty four, Mr. Foss made his first contact with what was to prove the major work of his life—the construction and development of the collection system for mountain water from the slopes of Haleakala on east Maui, to irrigate the fertile isthmus between east and west Maui in Hawaii. Again it was a time of stimulating contacts, and of rapid growth and development. Annexation of Hawaii by the United States had brought renewed growth to the sugar industry, and one of Hawaii's greatest men, H. P. Baldwin, was at the height of his career. He had initiated the use of east Maui water for irrigation twenty-five years before, and now the full utilization and development was to begin. The late M. M. O'Shaughnessy,[4] M. ASCE, later better known as engineer of the City of San Francisco (Calif.), was employed to build the Koolau Ditch—an aqueduct with a capacity of seventy million gallons per day, extending the system of collection to a distance of thirty miles from its use. To bring this water to the Maui Agricultural Company's fields, the new Hamakua Ditch was built simultaneously.

Employed on the construction of the Hamakua Ditch as a young engineer, Mr. Foss rose in the short time of fourteen months to the position of engineer in charge, completing twelve miles of tunnels, siphons, and open ditch around the rugged flanks of ten-thousand-foot volcano. With the completion of the new Hamakua Ditch in 1905, Mr. Foss moved to the plantation proper as a civil engineer. He remodeled and extended the irrigation system; rebuilt the railroad to transport the greater volume of cane to the mill; built reservoirs, distributing ditches, flumes, siphons, weirs and regulating works, and housing for plantation employees; and constructed the other myriad structures necessary for so complex an enterprise.

After this introduction to the full scope of sugar plantation engineering, Mr. Foss was drawn back to Stanford for a period of twelve years as assistant professor of civil engineering. His clarity of thought, warm and human approach to his students, and his endless patience made him a most valuable teacher, particularly in drafting room courses in which he specialized.

Even during this academic period he was closely associated with the growth of Maui. He returned for a sabbatical year in 1912 to plan and largely build the Honolula Ditch, an eight-mile aqueduct in West Maui. He was previously married to a Maui girl, Irene V. Crook, in 1909. Two other members of his family, a brother, J. C. Foss, also a civil engineer, and a sister who was married to David T. Fleming, a Maui pineapple and cattle ranch manager, made their homes on Maui. Thus, it was as a member of the close-knit island community, rather than as a stranger, that he returned in 1919 to head the civil engineering staff of the group of corporations owning and operating the majority of Maui's plantations (both sugar and pineapple), ranches, and ports.

From this time until his death in 1946, Mr. Foss' professional life was a summary of the progress of his community. During this quarter of a century, the production of sugar increased nearly fifty per cent, a great pineapple industry rose and became established, and the community prospered and ma-

[4] For memoir, see *Transactions*, ASCE, Vol. 100, 1935, p. 1710.

tured. His hand was everywhere. From the architecture of its churches to his latest improvement for the handling and shipping of sugar in bulk in specially designed ships, it was his designing, ability, and sound economic judgment which insured success.

His four children grew to maturity on Maui—John Harrison Foss, Jr.; Capt. William Crook Foss, who was killed in action on Okinawa in May, 1945; Francis Dickson Foss; and Nancy Virginia Foss. Mrs. Foss died in October, 1931, and in June, 1940, Mr. Foss was married to Helen E. Van Keuren who survives him.

The wide range of his civic interests and his sense of public duty are reflected in the long list of memberships in community enterprises listed in "Who's Who in Engineering."

The Wailoa Ditch, with ten miles of concrete lined tunnels and a capacity of one hundred and eighty million gallons per day, completed in 1923, was his most important work from a technical standpoint. Not only is it the greatest in capacity of Hawaiian aqueducts but, in its use of automatic gates, high concrete flumes, and self-supporting steel pipe bridges, it is a milestone in engineering progress in the islands.

The development of hydroelectric power as a by-product of an irrigation system was Mr. Foss' contribution to the economy of the plantation. He was first to develop accurately a statistical measurement of the duty of water in sugar cane irrigation and to determine its economics closely. As a consultant, his services in the reconstruction and completion of the Alexander Dam in 1932 contributed largely to the successful methods of internal drainage which made possible the use of highly colloidal material in hydraulic-fill construction. His exploration of underground water conditions in the basalts of east Maui was an adventure in economic geology whose importance is only beginning to be realized. His latest work was the design of the bulk sugar storage and loading plant at the harbor of Kahului, Maui. This plant has storage room for forty thousand tons of sugar per day and loads four hundred tons per hour into ships.

Throughout this period of achievement, Mr. Foss' personal qualities were a guide and an inspiration to the entire engineering profession in Hawaii. His complete integrity, his careful and painstaking accuracy and dependability, and his patient and comprehensive study and mastery of complex problems were an inspiration. His generous gifts of time and interest in the technical problems of others, and his patient and warm-hearted understanding of personal problems made him deeply beloved. His passing will leave a gap which cannot be filled, but his work will endure and his well-loved island home will profit by his building for generations to come.

Mr. Foss was elected a Junior of the American Society of Civil Engineers on December 1, 1903, and an Associate Member on October 4, 1910. He became a Life Member in January, 1945.

ABRAM NUTE GEORGE, Assoc. M. ASCE[1]

Died May 6, 1946

Abram Nute George, the son of Andrew and Grace (Nute) George, was born in Hastings, Nebr., on May 27, 1890. In 1898, the George family moved to California and settled in San Diego. He was graduated from San Diego High School in June, 1908, and in 1915 completed a civil engineering course through the International Correspondence School.

Between May, 1910, and February, 1912, he worked as chainman and instrumentman for the San Diego County Highway Commission. When the California State Highway Department was organized in 1912, Mr. George started on February 15 of that year as transitman; his name appears on the first payroll of District VII. He soon advanced to chief of party and held this position from the spring of 1914 until September 28, 1917, when he entered the U. S. Army Air Force during World War I.

Upon graduation from the U. S. School of Military Aeronautics at Berkeley, Calif., he was commissioned a Second Lieutenant in the U. S. Air Service and proceeded to France. While in France he taught aerial gunnery and was a pursuit pilot at the front until the end of the war.

On April 7, 1919, Mr. George returned to the Division of Highways of the State of California and held the positions of chief of party, resident engineer, and office engineer until the fall of 1927. At that time he resigned from state service to become chief engineer for the B. W. Kuhn Corporation, Contractors. However, the urge of public service was strong and after a year he returned to the Division of Highways.

Between September, 1928, and November, 1931, he held the position of resident engineer and was in charge of many large and important construction projects. In 1933, his outstanding ability was further recognized by his promotion to acting district construction engineer, and on June 15, 1934, he was advanced to district construction engineer, which position he held until his death. As district construction engineer he supervised the construction of the Arroyo Seco Parkway, the first freeway built in the Los Angeles (Calif.) metropolitan area; the section of the Ramona Parkway in the City of Los Angeles; and many other noteworthy projects.

Mr. George was held in the highest esteem, both as an engineer and as a man of strong character and inflexible principles. These outstanding qualities won for him the respect and admiration of his associates and aided him materially in establishing and maintaining the reputation of the Division of Highways on its present high plane.

In 1924, Mr. George was married to Josephine K. Hirschler. He is survived by his widow; two sons, Abram N. George, Jr., and Jack Alan George; and a sister, Mrs. Emma Sherburn.

Mr. George was elected an Associate Member of the American Society of Civil Engineers on January 19, 1920.

[1] Memoir prepared by S. V. Cortelyou, M. ASCE.

SUMNER GOWEN, Assoc. M. ASCE[1]

Died February 18, 1947

Sumner Gowen was born in Boston, Mass., on June 30, 1874. He was the son of Franklin Augustus Gowen and Mary Jane (Horne) Gowen and the oldest of four children. His mother came from a Maine family. The Gowen family moved to Wakefield, Mass., where his education was started and where he was graduated from high school. In the Massachusetts Institute of Technology at Boston, he took the civil engineering course and received the degree of Bachelor of Science in Civil Engineering in the class of 1897.

In August of that year, he was employed in the drafting room of the Phoenix Bridge Company at Phoenixville, Pa., and remained with that company for forty-nine and one-half years, until his death in February 1947—a record as unusual as it was remarkable.

In a short time after starting in the drafting room, he became familiar with detailing procedure and shop practice and showed such an interest in structural design that he was transferred to the designing department. At that time, the Phoenix Bridge Company principally produced railroad bridges, its contracts including designing, detailing, fabricating, and erecting girder and truss spans, drawbridges, turntables, cantilevers, etc. Railroad companies then generally did not have designing departments and there were relatively few consulting engineers. Bridge fabricating companies furnished designs for the majority of the contracts they executed.

Mr. Gowen's talents were particularly adapted to work of this type as he had a complete and lightning-like grasp of the mathematical phase of design, and also possessed an innate sense of the functional fitness of details and of assemblages. As a result of this happy combination of faculties, any design he turned out was adequate, economical, and most suitable.

Soon after he joined the Phoenix Bridge Company, that firm built the 3,000-ton Cornwall Bridge over the Saint Lawrence River in Canada—including a viaduct, three 368-foot through pin truss spans, one 240-foot draw-span, and an 841-foot cantilever. During the following years, Mr. Gowen contributed largely to designs which were required for bridges all over the United States and for others exported to Central and South America, to China, to Japan, and so on. In 1903 work involving unprecedented problems was begun on the first Quebec cantilever bridge over the Saint Lawrence River—a bridge with an 1,800-foot main span and two 500-foot anchor arms. In 1904 the 8,000-ton Cambridge Bridge, with its eleven plate girder arch spans, was built in Boston.

During his lifetime, Mr. Gowen saw many changes in steel construction and participated in advances in design. In the first two decades of the century, many bridges of various types were required for railroads—changes for line

[1] Memoir prepared by Roberts S. Foulds, Contracting Engr., The Phoenix Bridge Co., Phoenixville, Pa.

extensions and renewals for heavier rolling equipment. For example, there were numerous orders from railroads such as the Southern Pacific Lines and the Southern Railway System requiring stress sheets. At first, in design and construction practice, plate girders were used for relatively short spans, and trusses were pin connected. Gradually, plate girders were used for longer and longer spans, and in the shorter truss spans riveted joints began to be used. Finally the pin-connected truss became almost obsolete. Where viaducts with 30-foot steel towers and 60-foot spans—or a similar arrangement—had been common practice, high masonry piers and long span plate girders were preferred. Plate girder and truss swing spans gave way in general to the rolling lift, the trunnion, and later to the vertical lift types of movable bridges. Mr. Gowen's work for the Phoenix Bridge Company was in the front line of this march of progress.

One of his attractive designs in 1915 was the 665-ton, 600-foot highway cantilever bridge for the Palisades Interstate Park Commission with an outline like the braced arch for the Popolopen Creek crossing in New York near Bear Mountain Bridge.

With the improvement of highways, accelerated by the automobile, contracts for highway bridge work replaced railroad bridge contracts to a considerable extent. Railroads and state highway departments began to do much of their own designing. For most of the larger projects, consulting engineers were retained. About 1920, the Phoenix Bridge Company began to contract for steel for buildings, and Mr. Gowen made many building designs. To design had been added cost estimating and, as time went on, Mr. Gowen's work included less designing and more estimating until in later years estimating took the major part of his time. In estimating, just as in designing, he could turn out a prodigious amount of work—all carefully done.

Until the last few years, golf was his principal recreation. Earlier he had played a good deal of tennis and had side interests such as photography and literature. An omniverous reader, he had a particular mastery of English history and literature from the time of Elizabeth to George IV. Over the years, his associates could always count on getting help from him and many found contact with his keen mind delightful. He was clear headed and kind of heart.

On May 12, 1909, he was married to Keturah Kreamer Reeves of Phoenixville. His only brother had died at the age of twenty one and his sisters, Jessie (Mrs. Ernest E. Tyzzer) and Ruth (Mrs. Harry B. Fiske), died in recent years. He is survived by his widow and three nephews, Gerald and Franklin Tyzzer and Benjamin Fiske.

Mr. Gowen was elected a Junior of the American Society of Civil Engineers on May 2, 1899, and an Associate Member on June 4, 1902.

JOHN GREER, Assoc. M. ASCE[1]

DIED MAY 23, 1946

John Greer, the son of William and Mary (Greenfield) Greer, was born at Belfast, Ireland, on February 5, 1885. He received his education at Queens University in Belfast, and was graduated with the degrees of Bachelor of Arts and Bachelor of Engineering in 1907 and 1911, respectively.

His professional career began immediately after graduation, and, from 1911 to 1913, he held the position of surveyor with the Irish Land Commission. In 1909, he became an associate member of the British Institute of Civil Engineers.

He emigrated to Canada and from March, 1913, to December, 1914, he was an instrumentman for the Canadian Northern Railway, stationed at Vancouver Island, B. C., Canada. From January to December, 1915, he was an instrumentman at Portland, Ore., on various surveys, including a toll line survey for the Pacific Telegraph and Telephone Company on the new Columbia Highway in Oregon.

During World War I, from January, 1916, to November, 1918, he was with the Canadian Expeditionary Force in France, including one year on railway construction and bridge repair with the First Canadian Railway Troops.

After the war, from March to June, 1919, he was employed as draftsman by the Foundation Company of New York, N. Y., on details in new power plant construction at Sidney, Nova Scotia, Canada. Between July, 1919, and December, 1921, he was employed by the Grand Trunk Lines for one year as assistant engineer on a valuation survey, and for one and a half years as assistant engineer in full charge of maintenance of way and structures of its Portland Division in New England.

In July, 1922, he entered the service of the Maine Central Railroad Company in the capacity of resident engineer, reporting to the engineer of construction. As resident engineer he was responsible for laying out and supervising the construction of various structures, including bridges, roundhouses, shops, and trackwork. He resigned in May, 1926, and for the next six months was employed by the Technical Advisory Corporation of New York, as assistant engineer in charge of making studies and reports for the elimination of grade crossings at Elmira, N. Y.

His next employment, during 1927, was with Allen N. Spooner and Sons of New York, as superintendent of construction, building piers and retaining walls on New York City's waterfront.

The following year he was engaged by the Town of Belleville, N. J., as assistant engineer in connection with a special study it was making of its sanitary sewer system.

Completing this study he entered the service of the Erie Railroad Company as designing draftsman in the office of the engineer of structures. He

[1] Memoir prepared by W. R. Swatosh, M. ASCE.

was engaged principally on design of railroad and highway bridges in connection with grade crossing eliminations. In 1945, he was promoted to designer, which position he held at the time of his death.

Mr. Greer's work was always characterized by accuracy and good judgment. He was a gentleman of very likable personality and made many lasting friendships.

He was married in Belfast on October 9, 1916, to Katherine Gemmel who, with two daughters, Elizabeth Barbara (Mrs. Philip Tremain Johnson) and Mary Clarke, survives him.

Mr. Greer was elected an Associate Member of the American Society of Civil Engineers on February 25, 1924.

ISAAC HAUSMAN, Assoc. M. ASCE[1]

Died October 29, 1946

Isaac Hausman, the son of Dr. Jacob L. and Jennie (Burna) Hausman, was born in Russia on February 5, 1889. His parents, coming to the United States when he was about three years old, settled in Kansas.

He completed his early education there and obtained part of his engineering training at the University of Kansas in Lawrence, finishing his college work at the Massachusetts Institute of Technology in Boston, in 1911, when he was graduated with the degree of Bachelor of Science in Civil Engineering.

During his college years and after his graduation, Mr. Hausman spent some time on field work with the Union Pacific Railroad Company; with C. M. Bolton and Company in Garrison, Mont.; with Tunnel Contractors in Garrison, Mont., and Millwood, N. Y.; and with Post and McCord and George A. Just and Company, both in New York. In 1913 he moved to Toledo, Ohio, to work as structural engineer, designer, and detailer for the Toledo Bridge and Crane Company.

The following year Isaac Hausman started his own business, The Hausman Steel Company in Toledo, engaging in structural engineering and supplying fireproof building materials. Thousands of schoolhouses, offices, hotels, and apartment houses were subsequently handled by his firm; the emphasis was gradually placed on fireproof construction and, especially, on reinforced concrete structures. He acquired the patent rights of the Ambursen Form System from the Blaw-Knox Company and subcontracted for the steel form work on reinforced concrete buildings throughout the eastern United States. The jobs were scattered from Maine to Wisconsin, and from Texas to Florida, including such work as the eighteen million dollar charity hospital in New Orleans, La. His firm specialized in rigid frame construction and other indeterminate forms of concrete work, developing some very interesting and novel designs.

---

[1] Memoir prepared by Raymond C. Reese, Assoc. M. ASCE.

Mr. Hausman was a member of the American Concrete Institute, the Alumni Association of the Massachusetts Institute of Technology, and the Toledo Rotary Club; he was a registered professional engineer in the State of Ohio. He was always very active in the affairs of the Concrete Reinforcing Steel Institute, particularly the Concrete Form Section, in standardizing sizes, improving techniques, raising ethical standards, and any other work that would fall to this section.

Besides his professional and business activities, one of his chief interests was golf, a game which he learned late in life, after the pressure of developing a business permitted some relaxation. For a number of years he was a prominent member of the Glengary Country Club in Holland, Ohio, where he was once presented with a plaque commemorating his guidance in reconstructing the club.

Although trained in the cold science of engineering, Isaac Hausman's interests were very largely in human beings. He was vitally interested in all his employees, their families, home life, successes, and difficulties, and was similarly interested in the personal lives and successes of his customers and suppliers—with anyone with whom he came in contact. His memory of intimate details in the lives of casual acquaintances was phenomenal.

On March 10, 1915, in Toledo, Mr. Hausman was married to Clara Staadecker. He is survived by his widow; three sons, Frederick I., James S., and William L. Hausman; his mother; and four brothers, Myer R., Benjamin F., Lewis W., and Nathan Hausman.

Mr. Hausman was elected an Associate Member of the American Society of Civil Engineers on May 28, 1923.

WILLIAM ELLIS ROW IRWIN, Assoc. M. ASCE[1]

Died March 25, 1946

William Ellis Row Irwin, the son of Franklin Fisher and Minnum (Row) Irwin, was born in Philipsburg, Pa., on July 15, 1896. He was graduated from Philipsburg High School and received the degree of Bachelor of Science, in 1922, from the School of Civil Engineering at the University of Michigan in Ann Arbor. Later he studied finance and economics at the Wharton School of the University of Pennsylvania in Philadelphia. Prior to his graduation he served as an Ensign in the United States Navy during World War I, seeing action in European waters and in Germany and England; and, as a member of Col. Edward M. House's staff, he attended the Peace Conference in Versailles, France.

Mr. Irwin's first assignment after graduation was with the Pennsylvania Department of Highways as inspector on concrete and asphalt road con-

[1] Memoir prepared by Leo M. Odom, M. ASCE, and Byron P. Lyons, Dept. of Public Works, State of Louisiana, Baton Rouge, La.

struction. In the early part of 1923, he entered the service of Day and Zimmerman as instrumentman in charge of a field party on construction of the Holtwood Power Plant at Holtwood, Pa.

In December, 1923, he was employed by Gibbs and Hill, who were working on the electrification of the Virginia Railway. His first position with this firm was as instrumentman at Narrows, Va., on transmission line surveys, estimates, and inspection during construction of the Narrows Power Plant. He advanced rapidly with Gibbs and Hill, his next assignment being chief of party in charge of construction of shops and other facilities at Mullens, W. Va. He then became office engineer at Roanoke, Va., and later assistant engineer.

In 1926 he severed his connection with Gibbs and Hill and returned to the employ of Day and Zimmerman as assistant engineer at West Chester, Pa., in charge of the drafting room. In this capacity he prepared data for the construction of the Conowingo transmission line. From 1928 until 1933 he was field engineer for the firm in charge of construction of the New Eastern State Penitentiary at Graterford, Pa.

In 1933 Mr. Irwin entered the service of E. I. du Pont de Nemours and Company as assistant construction superintendent. His first assignment was at Deepwater, N. J., on construction of units of the Dye Works. In 1936 this company started construction of a plant to manufacture tetraethyl lead for the Ethyl Corporation at Baton Rouge, La. Mr. Irwin was selected as superintendent of construction and, under his supervision, the plant was built and put into operation. In 1941 he was called to the main office of E. I. du Pont de Nemours and Company at Wilmington, Del., and was made district superintendent of general construction. In this capacity he supervised part of the large war construction program of the company throughout the United States. In June, 1943, he devoted his entire time to the construction of the atomic bomb project at Oak Ridge, Tenn., and, although he remained in Wilmington, he supervised all construction at Oak Ridge until this plant went into operation late in 1943. Early in 1944, he was assigned to special work at the atomic bomb project in Pasco, Wash. In May, 1944, upon completion of the war construction program, Mr. Irwin returned to Baton Rouge to become works engineer in the organic chemicals department, in charge of the operation of several departments at the ethyl plant.

In the latter part of 1945, all interests of E. I. du Pont de Nemours and Company were closed out in Baton Rouge and the operation of the plant manufacturing tetraethyl lead was taken over by the Ethyl Corporation. Mr. Irwin was appointed assistant resident manager by the Ethyl Corporation and held this position until his death. He was stricken while attending to his duties at the ethyl plant and died March 25, 1946. He was buried at Media, Pa.

He was a man respected by all who knew him and was known as "Bill Irwin" to men connected with the construction and operation of the Baton Rouge plant. He always had time to listen to any man who thought he had a complaint, regardless of what position the man held.

William Irwin was married to Virginia Kinnier on July 15, 1918, at Charleston, S. C. His widow and son, William K., survive him.

He was a member of the American Legion, the University of Michigan Club of Philadelphia, and the Phi Mu Alpha fraternity.

Mr. Irwin was elected an Associate Member of the American Society of Civil Engineers on January 14, 1929.

OSCAR WILLIAM LANZENDORF, Assoc. M. ASCE[1]

Died April 13, 1945

Oscar William Lanzendorf, the son of Ernest William and Bertha (Hanisch) Lanzendorf, was born in San Francisco, Calif., on July 5, 1888.

After receiving his preparatory education at the California School of Mechanical Arts in San Francisco, he was employed by the William Little Estate Company, contractors and builders, in San Francisco, from 1907 to 1908, as a draftsman, estimator, and bookkeeper. He then entered the University of California in Berkeley, where he completed a course in the College of Civil Engineering and was graduated with the degree of Bachelor of Science in 1913.

From 1913 until 1917 he was employed by the California Highway Commission, first as draftsman and later as resident engineer on highway planning, construction, and bridge design.

The United States Army called in 1917, and he enlisted as a private in the Corps of Engineers. He served in Forty-Third Engineers and Twentieth Engineers in France, attaining the rank of First Lieutenant.

When he returned to civilian life after World War I, he was again employed by the California Highway Commission from 1919 until 1921, engaged in general engineering in the office of Division IV in San Francisco.

In 1921 he was employed by Sutter County, California, as assistant county engineer and in 1925 became county engineer, working on the many phases of road and bridge design and construction until 1942. During World War II, he was assistant post engineer at Camp Beale, California.

On December 24, 1927, Mr. Lanzendorf was married to Julie White. He is survived by his widow.

Mr. Lanzendorf was elected an Associate Member of the American Society of Civil Engineers on January 19, 1920.

[1] Memoir prepared by a Committee of the Sacramento Section consisting of Harold F. Percival, Chairman, Joel B. Hodges and Martin H. Blote, Assoc. Members, ASCE.

LESLIE LOU LEVEQUE, Assoc. M. ASCE[1]

Died May 5, 1946

Leslie Lou LeVeque was born on November 9, 1892, in Porie, Mich. He was the son of Lou J. and Anna B. (Coltes) LeVeque. His primary and preparatory schooling were completed in Marquette, Mich., and in 1916 he was graduated from the University of Michigan at Ann Arbor, with the degree of Bachelor of Science in Civil Engineering.

Immediately following his graduation and until the beginning of World War I, Mr. LeVeque was associated with A. Bentley and Sons in Toledo, Ohio, as structural engineer. With the declaration of war in 1917, he enlisted in the United States Army and received his commission as a Second Lieutenant at Fort Sheridan, Ill. Promoted to First Lieutenant in the field, he saw action with the First Gas Regiment (Thirtieth Engineers), Company E, in the Meuse-Argonne and St.-Mihiel offensive and was decorated three times.

Upon his return from the war he was married to Elsa Will, M.D., from Rochester, N. Y., on May 1, 1920.

Prior to the organization of his own construction company, Mr. LeVeque was associated with H. J. Speaker, General Contractors, in Toledo as engineer and superintendent of construction; he left that company to do some research at Ohio State University in Columbus where he taught mathematics in the Engineering Department.

In early spring of 1921 he left the university and opened a Columbus Office for the Watts-Survier Company, General Contractors, in Toledo. He had full charge of all operations in this area and under his management this office soon had more contracts than did the main office.

In the fall of 1921 he resigned from Watts-Survier Company and organized The L. L. LeVeque Company in Columbus; and, as president of the company, he directed the construction of schools, hospitals, dormitories, industrial plants, federal buildings, apartment buildings, theaters, and warehouses throughout the United States and Canada. These structures varied from $300,000 warehouses to $7,500,000 apartment dwellings. Among the principals with whom Mr. LeVeque contracted were the Great Atlantic and Pacific Tea Company, the Ohio Bell Telephone Company, Ohio State University, the Ralston Steel Car Company, as well as city, state, and federal governments.

As early as 1935 Mr. LeVeque envisioned the plans of a model village that would not merely "house" families, but that would also afford the comforts and social enjoyments generally attained by only the most successful businessmen. In Columbus, on the scenic banks of the Olentangy River, on a sixty-six acre tract, lies the fullfilment of that vision. Olentangy Village is a

[1] Memoir prepared by Myron T. Jones and Howard E. Bonham, Members, ASCE, and Sanders A. Frye, Business Mgr., Otterbein College, Westerville, Ohio.

beautifully landscaped plan of apartment dwellings, capturing the spirit of old Williamsburg (Va.). Here, a living memorial is perpetuated in the community spirit of the 1,150 Olentagny residents, whose public pride is engendered by their own Olentangy club rooms, victory gardens, swimming pool, tennis and badminton courts, horseshoe courts, ball diamonds, picnic grounds, playgrounds, and fishing and boating facilities.

In 1940 a family recreation center was designed and constructed in Olentangy Village. The Olentangy Village Bowling Center was a pioneering venture. Skeet, rifle, and archery ranges, as well as golf driving mats and table tennis were included with the thirty-two bowling lanes. The pleasant atmosphere, in addition to the strict policy forbidding the selling of any alcoholic beverage, has made Olentangy a community for the young people in Columbus.

In 1942 Mr. LeVeque directed his energies from the field of construction to the field of manufacturing. With record-breaking speed and precision, the Wolab Corporation made delivery of vital tools, jigs, and fixtures for military aricraft. No undertaking seemed too great—no obstacle was too big. As an industrial engineer, Mr. LeVeque exemplified the spirit of the "Army-Navy E" to which award he led his employees.

Born from his intolerance of waste, a fully mechanical, antomatic, pin setting machine for tenpins in bowling was developed by Mr. LeVeque at the close of the war. Steps for the reconversion of the Wolab factories were already being taken when the tragedy of his plane crash took the lives of Mr. and Mrs. LeVeque.

Mr. LeVeque organized and was president of many realty companies, residential hotels (including the Parc Vendome in New York, N. Y.), apartment buildings, manufacturing companies, and office buildings (including the LeVeque-Lincoln Tower in Columbus).

His professional contributions and achievements in the fields of civil and industrial engineering and finance reflect the intenseness with which Mr. LeVeque lived every hour of his career. Mr. LeVeque was modest in self-appraisment, daring in his conceptions, and courageous in the execution of his plans which made his life one that was full of action. He was a man of his time, reflecting the tempo of the era in which he lived. He was not one to seek the limelight—he preferred to have appraisal of his fellow citizens based on his accomplishments. His efficiency, pioneering foresight and vision, and the tenacity with which he saw every undertaking completed enabled him to translate his ideas into practical action and made him one of the outstanding figures of his time.

All those who knew him will remember him not as much in the light of his personal accomplishments but more as the man he was. This fact stands out above all others regardless of the association, whether it was one of business or one of personal friendship. His generosity and thoughtfulness, his genuine smile, his good humor, his love of life and work, his honesty, his efficiency, his modesty, and sense of fair play live in the memories of those who knew him.

Financier, engineer, sportsman, and patron of the arts, Mr. LeVeque lived a full life. His untimely death has deprived his community of an esteemed citizen and a great leader, but his spirit and the good of his accomplishments will remain as a perpetual memorial to him and his ideals. He is survived by a son, Frederick Will, and two daughters, Betty Marx and Patricia Lou.

Mr. LeVeque was elected an Associate Member of the American Society of Civil Engineers on August 28, 1922.

JAMES EVERETT MACKIE, Assoc. M. ASCE[1]

DIED FEBRUARY 21, 1946

James Everett Mackie, the son of William G. and Caroline (Overman) Mackie, was born on March 18, 1898, at Duluth, Minn. He received his early education in Green Bay, Wis., and was employed in that city at the beginning of World War I.

During that war he served as private, corporal, and sergeant in Battery E, 121st Headquarters Field Artillery, 57th Brigade, 32d Division, American Expeditionary Forces. Shortly after receiving his discharge, he entered the University of Wisconsin at Madison, from which he was graduated in 1923 with the degree of Bachelor of Science in Civil Engineering. In 1929 he was awarded the degree of Civil Engineer by the University of Wisconsin.

During summers and holidays of his college years Mr. Mackie obtained practical experience with construction firms, and in various capacities with the Wisconsin State Highway Commission. He subsequently moved west to Long Beach, Calif., where he was employed in the city building inspection department from 1924 until 1927, having been appointed chief building inspector in December, 1925.

During this period he became interested in the pioneering efforts, started in 1922, by a group of western building officials to formulate a "Uniform Building Code." Progress on this project had reached the third preliminary draft stage in 1926 when Mr. Mackie was elected secretary of the Pacific Coast Building Officials Conference. For several years afterward he was largely responsible for the preparation and editing of the various printed editions of the "Uniform Building Code" of the conference.

Perhaps the outstanding accomplishment of his career was the guidance of the early editions of this code through the troubled waters of politics, engineering principles, taxpayers' pulling and materials producers' hauling, and the practical possibilities of enforcement. Truly it was a task well done.

From July, 1927, to April, 1929, Mr. Mackie was employed as full-time secretary of the conference. In April, 1929, he left that position to become structural engineer for the National Lumber Manufacturers' Association.

---

[1] Memoir prepared by Arthur C. Horner, Assoc. M. ASCE.

During the many months he spent lecturing on wood as a structural material at colleges and technical schools throughout the United States, and consulting with engineers, architects, and wood users—generally on a wide range of problems pertaining to the use of wood—he had the opportunity not only to put to use his considerable engineering ability but also to make a host of friends throughout the profession. At his death, on February 21, 1946, Mr. Mackie was western manager of the National Lumber Manufacturers Association, with offices in San Francisco, Calif.

His interest in public welfare, as attested by the many hours of gratuitous work spent on building codes with city councils and civic organizations, as well as on technical and lay committees, was fittingly recognized by his election as an honorary member of the Pacific Coast Building Officials Conference.

On October 25, 1923, Mr. Mackie was married to Gene Langson Plumb. He is survived by his widow and one daughter, Travis.

Mr. Mackie was elected a Junior of the American Society of Civil Engineers on November 26, 1923, and an Associate Member on June 9, 1930.

LEROY MONROE MILNER, SR., Assoc. M. ASCE[1]

DIED MAY 7, 1946

LeRoy Monroe Milner, Sr., was born in Birmingham, Ala., on March 8, 1890. He was the son of John A. and Sally Milner, early settlers of that city.

From September, 1909, to February, 1913, Mr. Milner was a mining engineer with the Tennessee Coal, Iron, and Railroad Company in Birmingham. For the next four years, until 1917, he was associated with the Milner and Browne Engineering Company of Birmingham, engaged in a general engineering practice.

In 1917 he returned to the Tennessee Coal, Iron, and Railroad Company, remaining in its engineering department until 1922. The following year he became a partner in the Milner Engineering Company of Sheffield (Ala.), Florence (Ala.), and Tuscumbia (Ala.). This organization played an important part in the development of the Muscle Shoals district at Wilson Dam in Alabama.

From September, 1928, until his death, Mr. Milner was an inspector in the Memphis District of the United States Engineer Department. His various activities included construction of levees and inspection of revetments, maintenance and improvement work on the tributaries of the Mississippi River, and emergency flood protection measures on the tributary rivers.

In 1912 he was married to Myrtle Lucy Rutherford of Birmingham. He is survived by his widow in Memphis, Tenn., and two sons, both engineers, LeRoy Milner, Jr., of Sheffield, and Robert Milner of Memphis.

---

[1] Memoir prepared by Robert Milner, Mech. Engr., Buckeye Cotton Oil Co., Memphis, Tenn.

Mr. Milner belonged to the St. Johns Methodist Church of Memphis, the Memphis Engineers Club, and the Rotary Club of Newport, Ark.; and he was a member of the Society of American Military Engineers.

He was highly respected by his many friends throughout the midsouth for his strong character, professional loyalty, honesty, and perseverance.

Mr. Milner was elected an Associate Member of the American Society of Civil Engineers on May 13, 1940.

RALPH NOBLE PRIEST, Assoc. M. ASCE[1]

DIED MAY 14, 1946

Ralph Noble Priest was born in Roxborough, Pa., on August 9, 1882. His parents were Andrew Priest and Sarah Noble, descendants of the pioneer German stock that has been so prominently identified with the growth of eastern Pennsylvania.

After attending Philadelphia (Pa.) High School at night, for about three years, he entered the drafting room of the Pencoyd Iron Works, at the age of eighteen, where he worked for a short time. From 1900 to 1908, he was with Amos W. Barnes, an engineer in Philadelphia.

Studying diligently under the direction and encouragement of Mr. Barnes, he showed early natural ability and capacity for hard work. He attended classses at Drexel Institute of Technology, in Philadelphia, and then completed a course of study with the International Correspondence Schools, receiving their certificate in civil engineering. During this period Mr. Priest designed structural work for an incinerating plant in Atlantic City, N. J.; for the Lardners Point Pumping Station in Philadelphia; and for an addition to the Coplay Cement Company plant, in Coplay, Pa. In addition, he was in charge of a survey for an electric freight line in Delaware—about one hundred miles long.

Mr. Priest was in charge of the structural steel design and erection of the original Forrest Theater in Philadelphia. From 1908 to 1910, he was with George F. Pawling, M. ASCE, engineer and contractor, as designer and estimator. In 1911 he was again with Amos W. Barnes as general assistant engineer, looking after details of a lift bridge across the Chicago River.

Associations with M. Ward Easby and W. E. Wark and Company, as vice-president, followed, covering the years to 1916. This period included work on the design of the Mulberry Street viaduct in Scranton, Pa., and on heavy shoring for deep foundations for large city buildings.

From 1916 to 1941, Mr. Priest maintained his own office at 1627 Sansom Street, Philadelphia, as consulting engineer. He was retained by Morris-Wheeler and Company, Incorporated, as an independent engineer and struc-

[1] Memoir prepared by W. E. Belcher, M. ASCE.

tural steel detailer for more than ten years. This work covered theaters, apartment buildings, office buildings, and other structures. Work completed from his own office included the design of the MacAndrews and Forbes plant in Camden, N. J., and the Electric Storage Battery Company buildings and Royal Apartments, both in Philadelphia.

His experience acquainted him with considerable wood truss and framing design work. This experience brought invitations for consultation with R. B. Okie and other prominent architects, and led to a special study of early American barn framing; church roof trusses of the early Pennsylvania type, and Pennsylvania Dutch architecture.

Some outstanding examples of Mr. Priest's work are: Roof trusses and timber framing of the Pennsbury Manor House on the Delaware River near Bristol, Pa. (R. B. Okie, architect); slow-burning wood framing for the Lang Paper Mills (Alfred Mackay, supervising engineer); trusses and framing for the barn of A. E. Pew in Elberson, Pa., and for the residence of John M. Cross in Bethlehem, Pa. (R. B. Okie, architect); truss and beam construction for McDowell Paper Mill in Manayunk, Pa., for the Bell residence in Devon, Pa., and for the Presbyterian Church at Mechanicsburg, Pa.

From 1941 to the spring of 1945, he was employed in the drafting room of the United Engineers and Constructors, Incorporated, as structural designer and checker on various industrial and public utility projects. Because of ill health, Mr. Priest was obliged to cease active engineering work, about one year before his death.

He had a quiet unassuming disposition, was always ready to assist someone else, and was a good citizen in the community in which he lived. Having had no college training, he was well educated, however, and had unusual engineering ability. His experience was quite extensive, and he was ready for any problem.

Mr. Priest was a registered professional engineer of the State of Pennsylvania and a member of the Roxborough Lodge of the F. and A. M. For sixteen years he was an active member of the Mendelssohn Club, starting under Dr. Gilchrist. He had a fine bass voice and enjoyed choral work. As an ardent student of nature, he was well versed in bird lore, and was a member of the Delaware Ornithological Society. He also took great pride in his home, garden, and flowers.

On October 25, 1917, he was married to Irene Thompson at Roxborough, where they made their home for many years, until recently, when they moved to Gwynedd Valley, Pa. He is survived by his widow and their son, Ralph N. Priest, Jr.

Mr. Priest was elected an Associate Member of the American Society of Civil Engineers on March 12, 1923.

ROBERT CHARLES RATCLIFFE, Assoc. M. ASCE[1]

DIED AUGUST 16, 1945

Robert Charles Ratcliffe, the son of George McAfee Ratcliffe and Susie (Hetherwick) Ratcliffe, was born on April 12, 1903, in Natchitoches, La. He was the sixth in a family of seven children and was left an orphan at five years of age. His mother died when he was four years old and his father before he was six. In 1912, the family moved to Colorado under the guardianship of the oldest sister.

He was graduated from North Denver High School in 1920, and entered the University of Colorado at Boulder, in 1922. During this interval he worked for the local telephone company. He was graduated from the University of Colorado in 1927 with the degree of Bachelor of Science in Civil Engineering. During the summer vacations he had worked for the United States Bureau of Public Roads as rodman, chainman, and levelman on highway location and construction in Colorado.

After graduating from the university, he worked as draftsman and instrumentman on a real estate subdivision for the Redfeather Lakes Development Company. This was followed by eight years of work on highway inspection and construction. In March, 1928, he joined the Iowa State Highway Commission at Ames, as proportioning plant and concrete slab inspector, and later became bridge inspector and chief of party on highway construction and location; in 1931, he became bridge inspector for the Wyoming State Highway Department, a position that he held for two years; and finally he worked as bridge inspector for the Colorado State Highway Department for three years, becoming eligible for appointment as resident engineer.

Robert Ratcliffe was appointed chief of the Department of Public Works of the City of Grand Junction, Colo., in July, 1936. He was in charge of the water sewer and highway divisions, and was actively engaged in the design, construction, maintenance, and development of these public utilities. In 1940, he became resident engineer for the construction of the sewage disposal plant in Grand Junction.

At the approach of World War II, he turned his energy and skill to army camp construction, with particular reference to the sanitary problems involved —water supply and sewage disposal. Working for several contracting firms in Colorado he was assigned to the United States Army housing project at Fort Logan, the Denver ordinance plant, and the Camp Carson project. At the outbreak of the war, Robert Ratcliffe joined the staff of United States Army Engineers at Albuquerque, N. Mex., as engineer on specifications, and was soon rated associate civil and sanitary engineer. He either designed or passed on all designs for sanitary works in the area under the jurisdiction of the Albuquerque office, an area which comprised New Mexico, Arizona, southern Colorado, western Texas, and Oklahoma.

---

[1] Memoir prepared by Roland B. Queneau, M. ASCE.

Early in 1943, he applied for a commission in the miltary government teams that the U. S. Army was organizing for use in conquered territory; the application was favorably considered, but he was turned down after failing to pass the physical examinations because of perforated eardrums. In January, 1945, he joined the United States Bureau of Reclamation as engineer in the Cheyenne (Wyo.) district, where he worked until his death on August 16, 1945.

Robert Ratcliffe was married to Charlotte West, a childhood friend, on November 29, 1933, in Denver. He is survived by his widow and a son, Peter Gordon Ratcliffe.

From early childhood, Robert Ratcliffe's character was earnest and serious. The tragedy in his childhood and, later, his partial deafness, caused by a delicate ear operation during his student days, merely increased his determination to acquire a thorough education and become a fully self-reliant and capable engineer. His personal integrity was always beyond question, he strove constantly for perfection in himself and expected others to do likewise; he had little patience with shoddy or dishonest work. His personality was open and generous, and he was devoted to his family and friends.

As an engineer, Robert Ratcliffe's contribution to the modern age consisted in work carefully planned with thorough technical skill and ample vision, and carried out under scrupulous supervision.

Mr. Ratcliffe was elected a Junior of the American Society of Civil Engineers on November 14, 1927, and an Associate Member on November 9, 1936.

CHARLES MORRISON SCUDDER, Assoc. M. ASCE[1]

Died July 12, 1946

Charles Morrison Scudder was born in Marinette, Wis., on February 27, 1890, the son of Henry Townsend and Janet (Morrison) Scudder. He attended the public school at Marinette and was graduated, as valedictorian of his class, from the Marinette High School, in 1907. He received the degree of Bachelor of Science in Civil Engineering from the University of Wisconsin at Madison, in 1911, and the degree of Civil Engineer in 1912, after a year's postgraduate work in hydraulics.

For two years he was with the Knoxville Power Company in Alcoa, Tenn., in various capacities, and then served for three years as an instructor in surveying and mechanics at the University of Wisconsin. During World War I he served as Captain of Company C, First Battalion, Wisconsin Engineers, of the National Guard, and Company F, 107th Engineers, in the Thirty-Second (Red Arrow) Division.

Following the war he worked with the Allis-Chalmers Company at the West Allis (Wis.) plant on hydraulic power plant and other design work for several

[1] Memoir prepared by Lewis M. Hammond, M. ASCE.

years. In 1928 he was with the First Wisconsin National Bank of Milwaukee (which was later a part of "Wisconsin Bankshares") and for ten years was employed by them in various capacities, where his engineering education and experience were of value. Much of this time he was in charge of the Gilson-Bolens plant at Port Washington, Wis., a plant in which the bank was interested.

Mr. Scudder enjoyed this work very much, as it gave him an opportunity to apply his engineering training to practical business problems. In 1938 he went back to engineering, and for the last eight years was assistant engineer in charge of drafting and pressure vessels at the A. O. Smith Corporation in Milwaukee.

He had two hobbies, boats and music. The Wisconsin lakes, in summer, were a never-ending invitation and opportunity for him to enjoy his boats. They were mostly motorboats although he was also interested in sailing. His music he enjoyed everywhere. During his service in World War I, he organized, outfitted, and led the 107th Engineers' Band. He played almost every instrument well, and he and his piano accordion were the life of countless parties. He was always ready to give of his talents to entertain or amuse his friends. Mr. Scudder enjoyed singing, too. He took a keen interest in the National Association for the Preservation and Encouragement of Barber Shop Quartets and he helped organize and sang in one of the Milwaukee quartets.

He took an active interest in the affairs of the Local Section of the Society, the Wauwatosa (Wis.) Co-operative Club, and the American Legion. In the American Legion he was first affiliated with the Alonzo Cudworth Post in Milwaukee, later transferring to the Bernard Diedrich Post in Wauwatosa. At the time of his death he was writing a history of the 107th Engineers.

In 1916 Mr. Scudder was married to Eleanor Lee, of Oconto, Wis. He is survived by his widow; a daughter, Janet; a son, Charles; and a sister, Marjorie Scudder.

Because of his connections over a period of twenty-seven years with two of Milwaukee's largest industrial concerns, and its leading bank, Mr. Scudder had an unusually large circle of friends.

Mr. Scudder was elected a Junior of the American Society of Civil Engineers on May 28, 1912, and an Associate Member on October 2, 1922.

FELIX CHARLES STEHLE, Assoc. M. ASCE[1]

Died August 14, 1946

Felix Charles Stehle was born on May 10, 1872, in New York, N. Y. His parents were Francis S. and Phillipina (Hausel) Stehle.

He received his early education in New York City schools, and was graduated from De La Salle Institute in 1888, after completing the academic course.

[1] Memoir prepared by Glenn B. Woodruff, M. ASCE.

In 1892 he received the degree of Civil Engineer from Manhattan College, also in New York City.

His engineering career began with the position of structural draftsman with the Cornell Iron Works in Brooklyn, N. Y., and later with the Union Bridge Company at Athens, Pa. Upon the consolidation of the latter company with the American Bridge Company, he was transferred to Pencoyd, Pa., and later was made assistant plant engineer at Brooklyn.

In 1913 Mr. Stehle accepted the position of bridge inspector of the Lehigh Valley Railroad Company, with headquarters in Bethlehem, Pa., making his home in Towanda, Pa. At this time the railroad started a program of rebuilding most of its main line bridges. He continued in this work for the remainder of his active professional life.

In addition to his duties in charge of all bridge inspection, Mr. Stehle directed all field work on this reconstruction. The work proceeded with a remarkable freedom from accidents. No fatal or permanent disability cases occurred on any of this work, which was conducted without interruption of traffic. Mr. Stehle was retired from active service in 1941.

During his career he was most concerned with aiding the younger men with whom he came in contact. His knowledge of steel details, acquired in the drawing room and in the inspection of structures in service, made his advice invaluable.

In 1904 he was married in Towanda, to Mary Espy, who, with one daughter Katrina (Mrs. Edson Barnes), survives him. Another daughter, Adelaide (Mrs. Joseph Stevens) of New York City died on November 23, 1942. He was a member of the Roman Catholic Church and of the Knights of Columbus.

Mr. Stehle was elected an Associate Member of the American Society of Civil Engineers on June 3, 1903.

FRED WALTER STIEFEL, Assoc. M. ASCE[1]

Died July 25, 1946

Fred Walter Stiefel was born in New York, N. Y., on September 12, 1892. He began his engineering work in July, 1910, and thereupon was engaged on city surveys, building construction, highway projects, and sewer work in New York City.

Although he started work at an early age, without the opportunity of attending engineering school, Mr. Stiefel studied during the evenings. He attended engineers' meetings and was able to learn through his own experience many engineering principles relating to the important projects with which he was connected. In his work as an engineer he showed confidence and originality.

[1] Memoir prepared by James F. Sanborn, M. ASCE.

In October, 1911, he went to work as junior engineer for the Public Service Commission in the Office of Transit Construction (later the Transit Commission) in New York City. He supervised subway construction work, which was actively under way at that time. During this experience, he became acquainted with the late Robert Ridgway,[2] Past-President, ASCE, at that time chief engineer of the subway program. Mr. Stiefel greatly admired Mr. Ridgway, who also had succeeded in his engineering work without a formal education.

Mr. Stiefel left the employ of the Transit Commission in 1918 and worked for the Mason and Hanger Company for about four years, as engineer and assistant manager of construction on two contracts of the New York subway. For the same company he was later engaged on the construction of a two and one-half mile rock tunnel for a hydroelectric project in Vermont.

After 1925, Mr. Stiefel was employed by the Rosoff Subway Construction Company under the late Harry Sanford, M. ASCE, on the construction of a section of the Eighth Avenue Subway at St. Nicholas Avenue. On the death of Mr. Sanford in 1928, Mr. Stiefel was appointed chief engineer of the contracting company, a position he held until he resigned in 1942.

During this period he was also chief engineer of the Rosoff Tunnel Corporation and associated contracting companies, in charge of all engineering and construction contracts. The work performed by these companies included subways and sewer tunnels in New York City, a section of the Delaware Aqueduct tunnel (seventy-five thousand feet long), the "Third Lock" project for the Panama Canal, and other construction jobs.

Mr. Stiefel was always ready to try new devices on the work with which he was connected, and he designed many ingenious methods to reduce cost and promote safety. Some of his progressive ideas included the use of the following: Diesel locomotives in mining and tunnel construction; Diesel driven shovels under decking for subway work; welded steel pipe for by-passing gas mains; special equipment for reclaiming trolley tracks rapidly and cheaply; subway decking on underpinning piers for the support of elevated columns; the cofferdam method for supporting buildings along a subway excavation; and many others.

In 1944 Mr. Stiefel was awarded the Construction Engineering Prize of the Society for his paper, "Inclined Mine Shaft Sunk in the Adirondacks."[3] He also contributed papers to the American Institute of Mining and Metallurgical Engineers of which he was a member.

At his death in July, 1946, he was president of the Stiefel Construction Corporation in New York City.

Mr. Stiefel was elected an Associate Member of the American Society of Civil Engineers on August 4, 1924.

---

DONALD RAYMOND BROWN, Jun. ASCE[1]

DIED JANUARY 17, 1946

Donald Raymond Brown was born in Watsonville, Calif., on July 17, 1915. He was the son of G. Raymond Brown and Myrtle Esther (Wolfe) Brown.

He attended school at Healdsburg, Calif., and the Santa Rosa District Junior College, at Santa Rosa, Calif. During that time he was employed, through vacation periods, by Marshall M. Wallace, the county surveyor. Mr. Brown continued his education at the Oregon State College, at Corvallis, and immediately upon receiving the degree of Bachelor of Science in Civil Engineering in June, 1939, he was employed by the County of Sonoma (California) on highway and bridge design. In September, 1939, his ability and interest in his profession won him an appointment to the position of deputy county surveyor.

While serving as deputy county surveyor, Mr. Brown designed and superintended construction of several bridges, including the Franquelin Bridge over Sonoma Creek, west of Sonoma, Calif.—a reinforced concrete structure consisting of two twenty-foot approach spans, two thirty-five-foot approach spans, and one seventy-foot main span.

In May, 1942, Mr. Brown enlisted in the United States Naval Reserve and entered the United States Naval Academy at Annapolis, Md., for officers' training, receiving his commission as Ensign on September 8, 1942. Upon volunteering for submarine duty, Ensign Brown was sent to Key West, Fla., and New London, Conn. Completing this training on June 26, 1943, Ensign Brown was assigned to duty on the submarine *Wahoo* in the Pacific Area. While on patrol duty in the Sea of Japan, the *Wahoo,* after completing her mission, attacked an enemy convoy with surface guns, was torpedoed amidship, and sank at once with loss of the entire crew.

Lieutenant Brown received his promotion on October 1, 1943, was reported missing on November 30, 1943, and continued in that status until declared as officially deceased by the Navy Department, as of January 7, 1946. He was awarded the Silver Star Medal, with citation; the Submarine Combat Insignia, with gold stars; and the Purple Heart Medal, with certificate. He is survived by his parents, who received his decorations.

He was an active member of the Order of DeMolay, having received the Order of Chevalier; the Masonic Order, Sotoyome Lodge No. 123, of Healdsburg; and the 20–30 Club of Healdsburg. He actively participated in such sports as golfing, skiing, hunting, fishing, and swimming, and was a qualified Red Cross campaign instructor and lifesaver.

Lieutenant Brown was elected a Junior of the American Society of Civil Engineers on October 16, 1939.

[1] Memoir prepared by Marshall M. Wallace, County Surveyor & Road Commissioner, Santa Rosa, Calif.

JAMES CRISP AKERS SALTER, Jun. ASCE[1]

DIED AUGUST 2, 1945

James Crisp Akers Salter, the son of Martha (Akers) Salter and James C. Salter, was born on November 15, 1919, in Montgomery, Ala. He was graduated from the Boys High School in Atlanta, Ga., in 1938; and for one year he attended Wheaton College, in Wheaton, Ill., later transferring to Clemson College in Clemson, S. C. In May, 1942, he received the degree of Bachelor of Science in Civil Engineering from Clemson and, at the same time, was commissioned a Second Lieutenant, Corps of Engineers, Army of the United States.

Lieutenant Salter immediately transferred to the Army Air Forces and thereupon was ordered to Maxwell Field at Montgomery on August 6, 1942, for pre-flight training. After subsequent pilot training at Dorr Field in Florida and at Cochran Field and Turner Field in Georgia, he was assigned to the 87th Bomb Squadron, 46th Bomb Group, at Will Rogers Field, Oklahoma, as pilot of an A–20 bomber.

Because of the acute need for capable pilots in the Pacific theater of operations, he was transferred to the 499th Bomb Squadron, 345th Bomb Group, and arrived at Port Moresby, Australia, on August 8, 1943. There he served as a B–25 pilot, attached to the 5th Air Force under Lt.-Gen. George C. Kenney. During Lieutenant Salter's assignment to this command he participated in the entire New Guinea campaign and the campaign of the Bismarck Archipelago, bombing Rabaul, New Britain, and the Admirality Islands. His squadron was then moved up to Hollandia, from which base he bombed Sorong, Halmahera, the Moluccas, and Nenado. By this time he had been promoted to Captain. He also participated in the invasion of the Philippines, before being returned to the United States because of combat fatigue.

During his assignment to the 499th Squadron from August, 1943, to February, 1945, Captain Salter flew about a thousand hours on fifty-eight combat missions; he, personally, was cited for bravery by General Kenney; he was awarded the Air Medal three times; and he became squadron leader of this "Bats Out O'Hell" Squadron. Captain Salter's combat flying, as shown on his officer's qualification card, was graded "excellent" or "superior" in every instance. In addition to the Air Medal with two clusters, he wore the Asiatic-Pacific ribbon with three bronze stars, representing the New Guinea, Bismarck Archipelago, and Philippine liberation campaigns.

Upon his return to the United States, Captain Salter was stationed at Williams Field, Arizona, where he served as a radar precision bomber pilot. His death, at the age of twenty five, occurred in an automobile accident while he was at that station. He was buried in Atlanta on August 7, 1945, with full military honors.

[1] Memoir prepared by Harry B. Johnston, Jr., D.D.S., Atlanta, Ga.

Captain Salter's death, so early in life, prevented active participation in his profession, yet during his brief lifetime he displayed such skill and devotion to assigned duty as is seldom seen. Throughout his entire life, he exhibited all the rare traits of the fine Christian gentleman that he was.

He is survived by his mother and his grandmother, Mrs. F. M. Akers.

Captain Salter was elected a Junior of the American Society of Civil Engineers on September 9, 1942.

Education, 789.

DOYLE, JOHN STEPHEN
Memoir of, 1438.

DUGGAN, GEORGE HERRICK
Memoir of, 1406.

DUNCAN, FRANK KEYS
Memoir of, 1439.

DUNHAM, JOHN W.
"Design Live Loads in Buildings," 725.

DYKSTRA, C. A.
Education, 814.

EASLEY, ROBERT PURL
Memoir of, 1440.

EBELING, DICK W.
Plywood I-beams, 965.
ELLIS, GWYNNE WALLACE
Memoir of, 1565.
EMIGH, WILLIAM CHESTER
Memoir of, 1441.
EREMIN, A. A.
Method of segments, 275.
FAHLQUIST, FRANK E.
Relief wells, 1362.
FAUNTLEROY, JAMES DEARING
Memoir of, 1442.
FELD, JACOB
Express highway planning, 670.
Landslide correction, 411.
FERGUSON, DAVID
Memoir of, 1567.
FERGUSON, PHIL M.
Spandrel girders, 372.
FIESENHEISER, E. I.
Spandrel girders, 363.
FITZ HUGH, M. M.
"Shipways with Cellular Walls on a Marl Foundation," 298.
FLORIS, A.
Matrix analysis, 1164.
FORBES, HYDE
"Landslide Investigation and Correction," 377.
FORREST, CHARLES NEEDHAM
Memoir of, 1568.
FOSS, JOHN HARRISON
Memoir of, 1570.
FRANKLAND, F. H.
Safety factors, 160.
FREEMAN, N. N.
Building loads, 741.
FREUDENTHAL, ALFRED M.
"The Safety of Structures," 125.
FUELLHART, DONALD EGBERT
Memoir of, 1446.

GANT, EDWARD V.
Spandrel girders, 368.

GAYLORD, EDWIN H.
Lateral buckling, 1297.
Yield points, 1218.

GEORGE, ABRAM NUTE
Memoir of, 1573.

GILBOY, GLENNON
Relief wells, 1344.

GILLETTE, EDWARD, JR.
Memoir of, 1447.

GODFREY, STUART CHAPIN
Memoir of, 1449.

GOLDBERG, JOHN E.
Spandrel girders, 360.

GOLZÉ, ALFRED R.
Education, 821.

GOODWIN, GEORGE ESTYN
Memoir of, 1453.

GOUDEY, R. F.
Location of industries, 589.

GOWEN, SUMNER
Memoir of, 1574.

GRAY, NOMER
Safety factors, 167.
"Technical Survey—Brooklyn Bridge after Sixty Years (Symposium): Physical Examination and Field Observations," 220.

GREER, JOHN
Memoir of, 1576.

GRINTER, L. E.
Education, 779.

GRONQUIST, C. H.
Brooklyn Bridge, 250.

GUNDER, DWIGHT, F.
Thin flanges, 558.

GURLEY, NORMAN BASSETT
Memoir of, 1455.

HADLEY, HOMER M.
Express highway planning, 657.

HALL, DAVID B.
Lateral buckling, 1276.
HANSEN, HOWARD J.
"Design of Plywood I-Beams," 955.
HARBY, ISAAC
Memoir of, 1456.
HARMAN, GEORGE S.
Landslide correction, 413.
HARRIS, STEPHEN
Memoir of, 1458.
HARROLD, JOHN C.
"Cavitation in Hydraulic Structures (Symposium): Experiences of the Corps of Engineers," 16.
HASTINGS, E. M.
"The Engineer in Building for Peace," Annual Presidential Address, 1403.
HAUER, ROBERT V.
Spandrel girders, 362.
HAUPT, EDWARD
Memoir of, 1461.
HAUSMAN, ISAAC
Memoir of, 1577.
HEMPLE, HENRY W.
Urban triangulation, 338.
HENNEBIQUE, JULES JOSEPH
Memoir of, 1463.
HERROLD, GEORGE H.
Express highway planning, 688.
HESLOP, DERWENT GORDON
Memoir of, 1464.
HICKOX, GEORGE H.
"Cavitation in Hydraulic Structures (Symposium): Experiences in the Tennessee Valley Authority," 59.
HIGGINS, THEODORE R.
Lateral buckling, 1279.
HIGLEY, FRANK R.
Thermal action, 1094.
HILL, H. N.
Lateral buckling, 1287.
HILL, PHILIP BROCKETT
Memoir of, 1466.

HIRSCHTHAL, M.
Express highway planning, 694.
Safety factors, 169.

HODGES, THOMAS VICTOR
Memoir of, 1468.

HOFFMAN, OSCAR
Spandrel girders, 369.

HOFFMANN, ROBERT
Memoir of, 1408.

HOGUE, C. J.
Plywood I-beams, 967.

HOLDREDGE, NEIL CUMMINGS
Memoir of, 1470.

HOLLAND, PAUL
Memoir of, 1472.

HOLMES, HAROLD RISTINE
Memoir of, 1473.

HOLMES, W. H.
Uplift pressure, 506.

HOLT, ARTHUR GRANT
Memoir of, 1475.

HOPKINS, CHARLES D.
"Balanced Design in Urban Triangulation," 325.

HOWSON, LOUIS R.
"Future Costs and Their Effects on Engineering Budgets" (presented before the Sanitary Engineering Division of the ASCE on January 17, 1946), 701.

HOYT, JOHN CLAYTON
Memoir of, 1476.

HUNT, HENRY J.
"Correction of Tailwater Erosion at Prairie du Sac Dam," 1173.

HUSSEY, H. D.
Lateral buckling, 1290.

HUTCHINSON, FRANK DAVID
Memoir of, 1478.

HUTCHINSON, RALPH W.
Method of segments, 269.

IRWIN, WILLIAM ELLIS ROW
Memoir of, 1578.

JACOB, C. E.
"Drawdown Test to Determine Effective Radius of Artesian Well," 1047.

JERVIS, WILLIAM H.
"Relief Wells for Dams and Levees," 1321.

JOHNSON, CARTER V.
Relief wells, 1361.

JOHNSON, HORACE A.
Matrix analysis, 1152.
Relief wells, 1350.

JOHNSON, J. W.
Debris barrier, 1019.

JOHNSON, S. J.
Relief wells, 1389.

JOHNSTON, BRUCE G.
Thin flanges, 567.

JONES, JONATHAN
Time loss on grades, 1043.

JULIAN, OLIVER G.
Lateral buckling, 1303.

KAROL, JACOB
Thin flanges, 556.

KAZMANN, RAPHAEL G.
Ground water, 996.

KEAYS, R. H.
Tailwater erosion, 1192.

KENDALL, THEODORE REED
Memoir of, 1480.

KENNEDY, ROBERT E.
Ice pressure, 892.

KERCHER, HENRY
Memoir of, 1481.

KINDSVATER, CARL E.
Cavitation, 97.

KNIGHT, MERRILL D., JR.
Express highway planning, 665.

KULP, BURR ROBERT
Memoir of, 1483.

LAMBE, T. W.
Landslide correction, 407.

LANDERS, CHARLES SCOTT
Memoir of, 1484.

LANE, KENNETH S.
Relief wells, 1392.

LANZENDORF, OSCAR WILLIAM
Memoir of, 1580.

LAURENT, LOUIS EMILE
Memoir of, 1486.

LAUSHEY, LOUIS M.
Tailwater erosion, 1187.

LAVIS, FRED
Express highway planning, 657.

LEE, WILLIAM IRA
Memoir of, 1487.

LEFFLER, RALPH R.
Express highway planning, 693.

LEGATSKI, L. M.
Thin flanges, 561.

LEGGET, ROBERT F.
Landslide correction, 414.

LEGGETTE, R. M.
Artesian wells, 1067.

LELIAVSKY, SERGE
"Uplift Pressure in and Beneath Dams (Symposium): Experiments on Effective Uplift Area in Gravity Dams," 444.

LeVEQUE, LESLIE LOU
Memoir of, 1581.

LEWIS, HAROLD M.
Express highway planning, 673.
Location of industries, 587.

LEWIS, M. R.
Artesian wells, 1068.

LEWIS, ROBERT L.
Thin flanges, 558.

LIFSITZ, SOL
"Analysis of Unsymmetrical Beams by the Method of Segments," 254.

LILLY, SCOTT B.
Education, 806.

LLEWELLYN, FRED T.
Thin flanges, 555.

LOCHER, FRED
Cavitation, 95.
LOCHNER, HARRY W.
Express highway planning, 655.
LOTHERS, J. E.
"Torsion in Steel Spandrel Girders," 345.
LYNCH, HENRY B.
Education, 820.
MACKIE, JAMES EVERETT
Memoir of, 1583.
MANSUR, CHARLES I.
Relief wells, 1385.
MATTHES, GERARD H.
Mississippi River, 293.
MAUGH, L. C.
Thin flanges, 561.
McCROSKY, THEODORE T.
Express highway planning, 676.
McCULLOUGH, CONDE BALCOM
Memoir of, 1489.
McGRATH, B. R.
Ice pressure, 887.
McGUINNESS, CHARLES L.
"Recharge and Depletion of Ground-Water Supplies," 972.
McIVER, M. E.
Education, 799.
McNOWN, JOHN S.
Cavitation, 80.
Relief wells, 1368.
MELLINGER, FRANK M.
Ring stresses, 629.
MELVILLE, JAMES HENRY STEWART
Memoir of, 1491.
MENDELSOHN, ISADOR W.
Engineering budgets, 711.
MENSCH, L. J.
Yield points, 1224.
MIDDLEBROOKS, T. A.
"Relief Wells for Dams and Levees," 1321.

MILLER, A. L.
Thermal action, 1095.

MILLER, HIRAM
Memoir of, 1494.

MILLER, J. S.
"Shipways with Cellular Walls on a Marl Foundation," 298.

MILNER, LeROY MONROE, SR.
Memoir of, 1584.

MOCKMORE, C. A.
Cavitation, 73.

MOORE, R. L.
"Observations on the Behavior of Aluminum Alloy Test Girders," 901.

MORSE, WILLIAM PRENTISS
Memoir of, 1497.

NARVER, D. LEE
Building loads, 740.

NELIDOV, I. M.
Safety factors, 168.

NEWHOUSE, F.
Mississippi River, 291.

NICHOLS, CHARLES SABIN
Memoir of, 1498.

NORCROSS, T. W.
Aerial photography, 612.

NORTON, PAUL W.
Matrix analysis, 1155.

NOVICK, SIDNEY
Plywood I-beams, 967.

OESTERBLOM, I.
Education, 771.
Matrix analysis, 1141.
Moment-stiffness relations, 862.
Plywood I-beams, 966.
Spandrel girders, 361.
Thermal action, 1093.

OGLE, F. B.
Time loss on grades, 1045.

OKEY, CHARLES W.
Mississippi River, 291.

OLDENBURGER, RUFUS
Matrix analysis, 1151.

PEARL, WALTER
Memoir of, 1500.

PENCE, WILLIAM DAVID
Memoir of, 1501.

PERKINS, W. A.
Uplift pressure, 509.

PERRY, LYNN
Education, 774.
Safety factors, 164.

PETERSON, F. G. ERIC
"Effect of Stress Distribution on Yield Points," 1201.

PHILIPPE, ROBERT R.
Ring stresses, 629.

PIRIE, JAMES EDWARD
Memoir of, 1503.

POPOV, E. P.
Ring stresses, 631.

PRICE, PHILIP WALLIS
Memoir of, 1504.

PRIEST, RALPH NOBLE
Memoir of, 1585.

PUGSLEY, A. G.
Safety factors, 162.

RAIFFEISEN, OTTO JOHN
Memoir of, 1506.

RANDALL, ROBERT H.
Aerial photography, 615.

RATCLIFFE, ROBERT CHARLES
Memoir of, 1587.

REED, MELVILLE EMERSON
Memoir of, 1507.

REVELISE, THOMAS P.
Method of segments, 271.

RICHARDS, GORDON V.
Uplift pressure, 515.

RIPPERGER, E. A.
"Critical Stresses in a Circular Ring," 619.

ROBERTS, ELLIOTT B.
Safety factors, 162.

ROBERTS, H. H.
Relief wells, 1361.

ROBERTSON, J. M.
Cavitation, 77.

RODERICK, J. W.
Yield points, 1238.

ROHWER, CARL
Artesian wells, 1066.

ROSE, EDWIN
"Thrust Exerted by Expanding Ice Sheet," 871.

RUTLEDGE, P. C.
Relief wells, 1355.

SACKETT, ROBERT LEMUEL
Memoir of, 1508.

SALTER, JAMES CRISP AKERS
Memoir of, 1593.

SANKS, ROBERT L.
"Model Study of Brown Canyon Debris Barrier," 999.

SAUNDERS, HENRY JENNESS
Memoir of, 1510.

SCHIEBER, OLIVER JAY
Memoir of, 1512.

SCIMEMI, ETTORE
Debris barrier, 1016.

SCOTT, RONALD F.
Urban triangulation, 342.

SCUDDER, CHARLES MORRISON
Memoir of, 1588.

SEELY, HOMER R.
"Technical Survey—Brooklyn Bridge after Sixty Years (Symposium): Historical Features of Construction and Operation," 183.

SELIM, MOHAMED A.
"Uplift Pressure in and Beneath Dams (Symposium): Dams on Porous Media," 488.

SENOUR, CHARLES
"New Project for Stabilizing and Deepening Lower Mississippi River," 277.

SETTE, F. J.
"The Planning of Aerial Photographic Projects," 595.

SHEARWOOD, F. P.
Yield points, 1218.

SHUBIN, SYDNEY ABRAM
Memoir of, 1518.

SIDEBOTTOM, O.
Yield points, 1230.

SILL, RUSH T.
Landslide correction, 415.

SIMMONS, L. G.
Urban triangulation, 339.

SIMS, ALFRED VARLEY
Memoir of, 1520.

SMITH, WALTER LYNES
Memoir of, 1523.

SNOOK, SPENCER A.
Express highway planning, 678.

SNOWDEN, RUSSELL ELSTNER
Memoir of, 1524.

SOLMAN, HARRIS
Matrix analysis, 1142.

STEHLE, FELIX CHARLES
Memoir of, 1589.

STÈINMETZ, GEORGE P.
Tailwater erosion, 1186.

STEVENS, J. W.
"Truck Speed and Time Loss on Grades," 1023.

STIEFEL, FRED WALTER
Memoir of, 1590.

STONE, C. A.
Relief wells, 1346.

STREIFF, ABRAHAM
Tailwater erosion, 1189.

STROUSE, WILLIAM FRANKLIN
Memoir of, 1527.

TABER, EDWARD GRAY
Memoir of, 1531.

TERZAGHI, KARL
"Shipways with Cellular Walls on a Marl Foundation," 298.

THOMAS, ROBERT O.
Education, 781.

THOMPSON, CARROLL ROSE
Memoir of, 1533.

THOMSON, T. KENNARD
Brooklyn Bridge, 248.

TIMANUS, CLARENCE SYDNEY
Memoir of, 1534.

TOMMERUP, CARL C. H.
"Rigid-Frame Structures Subject to Nonuniform Thermal Action," 1071.

TREADWELL, LEE
Memoir of, 1536.

TRIEST, WOLFGANG GUSTAV
Memoir of, 1538.

TURNBULL, WILLARD J.
Relief wells, 1340.

UNDERWOOD, P. H.
"Space Resection Problems in Photogrammetry," 921.

van der VEEN, HERMAN
Memoir of, 1540.

VAN DRIEST, E. R.
Cavitation, 107.

VAN EENAM, NEIL
Lateral buckling, 1281.

VAN LONDON, W. J.
Express highway planning, 663.

VAUBEL, E. A.
Ground water, 995.

VENNARD, JOHN K.
"Cavitation in Hydraulic Structures (Symposium): Nature of Cavitation," 2.

VOORHIES, LOUIS JOSEPH
Memoir of, 1541.

WADDELL, CHARLES EDWARD
Memoir of, 1543.

WAGNER, H. A.
Education, 792.

WALL, W. A.
Relief wells, 1346.

WALTER, RAYMOND FOWLER
Memoir of, 1546.

WARD, C. N.
"Correction of Tailwater Erosion at Prairie du Sac Dam," 1173.

WARNOCK, JACOB E.
"Cavitation in Hydraulic Structures (Symposium): Experiences of the Bureau of Reclamation," 43.

WATERBURY, LAWRENCE S.
Express highway planning, 679.

WEINER, BERNARD L.
Express highway planning, 684.

WESSMANN, HAROLD E.
"Technical Survey—Brooklyn Bridge after Sixty Years (Symposium): Tests of Metals Removed from Cables and Stiffening Trusses," 235.

WHITE, WILLIAM MacINTIRE
Memoir of, 1548.

WHITMAN, RALPH
Memoir of, 1550.

WHITTEMORE, WALTER FRANK
Memoir of, 1553.

WHITTEN, C. A.
Urban triangulation, 340.

WILLIAMS, CLEMENT C.
Education, 785.

WING, S. P.
Uplift pressure, 510.

WINTER, GEORGE
Lateral buckling, 1272.
"Strength of Thin Steel Compression Flanges," 527.
Yield points, 1225.

WOLFORD, DON S.
Thin flanges, 568.

WOOD, CHARLES P.
"Factors Controlling the Location of Various Types of Industry," 577.

WOODBURY, WILLIAM HOOK
Memoir of, 1554.

WRIGHT, MARSHALL S.
Aerial photography, 614.

YAGER, LOUIS
Memoir of, 1556.

YOUNG, LAWRENCE RICHARD
Memoir of, 1557.
